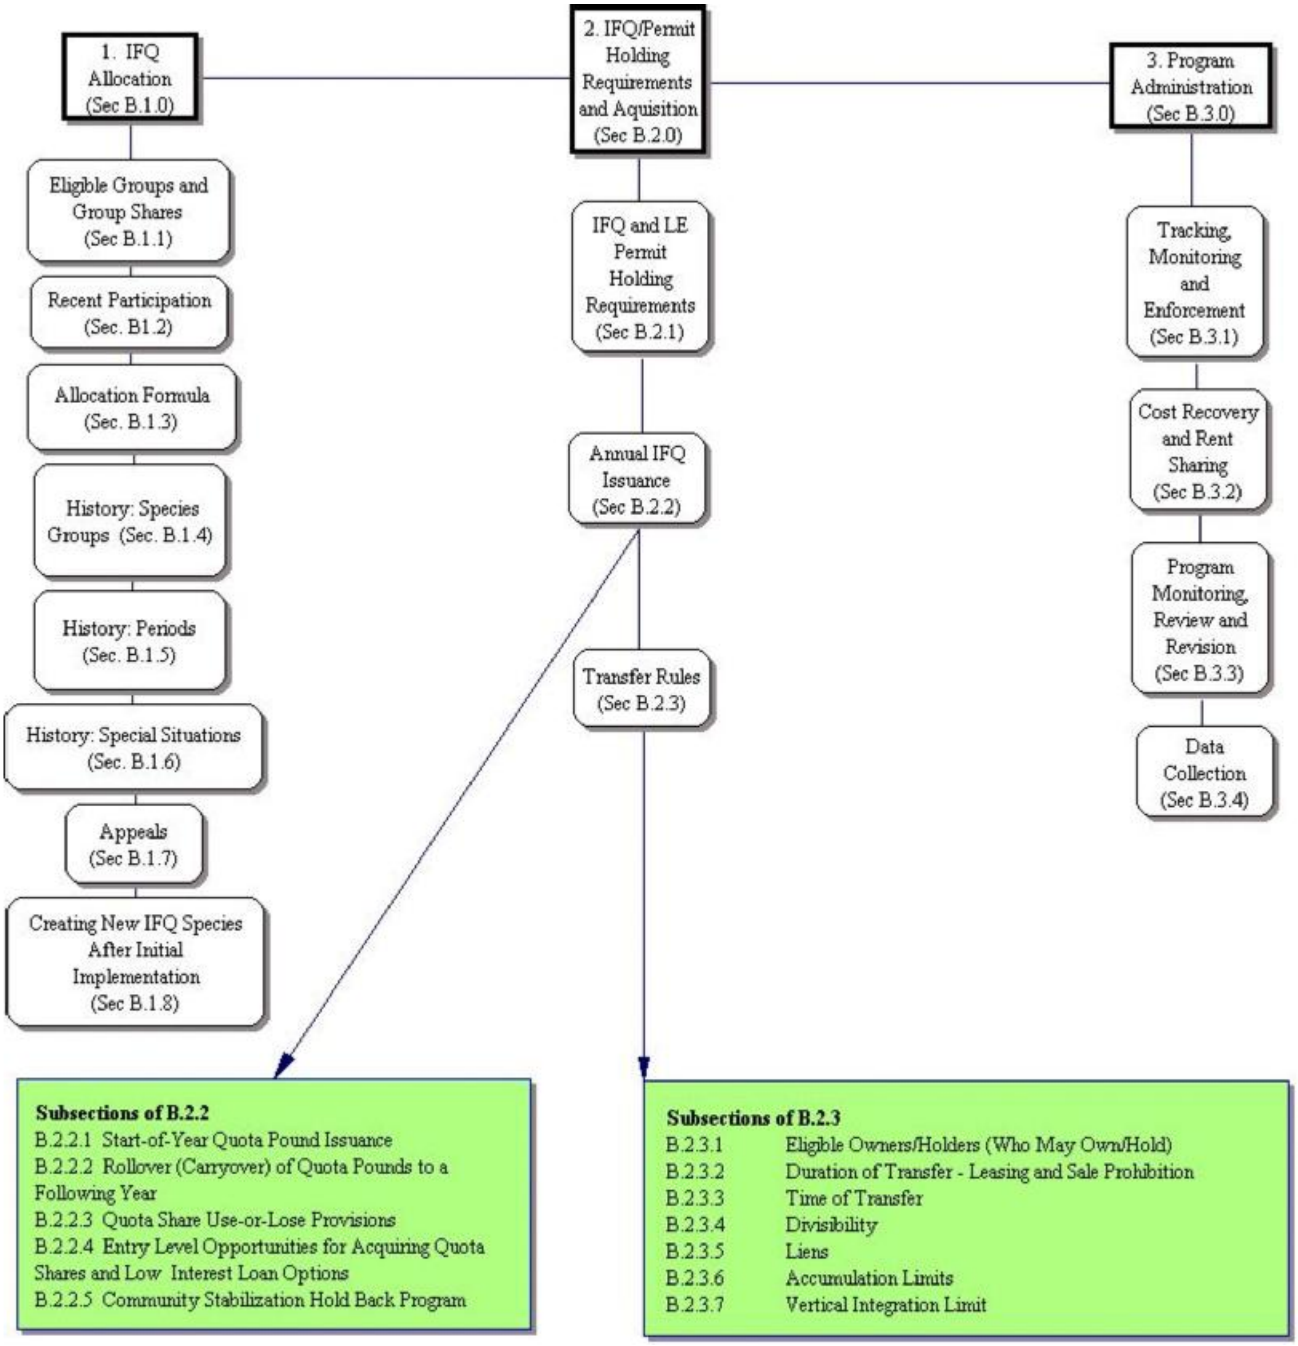
IFQ Program Primer

The design options covered in Appendix B of the scoping document are represented in the following diagram. Three pages of text follow providing a narrative description of the draft IFQ program and design options **(choice points are indicated in bold)**. This narrative is provided as an orientation on how the design options fit together to create an IFQ program.



IFQ Program Design Elements (from Appendix B)
General Description of the IFQ Program

Appendix B, Section B.1.0, IFQ Allocation

Section B.1.1, Eligible Groups and Group Shares

IFQ would be allocated to the following groups in the following proportions: . . . **[e.g., groundfish trawl permit holders (xx%), groundfish trawl vessel owners (xx%), processors (xx%)**]. Processors would be defined as . . . [FMP definition/alternative definition].

Section B.1.2, Recent Participation

In order to qualify for an initial allocation the applicant would . . . **[have to/not have to] . . .** demonstrate recent participation. If recent participation is required, the recent participation requirement for each group would be as follows: make/receive at least . . . **[X deliveries – number of deliveries to be determined]** . . . of trawl caught groundfish from . . . **[1998-2003 or 2000-2003]**.

Section B.1.3, Allocation Formula

Those eligible for an initial allocation will be allocated quota shares based on the following formula:
[0-100%] of the quota share issued for the group would be issued based on history of catch/landings/processing;
[0-100%] of the quota share issued for the group would be issued based on equal sharing;
[0-100%] of the quota share issued for the group would be allocated through an auction.
(Formula's may vary among groups.)

Section B.1.4 and Section B.1.5, History: Species Groups and Periods

For IFQ allocated based on delivery history, the applicant's . . . **[total groundfish; total for each IFQ species or species group; or total for each species, species group, or proxy species]** . . . **[caught; landed; or processed]** (Section B.1.4) . . . will be calculated for . . **[1994-2003, 1994-1999, 2000-2003, 1998-2003, or 1999-2004]** . . . , less . . . **[0, 1, 2, or 3]** . . . of the applicant's worst years. The calculation will be based on the applicant's . . . **[pounds, percent of total]** . . . for the relevant species/species group in each year. (Section B.1.5)

Section B.1.6, History: Special Situations

Permit history for combined permits would include the history . . . **[for all the permits that have been combined; for the permit originally associated with the permit number of the combined permit]**. Illegal deliveries would not count toward history. Catch in excess of trip limits, as authorized under an EFP and compensation fish . . . **[would/would not]** . . . count toward history.

Section B.1.7, Appeals

There would be no appeals process on the initial issuance of IFQ, other than that provided under the Administrative Procedures Act. Any proposed revisions to fishtickets would undergo review by state enforcement personnel prior to finalization of the revisions.

Section B.1.8, Creating New IFQ Species after Initial Implementation

When a management unit is subdivided, quota shares for that unit will be subdivided by issuing quota share holders amounts of shares for the subdivisions equivalent to their holdings of the shares being subdivided. If a new management unit is established that is not a subset of an existing unit managed with IFQ, the Council will need to take action at that time to develop criteria for quota share allocation.

Appendix B, Section B.2.0, IFQ/Permit Holding Requirements and Acquisition

Section B.2.1, IFQ and LE Permit Holding Requirements

In order to be used, IFQ representing quota pounds would need to be registered for use with a particular vessel (deposited to the vessel's quota pound account). Only LE trawl vessels would be allowed to participate in the IFQ fishery. A vessel would need to acquire quota pounds to cover a particular landing. . . **[by the time of the landing, no more than 24 hours after the landing, no more than 30 days after the landing].** A vessel . . . **[would not need to hold quota pounds; would need to hold at least xxx quota pounds]** . . . before leaving port on a fishing trip. An LE permit may not be transferred from any vessel for which there is deficit in the vessel's quota pound account for any species or species group (i.e., if the vessel has caught IFQ species not covered by quota pounds).

Subsection B.2.2.1, Start-of-Year Quota Pound Issuance and Subsection B.2.2.2, Rollover (Carryover) of Quota Pounds to a Following Year

Each year quota pounds would be issued to quota share holders based on the amounts of quota shares they hold (Subsection B.2.2.1). For species that are not overfished, a vessel . . . **[would/would not]**. . . be able to roll-over . . . **[up to . . . 5%, 10%, 20%, 30% . . . of its]** . . . unused quota pounds or cover an overage . . . **[of . . . 5%, 10%, 20%, 30%]** . . . with quota pounds from the following year. For overfished species, . . . **[a full; a partial; no]** . . . rollover allowance would be provided (Subsection B.2.2.2).

Subsection B.2.2.3, Quota Share Use-or-Lose Provisions

Quota share use would be monitored as part of the TIQ program review process. **[Quota shares not used in at least one of three years would be revoked . . . OR . . . During program review processes, if it is determined that significant portions of the available quotas shares are not being used (catch is not being recorded against quota pounds issued for those shares), use-or-lose or other provisions will be considered to encourage more complete utilization]**.

Subsection B.2.2.4, Entry Level Opportunities for Acquiring Quota Shares and Low Interest Loan Options

There are many program features that would facilitate new entry and participation by small fishing operations (e.g., highly divisible access privileges as compared to limited entry licenses). Additional provisions for such purposes could include . . . **[none; a low interest loan program; provisions for new entrants to qualify for revoked shares being reissued (the latter two options are not mutually exclusive)]**.

Subsection B.2.2.5, Community Stabilization Quota

A percentage of the quota pounds each year . . . **[would/would not]** . . . be held back from that allocated to quota share holders **. . . [0-25%, based on analysis] . . .** would be awarded to proposals from fishermen and processors working together to benefit the local community.

Section B.2.3, Transfer Rules

[Anyone eligible to own a U.S. documented fishing vessel; Anyone eligible to own or operate a U.S. documented fishing vessel; Stakeholders] . . . would be eligible to own or otherwise control IFQ (quota shares or quota pounds) (Subsection B.2.3.1). Leasing . . . **[would/would not]** . . . be allowed (Subsection B.2.3.2). Quota pounds could be transferred any time during the year. Quota shares would be transferable . . . **[any time during the year/only at the end of the year]** (Subsection B.2.3.3). There would be no limit on the divisibility of quota shares for purpose of transfer. Quota pounds could be transferred in as little as single pound units (Subsection B.2.3.4). Liens on IFQ are a matter of private contract and would not be specifically limited by this program. A central registry might be created as part of the program administration (Subsection B.2.3.5). There . . . **[would/would not]** . . . be accumulation limits on the amounts of quota shares or pounds used on a vessel, owned, or controlled. The definition of control may extend beyond ownership and leasing. The range of limits being considered **varies from 1% to 50% to no cap.** The limits may **vary by species, segment of the fleet, or type of entity (e.g., vessel owner, permit owner, processor).** Accumulation limits for groundfish in aggregate may also be different than limits for individual species (Subsection B.2.3.6). There would be no direct limits on vertical integration (Subsection B.2.3.7).

Appendix B, Section B.3.0, Program Administration

Enforcement for the IFQ program may include one or more of the following elements:

- onboard compliance monitors;
- dockside compliance monitors (20%-100%);
- hailing requirements, small vessel exemptions for onboard compliance monitors;
- video monitoring systems;
- full retention requirements;
- a vessel-specific bycatch reporting system;
- electronic landings tracking system;
- limited delivery ports;
- limited delivery sites;
- electronic IFQ tracking systems; and
- VMS.

Section B.3.1, Tracking, Monitoring, and Enforcement

These measures have been arrayed into the enforcement and monitoring programs provided in Table B.3-1. While some likely specifics are identified to facilitate program design and impact analysis, the FMP amendment language on this issue may be general, specifying the Secretary will promulgate regulations to establish an adequate monitoring and enforcement regime. Strong sanctions may be recommended along with provisions specifying illegal overages be forfeited and debited against the vessel’s account. Fishing by the vessel would be suspended until the overage is covered. (Section B.3.1). As part of the program administration, a centralized publicly accessible registry for liens against quota shares would be requested with . . . **[all related ownership information/essential ownership information].** (Also see Section B.3.4, Data Collection.)

Section B.3.2, Cost Recovery and Rent Sharing

Landings fees would be charged to cover program costs and, over time, some elements of the program may be privatized, as appropriate.

Section B.3.3, Program Monitoring, Review, and Revision

The IFQ program would not have a built-in sunset provision nor would quota shares be issued for fixed terms (i.e., IFQs would not expire after a certain number of years). The program would be revised as necessary through standard FMP and regulatory amendment processes. Information on certain aspects of program performance would be compiled annually, and a program review would be conducted every four years.

Section B.3.4, Data Collection

The data collection program . . . **[would/would not]** . . . be augmented to include the . . . **[expanded and mandatory; expanded voluntary]** . . . provision of economic data from the harvesting and processing industry. All data collected would be maintained in a confidential manner. Aspects of these provisions would require modification of the MSA. A central registry of IFQ shareholders and transactions would be maintained and include market value information. Government costs would also be tracked.

Preparatory Briefing on Trawl Individual Quota Program Development (Agenda Item C.1, June 2005)

Major Decisions for Agenda Item C.5

- Alternatives for Analysis in the **Draft** EIS
- Impacts to be Covered In TIQ Analysis
- Timing for Intersector Allocation EIS

Council Action:
1. **Specify alternatives for analysis in an EIS and identify any impacts that should be addressed not already covered in Section 2.2 of Attachment *3*.**
2. **Decide on timing for the initiation of public scoping for an EIS on intersector allocations.**

Trawl IFQ and Intersector Allocation Processes

(Agenda Item C.5.a, Attachment 1, Last Page)

- Two Subprojects
  - Trawl Individual Quotas
    - Completed scoping and ready to initiate draft EIS with adoption of alternatives for analysis.
  - Intersector Allocation
    - Preliminary scoping process has been underway, decision needed on when to formally announce public scoping for an EIS in the *Federal Register*

PREPARATORY INFORMATIONAL BRIEFING ON TRAWL INDIVIDUAL QUOTA (TIQ) PROGRAM DEVELOPMENT

Council members will be provided an orientation briefing on the trawl IFQ agenda item and a preliminary review of the Trawl Individual Quota Committee report. The main focus of this briefing will be Attachments 1 and 2 of Agenda Item C.5. Ample time will be provided for Council member questions focused on understanding the content, organization, and tasks for the Thursday afternoon decision session on this issue (Agenda Item C.5).

As a point of emphasis, public testimony on the Council action is scheduled for Thursday afternoon, June 16. This agenda item is informational only in scope and strictly preparatory in nature to the primary agenda item, C.5. Those interested in providing comments intended to influence Council action should do so under agenda item C.5, not under this agenda item. Public comment under this agenda item will be limited to comment relative to matters such as accuracy and completeness of the information presented. Individuals or groups presenting comments on matters such as the policy decisions to be made under agenda item C.5 will be ruled out of order and asked to present their comments under agenda item C.5.

Council Task: None.

b. Questions of Clarification from Council Members
c. Public Comment
d. Council Discussion

PFMC
05/24/05

the Under Secretary for Oceans and Atmosphere has delegated authority to sign material for publication in the **Federal Register** to the AA.

Classification

This interim final rule is published under the authority of the ATCA, 16 U.S.C. 971 *et seq.* The AA has determined that these regulations are necessary to implement the recommendations of ICCAT and are necessary for management of the Atlantic tuna fisheries.

Notwithstanding any other provision of law, no person is required to respond to nor shall a person be subject to a penalty for failure to comply with a collection of information subject to the requirements of the Paperwork Reduction Act (PRA) unless that collection of information displays a currently valid Office of Management and Budget (OMB) Control Number.

This rule involves a collection of information requirement subject to the PRA and approved by OMB under Control Number 0648–0327.

This interim final rule has been determined to be not significant for purposes of E.O. 12866.

NMFS has determined that, under 5 U.S.C. 553(b)(B), there is good cause to waive the requirement for prior notice and an opportunity for public comment on this rule as such procedures would be contrary to the public interest. NMFS has underway rulemakings on this, and other, tuna fishery management issues. Specifically, NMFS published a proposed rule on March 4, 1997 seeking public comment on a variety of tuna issues. Additionally, NMFS published proposed quota specifications on April 21, 1997 seeking public comment on fishing category allocations. However, while the process for these actions remains ongoing, NMFS has received comment that a postponement for 1997 in the deadline to choose a permit category is necessary to allow the public an opportunity to assess the impacts of the pending final rules. As such, given the public interest in affording vessel owners to make a reasoned decision as to fishing category and the fact that NMFS has already received public comment on the subject matter of this rule, further delay in the implementation of this action to provide an opportunity for additional comment is contrary to the public interest.

Further, under 5 U.S.C. 553(d)(1), because this rule relieves a restriction, it is not subject to a 30-day delay in effective date. NMFS has the ability to rapidly communicate the extension of the deadline to fishery participants through its FAX network and HMS Information Line.

List of Subjects in 50 CFR Part 285

Fisheries, Fishing, Penalties, Reporting and recordkeeping requirements, Treaties.

Dated: May 14, 1997.

Nancy Foster,

Deputy Assistant Administrator for Fisheries, National Marine Fisheries Service.

For the reasons set out in the preamble, 50 CFR part 285, is amended as follows:

PART 285—ATLANTIC TUNA FISHERIES

1. The authority citation for part 285 continues to read as follows:

Authority: 16 U.S.C. 971 *et seq.*

2. In § 285.21, paragraph (b)(7) is added to read as follows:

§ 285.21 Vessel permits.

* * * * *

(b) * * *

(7) Except for purse seine vessels for which a permit has been issued under this section, an owner may change the category of the vessel's Atlantic tunas permit to another category a maximum of once per calendar year by application on the appropriate form to NMFS before the specified deadline. After the deadline, the vessel's permit category may not be changed to another category for the remainder of the calendar year, regardless of any change in the vessel's ownership. In years after 1997, the deadline for category changes is May 15.

[FR Doc. 97–13139 Filed 5–15–97; 9:41 am]

BILLING CODE 3510–22–F

DEPARTMENT OF COMMERCE

National Oceanic and Atmospheric Administration

50 CFR Part 660

[Docket No. 970403076–7114–02; I.D. 030397B]

RIN 0648–AI80

Fisheries off West Coast States and in the Western Pacific; Pacific Coast Groundfish Fishery; Whiting Allocation Among Nontribal Sectors

AGENCY: National Marine Fisheries Service (NMFS), National Oceanic and Atmospheric Administration (NOAA), Commerce.

ACTION: Final rule.

SUMMARY: This rule implements: Allocation of the commercial harvest guideline of Pacific whiting (whiting) among nontribal sectors of the Pacific groundfish fishery; a framework procedure for annually choosing the starting dates of the primary whiting seasons for the nontribal sectors; and allowing the processing of fish waste at sea when at-sea processing of whiting is otherwise prohibited. This rule also implements starting dates for the 1997 primary seasons under the framework. These actions are intended to provide equitable allocation of the whiting resource and to provide flexibility in harvesting and processing opportunities.

DATES: Effective May 14, 1997.

ADDRESSES: Comments on the information collection requirements imposed by this rule should be sent to William Stelle, Jr., Administrator, Northwest Region, NMFS, 7600 Sand Point Way NE., Seattle, WA 98115, and to the Office of Information and Regulatory Affairs of the Office of Management and Budget, Washington DC, 20503.

FOR FURTHER INFORMATION CONTACT: William L. Robinson at 206–526–6140.

SUPPLEMENTARY INFORMATION: NMFS is issuing this rule to allocate whiting, establish a framework for setting season dates, and to provide for at-sea processing of whiting waste under the authority of the Pacific Coast Groundfish Fishery Management Plan (PCGFMP) and the Magnuson-Stevens Fishery Conservation and Management Act (Magnuson-Stevens Act). These actions were recommended by the Pacific Fishery Management Council (Council) at its October 1996 meeting in San Francisco, CA and at meetings of its ad hoc whiting allocation subcommittee that were held in 1996. At the same time, NMFS is announcing the starting dates for the primary whiting seasons in 1997 and addressing several housekeeping measures. These actions were proposed in the **Federal Register** at 62 FR 18572, April 16, 1996. No comments were received during the 20-day public comment period which ended April 30, 1997. This final rule is substantively the same as proposed; the minor changes are explained in this preamble.

The background for these actions appears in the proposed rule and in the environmental assessment/regulatory impact review prepared by the Council for this action. The actions taken are summarized below.

Background

Whiting allocation

The most recent allocation of whiting among nontribal sectors in the whiting fishery was in effect from 1994–96. Its expiration left no allocation in place for 1997 and beyond. The 1994–96 allocation was based on an industry agreement to provide 40 percent of the whiting harvest guideline to catcher vessels delivering to shore-based processors, plus any additional whiting taken while all sectors competed for the first 60 percent.

The allocations for 1997 and beyond also were derived by industry agreement in a series of public meetings sponsored by the Council. The allocations, which are within a few percent of the proportions actually harvested in 1994–96, are: 42 percent for the shoreside sector (catcher vessels delivering to shoreside processors), 24 percent for the mothership sector (motherships and catcher vessels delivering to motherships), and 34 percent for the catcher/processor sector (catcher/processor vessels). When applied to the 1997 commercial harvest guideline of 207,000 metric tons (mt), these percentages result in whiting allocations of 86,900 mt for the shoreside sector, 49,700 mt for the mothership sector, and 70,400 mt for the catcher/processor sector. Surplus whiting from one sector may be reallocated (via notice in the **Federal Register**) to the other sectors, in proportion to their initial allocations, near September 15. As in 1994–96, only the framework process for calculating the allocations is codified. The allocations will be calculated and announced annually, generally with the annual cycle for announcing specifications and management measures for the groundfish fishery in January each year. Because the shoreside fishery in California (which is south of 42° N. lat.) may start earlier than in Washington and Oregon, a 5–percent cap (4,345 mt in 1997) is placed on the amount of the shoreside allocation that may be taken south of 42° N. lat. before the start of the shoreside primary season north of 42° N. lat. This cap will discourage effort shifts into California early in the year and is not expected or intended to constrain traditional operations. If the 5–percent cap is reached, the routine trip limit under § 660.323(b) is resumed until the northern season begins, at which time the southern primary season also would resume.

Additional constraints were agreed to by the industry to assure that each sector has the opportunity to take its allocation and is not preempted by the high-capacity catcher/processors participating in more than one sector in a given year.

1. Within the same calendar year, a catcher/processor may not also act as a catcher vessel that delivers shoreside or to another at-sea processor.

2. A catcher/processor may operate solely as a mothership for that calendar year, but only if this has been requested and so designated on renewal of its limited entry permit for the Pacific coast groundfish fishery (Office of Management and Budget (OMB) #0648–0203). NMFS has made a slight change to the final rule at § 660.323 regarding recision of a declaration to act as a mothership for the entire calendar year. The modification clarifies that any recision of that declaration can only be made before the vessel has harvested or received any unprocessed whiting during that calendar year.

3. A catcher/processor (that has not declared itself as a mothership for the year) may receive codends over-the-side from a catcher vessel, but any such catch would be counted toward the catcher/processor allocation and would end when the catcher/processor allocation is taken. Catcher vessels that do not process may deliver to any or all of the processing sectors as long as the season for that sector is open.

The Council intends this allocation to remain in effect for at least 5 years, at which time it will be reevaluated.

Seasons

A framework is established for annually setting separate starting dates for each sector's primary season, and the starting dates for 1997 also are announced. The primary seasons for the whiting fishery are: For the shore-based sector, the period(s) when the large-scale target fishery is conducted (when trip limits under § 660.323(b) are not in effect); for catcher/processors, the period(s) when at-sea processing is allowed and the fishery is open for the catcher/processor sector; and for vessels delivering to motherships, the period(s) when at-sea processing is allowed and the fishery is open for the mothership sector. The framework provides for setting separate starting dates for each sector to accommodate operational needs. However, other factors also must be considered during the Council's two-meeting process, which generally would coincide with the setting of the annual management measures in the fall.

These factors are: The size of the harvest guidelines for whiting and bycatch species; status of whiting and bycatch stocks; age/size structure of the whiting population; expected harvest of bycatch and prohibited species; availability and stock status of prohibited species; expected participation by catchers and processors; environmental conditions; timing of alternate or competing fisheries; industry agreement; fishing or processing rates; and other relevant information.

The starting dates also are constrained by the incidental take statement dated May 14, 1996, issued pursuant to section 7 (b)(4) of the Endangered Species Act (ESA) to protect threatened or endangered species of salmon. The incidental take statement requires that the fishery north of 42° N. lat. not begin before May 15. This constraint remains in effect unless changed in a subsequent incidental take statement.

In 1997, the starting dates are May 15 for the catcher/processor and mothership sectors and June 15 for the shore-based sector north of 42° N. lat. The shore-based fleet operating in California between 42° and 40° 30' N. lat. began fishing in April 1997, but will be able to use the framework to set the starting date for 1998. The season south of 40° 30' N. lat. remains unchanged at April 15 as stated at § 660.323(a)(3)(i), and is not subject to the framework provisions for changing the starting date primarily due to concerns over potential salmon bycatch and harvest of juvenile whiting. However, the whiting fishery in California is subject to the 5–percent cap in 1997, as discussed above.

A slight change was made to § 660.323(a)(3)(i) to clarify that the routine trip limit before and after the primary season potentially could apply to all sectors, as currently is the case, not just the shore-based sector as stated in the proposed rule. The trip limits before and after the primary season currently are designated routine to accommodate small bait and fresh fish markets and bycatch in non-whiting fisheries.

NMFS Action—Starting Dates for the 1997 Primary Whiting Seasons: The primary season for each sector begins at 0001 hours (local time) on the following dates: (1) Catcher/processor sector—May 15, 1997; (2) mothership sector—May 15, 1997; (3) shore-based sector north of 42° N. lat.—June 15, 1997.

Processing Waste Products At Sea

This rule also allows processing fish waste at sea by a ''waste processing vessel,'' even at times when at-sea processing of whiting by catcher/processors or motherships is prohibited. To be considered a ''waste-processing vessel,'' the vessel must make only meal, oil, or minced product and cannot make or have on board surimi, fillet, or headed and gutted fish. The following restrictions assure that no fishing or receipt of whole fish is occurring while at-sea processing of whiting is prohibited:

(1) The vessel must be incapable of fishing for whiting; i.e., trawl nets and doors must be stowed and made inoperable; (2) receipt of codends containing any species of fish would be prohibited; (3) the amount of whole whiting on board must be less than any trip limit for whiting authorized under 50 CFR 660.323(b); and (4) the vessel could not operate as a waste-processing vessel within 48 hours immediately before and after any primary season in which it operates as a catcher/processor or mothership.

Housekeeping

A current prohibition is revised to enable a mothership to carry trawl gear while operating in the whiting fishery as long as trawl gear, clarified to mean trawl nets and doors in this final rule, is stowed and rendered inoperable. Similarly, the requirement for a waste-processing vessel to stow trawl gear also is clarified to indicate that trawl gear means trawl nets and doors.

A regulation issued on June 6, 1996, (61 FR 28786, authorized under old § 663.24) provided for whiting not needed in the tribal fishery to be made available to other users. This provision was inadvertently deleted when the regulations governing the Pacific Coast groundfish fisheries were consolidated at 61 FR 34570, July 2, 1996, with all other regulations governing the fisheries off the west coast states and in the Western Pacific, and therefore is included in this rule. Also in the consolidation, an error was made in paragraph (b) of § 660.306 regarding the citation for the definition of prohibited species and a typo exists in paragraph (r) of § 660.306. The corrections are included in this rule.

As part of the 1996 reorganization of NMFS, Regional Directors were retitled as Regional Administrators; however, the term Regional Director is still used in codified text until a universal change is made to 50 CFR 660.

Paragraphs (s) and (t) in § 660.306 are ''reserved'' for implementation of Amendment 9 to the PCGFMP which was approved by NMFS on May 8, 1997. Proposed regulations to implement Amendment 9 were published on March 21, 1997 (62 FR 13583).

Classification

The Assistant Administrator for Fisheries, NOAA (AA), has determined that this rule is necessary for management of the Pacific Coast groundfish fishery and that it is consistent with the Magnuson-Stevens Act and other applicable law.

Without the final rule being in place by May 15, the season north of 42° N. lat. will open on May 15 (50 CFR 660.323(a)(3)) without any allocation between competing sectors. A derby fishery would ensue and a substantial portion of the harvest guideline could be taken before the final rule was made effective, thereby disrupting 1997 allocations that would be implemented by the final rule. For these reasons, good cause is found under 5 U.S.C. 553(d)(3) for making the rule effective without a 30-day delay.

This final rule has been determined to be not significant for purposes of E.O. 12866.

The Assistant General Counsel for Legislation and Regulation of the Department of Commerce certified to the Chief Counsel for Advocacy of the Small Business Administration, when this rule was proposed, that it would not have a significant economic impact on a substantial number of small entities. As a result, a regulatory flexibility analysis was not prepared. No comments were received regarding this certification.

Notwithstanding any other provision of law, no person is required to respond to, nor shall a person be subject to, a penalty for failure to comply with a collection of information subject to the requirements of the Paperwork Reduction Act unless that collection of information displays a currently valid control number.

This rule contains a collection-of-information requirement subject to the Paperwork Reduction Act. The collection of this information has been approved by the OMB, OMB Control Number 0648–0203. Public reporting burden is estimated to be negligible due to this action, as it involves, concurrent with renewal of a limited entry permit, checking a box to indicate if a catcher/processor will operate entirely as a mothership in the whiting fishery during the year covered by the permit. Fewer than 15 catcher/processors operate in this fishery, and even fewer are expected to exercise this option. Send comments regarding burden estimates, or any other aspect of this data collection, including suggestions for reducing the burden, to NMFS and OMB (see **ADDRESSES**).

A formal section 7 consultation under the ESA was concluded for the PCGFMP. In a biological opinion dated August 28, 1993, and subsequent reinitiations of consultation dated September 27, 1993, and May 15, 1996, the Assistant Administrator determined that fishing activities conducted under the PCGFMP and its implementing regulations are not likely to jeopardize the continued existence of any endangered or threatened species under the jurisdiction of NMFS or result in the destruction or adverse modification of critical habitat. This rule is within the scope of those consultations. In addition, coho salmon south of Cape Blanco, Oregon, recently have been listed as threatened (Northern California/Southern Oregon) and endangered (Central California) under the ESA. This action will not affect coho salmon.

List of Subjects in 50 CFR Part 660

Administrative practice and procedure, Fisheries, Fishing, Reporting and recordkeeping requirements.

Dated: May 14, 1997.

Nancy Foster,

Deputy Assistant Administrator for Fisheries, National Marine Fisheries Service.

For the reasons set out in the preamble, 50 CFR part 660 is amended as follows:

PART 660—FISHERIES OFF WEST COAST STATES AND IN THE WESTERN PACIFIC

1. The authority citation for part 660 continues to read as follows:

Authority: 16 U.S.C. 1801 *et seq.*

2. In § 660.306, in paragraph (b), the reference to ''§ 660.302'' is changed to ''§ 660.323(c)'', paragraphs (j), (k), (m), (q), and (r) are revised, paragraphs (s) and (t) are reserved, and paragraphs (u), (v), and (w) are added, to read as follows:

§ 660.306 Prohibitions.

* * * * *

(j) Process whiting in the fishery management area during times or in areas where at-sea processing is prohibited for the sector in which the vessel participates, unless:

(1) The fish are received from a member of a Pacific Coast treaty Indian tribe fishing under § 660.324;

(2) The fish are processed by a waste-processing vessel according to § 660.323(a)(4)(vii); or

(3) The vessel is completing processing of whiting taken on board during that vessel's primary season.

(k) Take and retain or receive, except as cargo or fish waste, whiting on a vessel in the fishery management area that already possesses processed whiting on board, during times or in areas where at-sea processing is prohibited for the sector in which the vessel participates, unless the fish are received from a member of a Pacific Coast treaty Indian tribe fishing under § 660.324.

* * * * *

(m) Fish with groundfish trawl gear, or carry groundfish trawl gear on board a vessel that also has groundfish on board, without having a limited entry permit valid for that vessel affixed with a gear endorsement for trawl gear, with the following exception. A vessel with groundfish on board may carry groundfish trawl gear if:

(1) The vessel is in continuous transit from outside the fishery management area to a port in Washington, Oregon, or California; or

(2) The vessel is a mothership, in which case trawl nets and doors must be stowed in a secured and covered manner, and detached from all towing lines, so as to be rendered unusable for fishing.

* * * * *

(q) Carry on board a vessel, or deploy, limited entry gear when the limited entry fishery for that gear is closed, except a vessel may carry on board limited entry gear as provided in paragraph (m) of this section.

(r) Refuse to submit fishing gear or fish subject to such person's control to inspection by an authorized officer, or to interfere with or prevent, by any means, such an inspection.

(s) [Reserved.]

(t) [Reserved.]

(u) Participate in the mothership or shoreside sector as a catcher vessel that does not process fish, if that vessel operates in the same calendar year as a catcher/processor in the whiting fishery, according to § 660.323(a)(4)(ii)(B).

(v) Operate as a waste-processing vessel within 48 hours of a primary season for whiting in which that vessel operates as a catcher/processor or mothership, according to § 660.323(a)(4)(vii).

(w) Fail to keep the trawl doors on board the vessel and attached to the trawls on a vessel used to fish for whiting, when taking and retention is prohibited under § 660.323(a)(3)(v).

3. In § 660.323, paragraphs (a)(3)(i), (a)(3)(iv), and (a)(4) are revised to read as follows:

§ 660.323 Catch restrictions.

* * * * *

(a) * * *

(3) *Pacific whiting (whiting)*—(i) *Seasons*. The primary seasons for the whiting fishery are: For the shore-based sector, the period(s) when the large-scale target fishery is conducted (when trip limits under paragraph (b) of this section are not in effect); for catcher/processors, the period(s) when at-sea processing is allowed and the fishery is open for the catcher/processor sector; and for vessels delivering to motherships, the period(s) when at-sea processing is allowed and the fishery is open for the mothership sector. Before and after the primary seasons, trip landing or frequency limits may be imposed under paragraph (b) of this section. The sectors are defined at paragraph (a)(4) of this section.

(A) *North of 40*°30' N. lat. Different starting dates may be established for the catcher/processor sector, the mothership sector, catcher vessels delivering to shoreside processors north of 42° N. lat., and catcher vessels delivering to shoreside processors between 42°–40°30' N. lat.

(*1*) *Procedures*. The primary seasons for the whiting fishery north of 40°30' N. lat. generally will be established according to the procedures in the PCGFMP for developing and implementing annual specifications and apportionments. The season opening dates remain in effect unless changed, but will be announced annually, generally with the annual specifications and management measures.

(*2*) *Criteria*. The start of a primary season may be changed based on a recommendation from the Council and consideration of the following factors, if applicable: Size of the harvest guidelines for whiting and bycatch species; age/size structure of the whiting population; expected harvest of bycatch and prohibited species; availability and stock status of prohibited species; expected participation by catchers and processors; environmental conditions; timing of alternate or competing fisheries; industry agreement; fishing or processing rates; and other relevant information.

(B) *South of 40*°30' N. lat. The primary season starts on April 15 south of 40°30' N. lat.

* * * * *

(iv) *At-sea processing*. Whiting may not be processed at sea south of 42°00' N. lat. (Oregon-California border), unless by a waste-processing vessel as authorized under paragraph (a)(4)(vii) of this section.

* * * * *

(4) *Whiting—allocation*—(i) *Sectors and allocations*. The commercial harvest guideline for whiting is allocated among three sectors, as follows.

(A) *Sectors*. The catcher/processor sector is composed of catcher/processors, which are vessels that harvest and process whiting during a calendar year. The mothership sector is composed of motherships and catcher vessels that harvest whiting for delivery to motherships. Motherships are vessels that process, but do not harvest, whiting during a calendar year. The shoreside sector is composed of vessels that harvest whiting for delivery to shore-based processors.

(B) *Allocations*. The allocations are: 34 percent for the catcher/processor sector; 24 percent for the mothership sector; and 42 percent for the shoreside sector. No more than 5 percent of the shoreside allocation may be taken and retained south of 42° N. lat. before the start of the primary season north of 42° N. lat. These allocations are harvest guidelines unless otherwise announced in the **Federal Register**.

(ii) *Additional restrictions on catcher/processors*.

(A) A catcher/processor may receive fish from a catcher vessel, but that catch is counted against the catcher/processor allocation unless the catcher/processor has been declared as a mothership under paragraph (a)(4)(ii)(C) of this section.

(B) A catcher/processor may not also act as a catcher vessel delivering unprocessed whiting to another processor in the same calendar year.

(C) When renewing its limited entry permit each year under § 660.333, the owner of a catcher/processor used to take and retain whiting must declare if the vessel will operate solely as a mothership in the whiting fishery during the calendar year to which its limited entry permit applies. Any such declaration is binding on the vessel for the calendar year, even if the permit is transferred during the year, unless it is rescinded in response to a written request from the permit holder. Any request to rescind a declaration must made by the permit holder and granted in writing by the Regional Director before any unprocessed whiting has been taken on board the vessel that calendar year.

(iii) *Reaching an allocation*. If the whiting harvest guideline, commercial harvest guideline, or a sector's allocation is reached, or is projected to be reached, the following action(s) for the applicable sector(s) may be taken as provided under paragraph (a)(4)(vi) of this section and will remain in effect until additional amounts are made available the next fishing year or under paragraph (a)(4)(iv) of this section.

(A) *Catcher/processor sector*. Further taking and retaining, receiving, or at-sea processing of whiting by a catcher/processor is prohibited. No additional unprocessed whiting may be brought on board after at-sea processing is prohibited, but a catcher/processor may continue to process whiting that was on board before at-sea processing was prohibited.

(B) *Mothership sector*. (*1*) Further receiving or at-sea processing of whiting by a mothership is prohibited. No additional unprocessed whiting may be brought on board after at-sea processing is prohibited, but a mothership may continue to process whiting that was on board before at-sea processing was prohibited.

(*2*) Whiting may not be taken and retained, possessed, or landed by a catcher vessel participating in the mothership sector.

(C) *Shoreside sector*. Whiting may not be taken and retained, possessed, or landed by a catcher vessel participating in the shoreside sector except as authorized under a trip limit specified under § 660.323(b).

(D) *Shoreside south of 42°* N. lat. If 5 percent of the shoreside allocation for whiting is taken and retained south of 42° N. lat. before the primary season for the shoreside sector begins north of 42° N. lat., then a trip limit specified under paragraph (b) of this section may be implemented south of 42° N. lat. until the northern primary season begins, at which time the southern primary season would resume.

(iv) *Reapportionments*. That portion of a sector's allocation that the Regional Director determines will not be used by the end of the fishing year shall be made available for harvest by the other sectors, if needed, in proportion to their initial allocations, on September 15 or as soon as practicable thereafter. NMFS may release whiting again at a later date to ensure full utilization of the resource. Whiting not needed in the fishery authorized under § 660.324 also may be made available.

(v) *Estimates*. Estimates of the amount of whiting harvested will be based on actual amounts harvested, projections of amounts that will be harvested, or a combination of the two. Estimates of the amount of whiting that will be used by shoreside processors by the end of the fishing year will be based on the best information available to the Regional Director from state catch and landings data, the survey of domestic processing capacity and intent, testimony received at Council meetings, and/or other relevant information.

(vi) *Announcements*. The Assistant Administrator will announce in the **Federal Register** when a harvest guideline, commercial harvest guideline, or an allocation of whiting is reached, or is projected to be reached, specifying the appropriate action being taken under paragraph (a)(4)(iii) of this section. The Regional Director will announce in the **Federal Register** any reapportionment of surplus whiting to other sectors on September 15, or as soon as practicable thereafter. In order to prevent exceeding the limits or to avoid underutilizing the resource, prohibitions against further taking and retaining, receiving, or at-sea processing of whiting, or reapportionment of surplus whiting may be made effective immediately by actual notice to fishermen and processors, by phone, fax, Northwest Region computerized bulletin board (contact 206–526–6128), letter, press release, and/or U.S. Coast Guard Notice to Mariners (monitor channel 16 VHF), followed by publication in the **Federal Register**, in which instance public comment will be sought for a reasonable period of time thereafter. If insufficient time exists to consult with the Council, the Regional Director will inform the Council in writing of actions taken.

(vii) *Processing fish waste at sea*. A vessel that processes only fish waste (a ''waste-processing vessel'') is not considered a whiting processor and therefore is not subject to the allocations, seasons, or restrictions for catcher/processors or motherships while it operates as a waste-processing vessel. However, no vessel may operate as a waste-processing vessel 48 hours immediately before and after a primary season for whiting in which the vessel operates as a catcher/processor or mothership. A vessel must meet the following conditions to qualify as a waste-processing vessel:

(A) The vessel makes meal (ground dried fish), oil, or minced (ground flesh) product, but does not make, and does not have on board, surimi (fish paste with additives), fillets (meat from the side of the fish, behind the head and in front of the tail), or headed and gutted fish (head and viscera removed).

(B) The amount of whole whiting on board does not exceed the trip limit (if any) allowed under paragraph (b) of this section.

(C) Any trawl net and doors on board are stowed in a secured and covered manner, and detached from all towing lines, so as to be rendered unusable for fishing.

(D) The vessel does not receive codends containing fish.

(E) The vessel's operations are consistent with applicable state and Federal law, including those governing disposal of fish waste at sea.

[FR Doc. 97–13120 Filed 5–14–97; 4:59 pm]

BILLING CODE 3510–22–F

DEPARTMENT OF COMMERCE

National Oceanic and Atmospheric Administration

50 CFR Part 660

[Docket No. 960614176–7112–03; I.D. 041797B]

RIN 0648–AI19

Fisheries Off West Coast States and in the Western Pacific; Western Pacific Crustacean Fisheries; Technical Amendment

AGENCY: National Marine Fisheries Service (NMFS), National Oceanic and Atmospheric Administration (NOAA), Commerce.

ACTION: Final rule.

SUMMARY: NMFS announces a final rule to correct regulations implementing the Fishery Management Plan for the Crustacean Fisheries of the Western Pacific Region (FMP) to clarify what records must be made available by first-level buyers upon request by an authorized officer.

EFFECTIVE DATE: May 20, 1997.

FOR FURTHER INFORMATION CONTACT: Mr. Alvin Katekaru, NMFS, (808) 973–2985 or Mr. Svein Fougner, NMFS, (562) 980–4034.

SUPPLEMENTARY INFORMATION: Upon request, a first-level buyer must allow an authorized officer to access, inspect, and copy all records relating to the harvest, sale, or transfer of management unit species taken by vessels in the fishery. The original FMP regulations at 50 CFR part 681.11 stated this explicitly.

On July 2, 1996, the regulations at 50 CFR part 681 were consolidated with regulations for fisheries off west coast states and in the western Pacific; the regulations were codified at 50 CFR part 660 (61 FR 34570). In part 660, paragraph 660.14(f)(2) was not transferred correctly from § 681.11 (i.e., text was inadvertently left out). This rule corrects that paragraph to include: The name of the vessel involved in each transaction and the owner or operator of the vessel; the amount, number, and size of each management unit species involved in each transaction; and prices paid by the buyer and proceeds to the seller in each transaction.

Classification

This final rule is issued under the Magnuson-Stevens Fishery Conservation and Management Act, 16 U.S.C 1801 *et seq*.

In that this rule merely clarifies an existing requirement without creating

GROUNDFISH ADVISORY SUBPANEL STATEMENT ON INITIAL CONSIDERATION OF OPENING DATE OF CALIFORNIA SHORE-BASED WHITING FISHERY

The Groundfish Advisory Subpanel (GAP) reviewed the proposal to open the California shore-based whiting fishery south of 40E30' on March 15.

In general, the GAP agrees with the proposal, subject to the following conditions:

1. The fishery meets the same requirements for monitoring and shore sampling as other shore-based whiting fisheries conducted currently under an exempted fishing permit (EFP) and in the future under Amendment 10 to the Pacific groundfish fishery management plan.

2. The whiting taken in this area be included as part of the 5% allocation of shore-based whiting assigned to California.

3. Opening at the earlier date will not result in an unacceptable level of salmon bycatch.

On the last point, the GAP has no information that salmon bycatch will be higher, but notes a later opening date (April 15) was originally set based on those concerns.

PFMC
06/14/05

GROUNDFISH MANAGEMENT TEAM REPORT ON INITIAL CONSIDERATION OF OPENING DATE OF CALIFORNIA SHORE-BASED WHITING FISHERY

The Groundfish Management Team (GMT) reviewed the request by Mr. Barry Cohen to change the start date of the California shore-based whiting fishery south of 40°30' N latitude from April 15 to March 15 in 2006. It is the GMT's understanding that this date change affects one processor and potentially one to three shore-based whiting vessels.

To facilitate a discussion of this issue, the National Marine Fisheries Service (NMFS) provided the GMT with a brief history of the location and seasonality of the whiting fishery. During the 1980s, foreign processors were prohibited from operating south of 39° N latitude, primarily to minimize the harvest of rockfish and juvenile whiting. Foreign fishing was prohibited before June 1. Joint ventures (small U.S. trawlers delivering to foreign processing vessels at sea) did not have a season, but generally started one to two months earlier. In general, shore-based processors operated from April through September and were eventually regulated with different start dates along the coast.

During the early spring, Pacific whiting migrate north through California before reaching Oregon and Washington in late spring and early summer. In the late 1990s, an April 15 start date was proposed for California. To accommodate regional whiting availability, an early shore-based whiting fishery was provided starting April 1 for northern California (north of 40˚30' N latitude), which was the only area of California with an active fishery at that time. There has been recent interest in fishery participation south of 40˚30' N latitude, which still maintains a start date of April 15, two weeks after the northern California fishery. In 2005, Mr. Cohen was designated as a processor under the whiting exempted fishing permit (EFP) and attempted to prosecute the fishery after the start date. Mr. Cohen reported that only one small landing was made in early May and attributed this to starting after whiting had already moved through the area. Therefore, he requests the opportunity to commence fishing on March 15 to match the timing of the whiting migration through this area.

Historically, there has not been much of a whiting fishery south of 40°30' N latitude, but historical groundfish bycatch information suggests, that in the Monterey area, the bycatch of widow rockfish was greater than in other sections of the coast and was usually highest during June and July. Chilipepper rockfish was also taken as bycatch in the whiting fishery in the Monterey area, and catch was generally higher earlier in the year.

There are no data to indicate the species and catch rates likely to occur if the fishery occurred during March, except that offshore species (such as mackerel) are more likely to be encountered in southern waters.

By shifting the start of the southern whiting harvest from April 15 to March 15 south of 40°30' N latitude, the GMT anticipates the fishery may encounter younger, smaller whiting, as well as those whiting that are more emaciated following spawning. Historical catch suggests larger, older fish are proportionately more abundant in the catch in more northern areas than in southern areas. During the first two weeks of this year's California shore-based whiting fishery, which operates between 42° N latitude and 40°30’ N latitude with an April 1 start date, the vessels encountered a mixed grade of whiting that was predominately small fish. By week four of the fishery, the vessels encountered a larger, more desirable grade of whiting. The likelihood of encountering small whiting is variable and is not always an issue for this fishery.

NMFS also provided the GMT with a review of the Groundfish Fishery Management Plan (FMP) for the whiting fishery in particular, taking into consideration the Endangered Species Act (ESA) related biological opinions or reinitiated consultations in 1990, 1991, 1992, 1993, 1996, 1999, and 2002. Management constraints that still exist as a result of those consultations include (1) a delay in the start of the at-sea whiting season until May 15 north of 42° N latitude, (2) no targeted harvest of whiting shoreward of 100 fm in the Eureka area (the Eureka area extends from 43º30' to 40º N latitude), and (3) an overall annual bycatch limit of 11,000 chinook.

The current biological opinion prohibits targeted whiting harvest shoreward of 100 fm in the Eureka area (approximately 40º N latitude), but does not restrict fishing inside of 100 fm in the Monterey area. A depth restriction in the Monterey area was not previously considered because there was little or no fishing for whiting in the area at the time. However, the depth-based restriction for the Eureka area was put in place because chinook bycatch rates were generally found to be higher in shallow water. Although there are little data regarding the effect of depth on chinook bycatch in the Monterey area, a depth restriction in the area may be an appropriate consideration.

There are no data on the bycatch rate of chinook in the whiting fishery from recent years in the Monterey area. However, NMFS reviewed information available from the joint venture fishery when the effects of the whiting fishery on Sacramento winter-run chinook were first considered in 1991(November 26, 1991 Biological Opinion). From 1981 – 1990, the average bycatch rates in the Monterey and Eureka areas were 0.027 and 0.147 salmon per mt of whiting, respectively. As a frame of reference, the current bycatch rate for the entire whiting fishery that may reinitiate a consultation is 0.05 salmon per mt of whiting. In that same opinion, NMFS reported the probability of encountering a winter-run chinook was generally lower in the Monterey area than in the Eureka area (1/1,500 versus 1/5,500 chinook caught).

Opening dates for salmon fisheries are constrained because of concerns related to Sacramento winter-run chinook. Recreational salmon fisheries south of Point Arena (38º57'30" N latitude) open no earlier than the first Saturday of April. Commercial fisheries south of Point Arena open no earlier than May 1, and fisheries north of Point Arena are not constrained by these delayed opening dates. Because the shore-based fishery operates south of Point Arena, the Council may want to be aware of these season restrictions.

The GMT is aware of the goals of the Groundfish FMP, specifically those to promote year-round opportunities, extend fishing and marketing opportunities as long as practicable; and to encourage full utilization of groundfish resources. Changing the start date would be in keeping with promoting year-round fisheries and extending fishing and marketing opportunities. In the last eight years, the cap set for the California shore-based whiting fishery (5% of the total shore-based allocation) has been achieved three times (1997, 2000, 2004). Allowing the fishery to begin earlier in the year may encourage full utilization, if inadequate access to fish moving northward in April is the reason the cap is not being achieved.

The GMT did not consider how changing the whiting season start date south of 40°30’ N latitude could be affected by the ratification of the U.S./Canada whiting treaty. If an analysis is developed for this proposal as part of the rule-making process, implementation of the treaty should be considered in that analysis.

Given the above information, the GMT believes that changing the start date for the shore-based fishery south of 40°30’ N latitude April 15 to March 15 should be explored, but also recommends that the Council proceed cautiously. NMFS is in the process of evaluating whether or not it is possible to transition the shore-based whiting fishery from an EFP into federal regulations. Because this process is complex, it is possible the shore-based fishery will operate under an EFP in 2006. In 2006, the EFP could be used to exempt the fleet from the April 15 start date and evaluate the bycatch of groundfish, especially overfished species, and salmon associated with starting the fishery a month earlier. In 2004 and 2005, electronic monitoring systems have been deployed in the shore-based whiting fishery to document compliance with full retention/maximized retention requirements. Because of funding and contracting constraints, electronic monitoring systems have not been available for the April 1 shore-based whiting fishery (the fishery that occurs between 42°’ N latitude and 40°30’ N latitude) and may not be available earlier than March 15, 2006. NMFS is still evaluating the adequacy of electronic monitoring to document compliance with full retention/maximized retention requirements. Because this EFP would be collecting information on groundfish and salmon bycatch as well as gathering information on the size and condition of whiting south of 40°30’ N latitude, the GMT believes that observers, specifically 100% observer coverage, may be a more appropriate option for monitoring this sector of the shore-based whiting fishery. An increase in plant sampling would also be useful for this sector of the shore-based whiting fishery, but the GMT believes that any increase in plant sampling does not replace the need for observer coverage during harvesting.

If an EFP conducted in 2006 indicates that changing the start date from April 15 to March 15 does not increase the bycatch of groundfish or salmon or negatively affect the product quality and catch per unit effort of whiting, then a permanent date change could be considered through notice and comment rule making. The results of the 2006 EFP would likely not be available for inclusion in the 2007 – 2008 biennial specifications and management measures process, so the date change would need to be implemented in a separate rule making.

The GMT would like to bring to the Council’s attention the work load associated with this action. Adequate resources will need to be available to conduct the shore-based whiting EFP next year. In the event the shore-based EFP will not go forward in 2006, a separate EFP for the shore-based whiting fishery south of 40°30’ N latitude would need to be developed, conducted, and the results analyzed. Additional resources would need to be available to provide observer coverage for this EFP as well as for the rule making and environmental assessment process associated with this action.

In summary, if adequate resources are available, the GMT recommends that the effects associated with changing the start date be evaluated as part of the shore-based whiting EFP and that, if appropriate, the date change be considered through a full rule-making process. The current biological opinion requires a 100 fm depth restriction in the Eureka area (from 40°30’ N latitude to 40° N latitude). Therefore, the GMT recommends that a depth restriction to minimize salmon bycatch, similar to the one specified in the current biological opinion for the Eureka area, be considered for the Monterey area. Because of the uncertainty around salmon bycatch in southern areas, the GMT also recommends consideration of a salmon bycatch cap for this portion of the fishery.

INITIAL CONSIDERATION OF OPENING DATE OF CALIFORNIA SHORE-BASED WHITING FISHERY

Mr. Barry Cohen, a processor from central California and member of the Groundfish Advisory Subpanel, requested Council consideration of a change in the California shore-based whiting season start date from April 15 to March 15 beginning in 2006. The area affected under this proposal are waters south of 40°30' N latitude. The request for an earlier start date for this fishery is predicated on the higher abundance of Pacific whiting in these waters early in the year. Whiting migrate north as the season progresses and are in low abundance south of 40°30' N latitude when the California shore-based fishery opens on April 15. The shore-based whiting fishery south of 40°30' N latitude used to open as early as March 15 but, as interest in the southern fishery waned, the season started later to meet the needs of the California shore-based trawl fleet operating in waters north of 40°30' N latitude. Now, with renewed interest in targeting whiting south of 40°30' N latitude, the earlier start date is requested. It is also noteworthy that the California shore-based whiting fishery south of 42° N latitude operates under an annual 5% cap of the whiting allocated to the coastwide shore-based whiting sector. This ensures that the California fleet, which starts targeting whiting earlier than the northern fleet, will not usurp the whiting quota and prohibit opportunities for the more northern shore-based whiting fleets operating off of Oregon and Washington.

The task under this agenda item is to consider this request for an earlier season start date south of 40°30' N latitude for the shore-based whiting sector. This requires a two-meeting process since changing the primary whiting season is not defined as a routine management measure under the Groundfish Fishery Management Plan or in regulations. If the Council opts to recommend this change in the season start date, then this tentative decision will be announced to the general public subsequent to the June Council meeting. Notice will then be given that final Council consideration will be scheduled for the September Council meeting.

Council Action:

Consider and Recommend the Season Start Date for the 2006 Shore-based Whiting Fishery for Public Review.

Reference Materials: None.

Agenda Order:

a. Agenda Item Overview — John DeVore
b. Reports and Comments of Advisory Bodies
c. Public Comment
d. **Council Action:** Consider an Adjustment in the Opening Date for 2006 for Public Review

Summary of the Alternatives in the Groundfish Essential Fish Habitat DEIS

List of the Alternatives

Alternatives to Identify and Describe EFH

Alternative 1: No Action

✓ Alternative A.2: Depths less than 3,500 m (Preliminary Preferred Alternative)

✓ Alternative A.3: 100% HSP Area (Preliminary Preferred Alternative)

Alternative A.4: HSP Based on Management Status

Alternative A.5: 70% HSP Area

Alternative A.6: 30% HSP Area

Alternatives to Designate HAPC

Alternative B.1: No Action

✓ Alternative B.2: Estuaries (Preliminary Preferred Alternative)

✓ Alternative B.3: Canopy Kelp (Preliminary Preferred Alternative)

✓ Alternative B.4: Seagrass (Preliminary Preferred Alternative)

Alternative B.5: Core Habitat

✓ Alternative B.6: Rocky Reefs (Preliminary Preferred Alternative)

Alternative B.7: Areas of Interest

Alternative B.8: Oil Production Platforms

Alternative B.9: Process for New HAPC Designations

Alternatives to Minimize Adverse Impacts to EFH

Alternative C.1: No Action

Alternative C.2: Depth-based Gear-specific Restrictions

- Option C.2.1: Large footrope prohibited inside 200 fm, fixed gear inside 100/150 fm
- Option C.2.2: Large footrope prohibited in EEZ, fixed gear inside 100/150 fm
- Option C.2.3: Large footrope prohibited inside 200 fm, fixed gear inside 60 fm

Alternative C.3: Close Sensitive Habitat

- Option C.3.1: Close areas where $S \geq 2$ and $R \geq 1$ with trawl effort adjustment
- Option C.3.2: Close areas where $S \geq 0.5$ and $R \geq 0.5$ with trawl effort adjustment
- Option C.3.3: Close areas where $S \geq 2$ and $R \geq 1$ without trawl effort adjustment
- Option C.3.4: Close areas where $S \geq 0.5$ and $R \geq 0.5$ with trawl effort adjustment

✓ Alternative C.4: Prohibit the Geographic Expansion of Fishing (Preliminary Preferred Alternative)

✓ Option C.4.1: Prohibit expansion of trawl fishing

✓ Option C.4.2: Prohibit expansion of all bottom-tending gear

Alternative C.5: Prohibit a Krill Fishery

Alternative C.6: Close Hotspots

Alternative C.7: Close Areas of Interest

Option C.7.1: Close areas of interest to bottom trawling.

Option C.7.2: Close areas of interest to all bottom-contacting fishing activities.

Alternative C.8: Zoning Fishing Activities

Option C.8.1: Zoning for mobile bottom-contacting gear

Option C.8.2: Zoning for all bottom-contacting gear

✓ Alternative C.9: Gear Restrictions (Preliminary Preferred Alternative)

✓ C.9.1: Prohibit roller gear larger than 15 inches on bottom trawls.

✓ C.9.2: Prohibit the use of flat trawl doors (i.e., require cambered doors).

✓ C.9.3: Limit the length of a single longline groundline to 3 nm.

✓ C.9.4: Employ habitat-friendly anchoring system.

✓ C.9.5: Prohibit dredge gear.

✓ C.9.6: Prohibit beam-trawl gear.

✓ C.9.7: Prohibit set-gillnets in waters deeper than 60 fm.

✓ C.9.8: Prohibit dingle bar gear (troll groundfish gear).

✓ Alternative C.10: Central California No-trawl Zones (Preliminary Preferred Alternative)

✓ Alternative C.11: Relax Gear Endorsement Requirements (Preliminary Preferred Alternative)

✓ Alternative C.12: Close Ecologically Important Areas to Bottom Trawl (Preliminary Preferred Alternative)

✓ Alternative C.13: Close Ecologically Important Areas to Bottom-contacting Gear (Preliminary Preferred Alternative)

✓ Alternative C.14: Close Ecologically Important Areas to Fishing (Preliminary Preferred Alternative)

Research and Monitoring Alternatives

Alternative D.1: No Action

Alternative D.2: Expanded Logbook Program

Option D.2.1: All fishing vessels maintain a logbook

Option D.2.2: A sub-sample of fishing vessels maintain a logbook

Alternative D.3: Expanded Vessel Monitoring System

Alternative D.4: Research Reserve System

Description of the Alternatives

Alternatives to Identify and Describe EFH

Alternative 1: No Action

The no action alternative would maintain the current EFH identification and description, incorporated into the groundfish FMP by Amendment 11 in 1998. The more than 80 groundfish species in the management unit occupy diverse habitats at all stages in their life histories. As a consequence of the large number of groundfish fishery management unit (FMU) species and their diverse habitat associations, when all the individual EFHs are taken together, all waters from the mean higher high water line, and the upriver extent of saltwater intrusion in river mouths, along the coasts of Washington, Oregon, and California to the seaward boundary to the U.S. EEZ become EFH.

The FMP groups the various EFH descriptions into seven units called composite EFHs. This approach focuses on ecological relationships among species and between the species and their habitat, reflecting an ecosystem approach in defining EFH. Seven major habitat types are proposed as the basis for such assemblages or composites. These major habitat types are readily recognizable by those who potentially may be required to consult about impacts to EFH, and their distributions are relatively stationary and measurable over time and space. The seven composite areas identified as EFH are as: Estuarine; Rocky Shelf; Nonrocky Shelf; Canyon; Continental Slope/Basin; Neritic Zone; and, Oceanic Zone. Because it designates the entire EEZ including areas shoreward to the mean higher high water line, this alternative encompasses the largest area, 317,690 square miles.

✓ Alternative A.2: Depths less than 3,500 m (Preliminary Preferred Alternative)

In this alternative, EFH would be identified as 100% of the area where Habitat Suitability Probability (HSP) is greater than zero for all species and any additional area in depths less than or equal to 3,500 m (1,914 fm). HSP refers to the probability that the habitat is suitable for a managed species. This alternative would designate 187,741 square miles in the EEZ, and to the mean higher high water line and upriver extent of salt water, as EFH. By including areas out to the 3500 m depth curve, this alternative includes all habitats where groundfish have been observed with the addition of 100 m depth as a precautionary adjustment in case of unobserved species.

✓ Alternative A.3: 100% HSP Area (Preliminary Preferred Alternative)

Designate 100% of the area where HSP is greater than zero for all species. HSP refers to the probability that the habitat is suitable for a managed species. This alternative would designate 87,160 square miles as EFH, all of it within the area that would be designated by Alternative A.2.

Alternative A.4: HSP Based on Management Status

Designate the upper 90% of the HSP area of overfished species HSP, upper 80% of the HSP area for precautionary zone species, and upper 60% of the HSP area for all other groundfish, and all seamounts. HSP refers to the probability that the habitat is suitable for a managed species. The alternative would designate 79,481 square miles as EFH, most of which falls within the area described by the previous alternatives, with the addition of some deeper areas around seamounts

Alternative A.5: 70% HSP Area

Designate the upper 70% of the area where HSP is greater than zero. HSP refers to the probability that the habitat is suitable for a managed species. The alternative would designate 78,569 square miles as EFH, all of which falls within the area described by alternatives A.1, A.2, and A.3.

Alternative A.6: 30% HSP Area

Designate the upper 30% of the area where HSP is greater than zero for all species. HSP refers to the probability that the habitat is suitable for a managed species. The alternative would designate 66,589 square miles as EFH, all of which falls within the area described by the previous alternatives.

Alternatives to Designate HAPC

Alternative B.1: No Action

No HAPCs are currently designated for groundfish. Choosing this alternative would maintain no HAPC designations.

✓ Alternative B.2: Estuaries (Preliminary Preferred Alternative)

Estuaries are protected nearshore areas such as bays, sounds, inlets, and river mouths, influenced by ocean and freshwater. GIS data on West Coast estuaries were derived primarily from the USFWS' National Wetlands Inventory (NWI). Where digital data for the NWI were unavailable, data from NOAA's Coastal Assessment Framework were used.

✓ Alternative B.3: Canopy Kelp (Preliminary Preferred Alternative)

Areas where kelp has been documented and mapped would be designated as HAOC. GIS data for the floating kelp species, *Macrocystis* spp. and *Nereocystis* sp., are available from state agencies in Washington, Oregon, and California. These data have been compiled into a comprehensive data layer delineating kelp beds along the West Coast. Because kelp abundance and distribution is highly variable, these data do not necessarily represent current conditions. However, data from multiple years were compiled together with the assumption that these data would indicate areas where kelp has been known to occur.

✓ Alternative B.4: Seagrass (Preliminary Preferred Alternative)

Seagrass species found on the West Coast of the U.S. include eelgrass (*Zostera* spp., *Ruppia* sp.) and surfgrass (*Phyllospadix* spp.). These grasses are vascular plants, not seaweeds, forming dense beds of leafy shoots year-round in the lower intertidal and subtidal areas. Eelgrass is found on soft-bottom substrates in intertidal and shallow subtidal areas of estuaries. Surfgrass is found on hard-bottom substrates along higher energy coasts.

Alternative B.5: Core Habitat

This alternative designates core areas, defined as the upper 10% of area with an HSP greater than 0%, for the juvenile and adult life history stages of overfished and precautionary zone groundfish species. HSP refers to the probability that the habitat is suitable for a managed species.

✓ Alternative B.6: Rocky Reefs (Preliminary Preferred Alternative)

This alternative designates all rocky reef areas. Rocky habitat may be composed of bedrock, boulders, or smaller rocks such as cobble and gravel.

Alternative B.7: Areas of Interest

This alternative would designate areas that are of special interest due to their unique geological and ecological characteristics. The areas are: the northern portion of the northwest Olympic Coast National Marine Sanctuary (NMS), Grays Canyon, Astoria Canyon, Thompson Seamount, Daisy Bank, Heceta Bank, President Jackson Seamount, Rogue Canyon, Eel River Canyon, Mendocino Canyon, Gorda Escarpment, Cordell Bank, Gumdrop Seamount, Pioneer Seamount, Guide Seamount, Monterey Canyon, Monterey Bay, Taney Seamount, Davidson Seamount, Morro Ridge, San Juan Seamount, and the Cowcod Conservation Area(s). The Council could choose any combination of these areas as part of a preferred alternative.

Alternative B.8: Oil Production Platforms

This alternative designates areas around oil production platforms in Southern California waters. According to a report submitted to the Council by the California Artificial Reef Enhancement Program (CARE 2004), currently there are 27 such platforms remaining out of the 34 constructed since the late 1950s. Twenty-three of these are in federal waters and four are in California state waters.

Alternative B.9: Process for New HAPC Designations

This alternative establishes a streamlined process for designating new HAPCs, based on proposals submitted to the Council. The process would allow organizations and individuals to petition the Council at any time to consider a new designation and ensures, provided they submit a complete package as described below, that the Council will consider their proposal.

Alternatives to Minimize Adverse Impacts to EFH

Alternative C.1: No Action

There is a broad range of regulatory measures in effect on the West Coast, including areas that are closed to fishing or non-fishing activities, fishing gear restrictions, and measures to reduce fishing effort that may have a beneficial effect on EFH.

Alternative C.2: Depth-based Gear-specific Restrictions

This alternative contains three options closing waters shoreward of specific depth contours to large footrope trawl gear and fixed gear. The footrope runs along the bottom of the net opening and its size is regulated to dictate the maximum size of rollers that can be affixed to the footrope. Without larger footrope gear, bottom trawl nets snag more easily on rough, irregular terrain; thus restrictions on footrope size discourage fishing in rocky areas.

This alternative has three options:

Option C.2.1: Large footrope prohibited inside 200 fm, fixed gear inside 100/150 fm

Prohibit the use of large footrope trawl gear shoreward of 200 fm and prohibit all fixed gear shoreward of 100 fm north of 40°10' N latitude and 150 fm south of 40°10' N latitude.

Option C.2.2: Large footrope prohibited in EEZ, fixed gear inside 100/150 fm

Prohibit the use of large footrope trawl gear throughout the EEZ and prohibit all fixed gear shoreward of 100 fm north of 40°10' N latitude and 150 fm south of 40°10' N latitude.

Option C.2.3: Large footrope prohibited inside 200 fm, fixed gear inside 60 fm

Prohibit the use of large footrope trawl gear shoreward of 200 fm and prohibit all fixed gear shoreward of 60 fm coastwide.

Alternative C.3: Close Sensitive Habitat

Area closures are defined using these gear and habitat specific sensitivity and recovery index values. Habitat areas above index value thresholds for any gear type, as specified in the following options, are closed to all fishing. This alternative has four options:

Option C.3.1: Close areas where S ≥ 2 and R ≥ 1 with trawl effort adjustment

For each gear type, those areas where the sensitivity index value is greater than or equal to two and the recovery index value is greater than one are identified. The combined area is then screened to include only the area where the cumulative number of hours trawled from 2000 through 2002 is less than 100 hours. The resulting areas are closed to all fishing (i.e., to all gear types).

Option C.3.2: Close areas where S ≥ 0.5 and R ≥ 0.5 with trawl effort adjustment

For each gear type, those areas where both the sensitivity and recovery index values are greater than or equal to 0.5 are identified. The combined area is then screened to include only the area where the cumulative number of hours trawled from 2000 through 2002 is less than 100 hours. The resulting areas are closed to all fishing (i.e., to all gear types).

Option C.3.3: Close areas where S ≥ 2 and R ≥ 1 without trawl effort adjustment

The same as Option 1 except no adjustment is made for trawl effort.

Option C.3.4: Close areas where S ≥ 0.5 and R ≥ 0.5 with trawl effort adjustment

The same as Option 2 except no adjustment is made for trawl effort.

✓ Alternative C.4: Prohibit the Geographic Expansion of Fishing (Preliminary Preferred Alternative)

Under this alternative, areas that have not been fished recently (2000-2002) would be closed to fishing to protect areas that are potentially pristine. This alternative has two options:

✓ Option C.4.1: Prohibit expansion of trawl fishing

Trawl fisheries would be prohibited from fishing in areas that were untrawled during 2000-2002.

✓ Option C.4.2: Prohibit expansion of all bottom-tending gear

Apply the expansion limit to all bottom-tending gear types. The closure would extend west from a line approximating the 2,000 m (1,094 fm) depth contour to the seaward margin of the EEZ.

Alternative C.5: Prohibit a Krill Fishery

This alternative would designate krill as a component of EFH as part of this EIS and prohibit fisheries that target it.

Alternative C.6: Close Hotspots

This alternative prohibits trawling in hotspot areas, where–in this case–hotspots are defined as habitat that has high probability of being EFH for a large number of groundfish. Areas that are associated with 50 or more species/lifestage combinations would be closed to bottom trawling.

Alternative C.7: Close Areas of Interest

This alternative closes any combination of the areas of interest HAPCs designated under Alternative B.7 to fishing by specified gear types. (The 21 areas of interest listed under Alternative B.7 are underwater features, such as seamounts and submarine areas, or are currently under some form of protection.) Closures affect the following activities:

Option C.7.1: Close areas of interest to bottom trawling.

Option C.7.2: Close areas of interest to all bottom-contacting fishing activities.

Alternative C.8: Zoning Fishing Activities

Under this alternative NMFS limits the use of bottom-tending fishing gear to specified zones where the agency determines that such activities can be conducted without altering or destroying a significant amount of habitat. First, all areas deeper than the 2,000 m (1,094 fm) contour along the continental slope extending to the maximum westward range of groundfish EFH are closed to certain bottom-tending fishing gear types, according to the options described below. Second, a five-year transition period to gear specific zones is established for the remaining area inside the 2,000 m contour, which remains open to these activities, subject to any other restrictions, for the five years from implementation (e.g., 2007-2011). Third, during this five-year period, NMFS conducts the research necessary to delineate zones where specified fishing activities would be permitted. At the end of the five-year transition period, the gear-specific zones come into effect and any remaining unzoned area is closed to affected gear types, according to the options described below. (Restrictions applied outside 2,000 m remain in effect.)

In identifying fishing zones, NMFS must demonstrate that any unavoidable adverse impacts would be minimal and temporary, based on the best scientific information available.

Option C.8.1: Zoning for mobile bottom-contacting gear

Fishing zones are established for bottom-contact trawls, dredges, and similar bottom-tending mobile fishing gear. Other bottom-contacting gear types are unaffected by the zoning system, including the prohibition outside 2,000 m.

Option C.8.2: Zoning for all bottom-contacting gear

Fishing zones are established for all bottom-contacting gear types, including bottom longlines, traps, and pots. The immediate closure outside of 2,000 m applies to all bottom-contacting gear types.

In addition to establishing the zoning system, NMFS will conduct a gear substitution and modification research program, intended to redesign bottom fishing gear to reduce damage to habitat. This program will have a significant cooperative research element by employing fishermen in the design and testing of new gear.

The zoning system will be regularly modified to incorporate new information about habitat sensitivity and recovery factors, gear impacts on habitat, and to accommodate use of newly developed or modified gear.

✓ Alternative C.9: Gear Restrictions (Preliminary Preferred Alternative)

This alternative includes specific gear modifications and prohibitions that are based on that interaction. Under this alternative the following gear restrictions would be implemented in areas identified as EFH for groundfish:

- ✓ C.9.1: Prohibit roller gear larger than 15 inches on bottom trawls.
- ✓ C.9.2: Prohibit the use of flat trawl doors (i.e., require cambered doors).
- ✓ C.9.3: Limit the length of a single longline groundline to 3 nm.
- ✓ C.9.4: Employ habitat-friendly anchoring system.
- ✓ C.9.5: Prohibit dredge gear.
- ✓ C.9.6: Prohibit beam-trawl gear.
- ✓ C.9.7: Prohibit set-gillnets in waters deeper than 60 fm.
- ✓ C.9.8: Prohibit dingle bar gear (troll groundfish gear).

✓ Alternative C.10: Central California No-trawl Zones (Preliminary Preferred Alternative)

This alternative is based on a project being undertaken by two environmental advocacy organizations, The Nature Conservancy (TNC) and Environmental Defense Fund (EDF). and involves a public-private partnership under which private funds are used to purchase groundfish limited entry trawl licenses and vessels in concert with the designation, through the Council and NMFS, of no-trawl zones off the central

California coast. The project area extends from Point Conception to Davenport, California, and includes adjacent offshore seamounts (Gumdrop, Guide, Pioneer, Davidson, and Rodriguez).

TNC/ED have identified 23 permit holders they believe regularly trawl inside the project area. Most home port in Morro Bay, Moss Landing, Monterey, or Half Moon Bay. TNC/EDF intend to purchase a significant majority of the bottom trawling permits and vessels in this region if the Council/NMFS designates a significant portion of the project area as no-bottom-trawl zones. TNC/ED will identify areas they think should be designated no-trawl zones using the GIS data developed as part of this EIS in combination with a participatory process involving trawl fishermen in the project area. If this alternative is adopted as an FMP and regulatory amendment, these areas will be closed to bottom trawling by NMFS once TNC/EDF have negotiated purchase contracts or options for at least half of the limited trawl permit holders they have identified as operating in the project area.

✓ Alternative C.11: Relax Gear Endorsement Requirements (Preliminary Preferred Alternative)

Vessels holding a groundfish limited entry permit account for a large portion of groundfish landings. Currently, limited entry permits include a gear endorsement specifying the type of gear the permit holder may use. These endorsements identify three gear categories: trawl, longline, and pot. In addition, longline and pot gear permit holders may also have a sablefish endorsement. Permit holders with this species-specific endorsement may participate in the high-value primary sablefish fishery and are allocated vessel-specific catch quotas, known as tier limits because the endorsements fall into one of several categories, or tiers, with different catch quotas. Under this alternative, gear endorsements are relaxed but the sablefish endorsement is not. This would allow permit holders to switch gear types, providing fishermen greater flexibility in changing strategies based on prevailing conditions in the fishery.

✓ Alternative C.12: Close Ecologically Important Areas to Bottom Trawl (Preliminary Preferred Alternative)

This alternative was proposed by the environmental group Oceana and adopted by the Council. The alternative would close a network of areas to bottom trawling; set a maximum footrope size of eight inches on bottom trawl gear within open area; require Vessel Monitoring Systems on all bottom trawl vessels with positions recorded every 5 minutes; increase onboard observer coverage on bottom trawl vessels to a level determined to be necessary by NOAA to estimate annual bycatch of habitat-forming invertebrates; establish a process for setting a limit on the bycatch of habitat-forming invertebrates; require ongoing research including comprehensive benthic mapping.

✓ Alternative C.13: Close Ecologically Important Areas to Bottom-contacting Gear (Preliminary Preferred Alternative)

Under this alternative, the areas identified in Alternative C.12 are closed to all bottom-contacting gear types, defined as both fixed gear (longlines, pots, and traps) and bottom trawl.

✓ Alternative C.14: Close Ecologically Important Areas to Fishing (Preliminary Preferred Alternative)

Under this alternative, the areas identified in Alternative C.12 are closed to all fishing.

Research and Monitoring Alternatives

Alternative D.1: No Action

NMFS conducts extensive fishery-related research relevant to groundfish and has a variety of methods to monitor these fisheries. Section 7.1 in the 2005-2006 groundfish harvest specifications FEIS (PFMC 2004) describes groundfish monitoring programs carried out by NMFS, the states, and tribes, and is hereby incorporated by reference. Current monitoring programs especially relevant to the alternatives described here include the limited entry trawl logbook program, the West Coast Groundfish Observer Program, and VMS covering limited entry trawl and fixed gear vessels. These programs are primarily intended to monitor discards and landings of groundfish and to enforce current harvest limits and area restrictions. There is no component specifically intended to monitor the effects of fishing on EFH.

Alternative D.2: Expanded Logbook Program

Under this alternative vessels in all commercial sectors, including recreational charter (for hire) boats, will participate in an expanded logbook program.

Option D.2.1: All fishing vessels maintain a logbook

All fishing vessels maintain a logbook, recording information on fishing time, location, and catch composition similar to the current trawl logbook program.

Option D.2.2: A sub-sample of fishing vessels maintain a logbook

A representative, random sample of all fishing vessels is required to maintain logbooks, gathering the information described above.

Alternative D.3: Expanded Vessel Monitoring System

This alternative will identify expansion of the Vessel Monitoring Program to cover all West Coast groundfish commercial and recreational charter vessels as an important program objective to be implemented through tiered actions.

Alternative D.4: Research Reserve System

This alternative will establish a system of areas that are closed to fishing to foster habitat-related research and comparison of fished areas with unfished areas.

Summary of Public Comment on Specific Alternatives in the Groundfish EFH DEIS

The following tables summarize public comment received and reproduced under Agenda Item C.3.d. Only comments that are clearly in reference to one of the alternatives are summarized here. Where appropriate, qualified support or opposition to the adoption of a preferred alternative is noted. It should be noted that a lot of the public comment expressed general support or opposition to the intent, general measures, methodology, and analysis in the DEIS, which is not reflected here. The reader should refer to the public comment letters themselves for details on the recommendations summarized here, as well as the broader range of comments and recommendations the public made on the groundfish EFH DEIS.

A. Alternatives to Identify and Describe EFH (Alternatives A.1–A.6)

	A.1	A.2	A.3	A.4	A.5	A.6
Audubon Society of Portland		Choose as preferred				
Coos Bay Trawlers' Association	Choose as preferred	Second choice as preferred				
Craven, Robert				Choose as preferred		
Independent Scientific Review Panel			Received the most support of the panel with additional recommendations	Supported by 2 panel members		
Natural Resources Defense Council/The Ocean Conservancy		Choose as preferred, modified to include seamounts

UNITED STATES DEPARTMENT OF COMMERCE
National Oceanic and Atmospheric Administration
NATIONAL OCEAN SERVICE
Silver Spring, Maryland 20910

May 25, 2005

Donald K. Hansen, Chairman
Pacific Fishery Management Council
7700 NE Ambassador Place, Suite 200
Portland, Oregon 97220

Dear Chairman Hansen: Don

We appreciate the recent efforts of the Pacific Fishery Management Council (PFMC) to consider the request from the National Oceanic and Atmospheric Administration (NOAA) that the PFMC draft fishing regulations under the National Marine Sanctuaries Act to protect the Cordell Bank National Marine Sanctuary and for the proposed addition of the Davidson Seamount to the Monterey Bay National Marine Sanctuary. Your efforts reflect a positive level of partnership between the PFMC and the national marine sanctuaries on the west coast. I thank you and your colleagues for their leadership.

Your April 22, 2005 letter to the National Marine Sanctuary Program (NMSP) suggests that the fishing regulations proposed to protect these sanctuaries are more properly adopted under the Magnuson-Stevens Fisheries Conservation and Management Act. We understand that the June 2005 meeting of the PFMC will consider the Draft Environmental Impact Statement (EIS) for the Pacific Groundfish Essential Fish Habitat (EFH) program, and later meetings will address the regulatory strategies necessary to implement the selected alternatives.

Staff of the NMSP and NOAA Fisheries Service are actively discussing the proposal to adopt fishing regulations under the Magnuson-Stevens Act to protect the Cordell Bank and Davidson Seamount. Should NOAA adopt this approach, it will be important that your actions on EFH allow for adoption of fishing regulations that can meet the goals and objectives established for the Cordell Bank and Davidson Seamount. The purpose of this letter is to provide technical advice on the combination of EFH alternatives presently under consideration.

Based on an initial review, Alternative A.2, and management Alternatives C.13 and C.14, in the Draft EIS for EFH appear to accomplish the regulatory solution described in your April 22, 2005 letter for the protection of Cordell Bank and Davidson Seamount. We note, however, that portions of the Davidson Seamount area for which the NMSP proposes protection extend to 3,875 m water depth, beyond the 3,500 m water depth described in Alternative A.2. We suggest you consider adding this extra depth for the Davidson Seamount area to Alternative A.2.

Please note that this represents our preliminary assessment of what can be done under this particular pending Council action to promulgate fishing regulations for Cordell Bank and Davidson Seamount. However, this does not preclude the need for possible further action under the Magnuson-Stevens Act to achieve the goals and objectives of the Sanctuaries with respect to fishing regulations. Thank you for your consideration of this technical advice.

Don,
As I've conveyed to the "other" Don. We sincerely appreciate the Council's perspective and willingness to find the "common ground."

Sincerely,

Daniel J. Basta, Director
National Marine Sanctuary Program

cc: Rebecca Lent, Deputy Assistant Administrator, NOAA Fisheries
Rod McInnis, Southwest Regional Administrator
Robert Lohn, Northwest Regional Administrator
Donald McIsaac, Executive Director, PFMC
Dan Howard, Manager, Cordell Bank National Marine Sanctuary
William J. Douros, Superintendent, Monterey Bay National Marine Sanctuary

CALIFORNIA DEPARTMENT OF FISH AND GAME GROUNDFISH ESSENTIAL FISH HABITAT (EFH) ENVIRONMENTAL IMPACT STATEMENT: FINAL PREFERRED ALTERNATIVES

Alternative A.2: Depths less than 3500m

California supports the EFH Alternative 2 plus those seamounts within the EEZ in waters deeper than 3,500m. This provides for the greatest extent of known habitat supporting the ecosystem in which groundfish flourish or could flourish. This would provide habitat consideration and protection to all groundfish habitats within this zone. California supports adding or removing such habitat descriptions as information becomes available.

Alternative B.7: Areas of interest

California supports HAPC designations for the following areas only:
Seamounts within state borders - Unique, sensitive habitats which support rich communities of invertebrates and serve as habitat for some groundfish.
Monterey Canyon - Unique and diverse habitats in the largest submarine canyon off California.
Specific areas of the Cowcod Conservation Area (as designated on DFG proposed map) - Invertebrate (Gorgonian and coral) concentrations have been identified in four areas in and around the CCAs during recent submersible surveys. These include the Eastern CCA, Cherry Bank, Potato Bank, and Kidney/Hidden Banks. These are the only actual location data for concentrations of these invertebrates that are currently available.
Federal Waters MPAs in the CINMS as designated on DFG proposed map – (see further discussion below under C.14)
Cordell Bank - A productive high relief rocky reef area that is important to a number of overfished species including Canary rockfish.
Mendocino Ridge - An extensive high relief rocky reef area extending across depth zones in a transition area between biogeographic regions.

Alternative B.8: Oil Production Platforms

California is supporting HAPC designation for those platforms that show consistent high abundances of various groundfish living on or around these structures. Several PFMC designated "overfished species" are found in measurable concentrations on specific platforms. Currently, this would include 13 such structures in the Santa Barbara Channel area. Other platforms may be considered on a case-by-case basis as more information on their relationship to groundfish becomes available.

Alternatives C.4.1: C.9.6: C.10; C.12; C.13; and C.14

California supports alternatives to minimize adverse impacts on EFH due to fishing as the following prohibitions:

Alternative C.4.1: Prohibit geographic expansion of fishing

Trawl foot print designation – Use 700 fm as the outer boundary of the trawl foot print for areas north of Pt. Conception and 300 fm for areas south of Pt. Conception. These isobaths include nearly all recent trawl tracks and would also leave some "unfished" areas within that zone which would provide future opportunities for fishery flexibility, while closing all areas in deeper waters to protect habitats from future expansion of trawl fishing. Future justifiable requests could be considered to modify these boundaries to allow beyond these depths. This might involve establishing a process involving technical and regulatory review committees to consider and make recommendations on such proposals.

C.9.1: Gear restrictions: prohibit roller gear larger than 15"

Roller gear larger than 15" to prevent damage from trawl gear to high relief rocky reefs and sensitive attached invertebrates.

C.9.5: Gear restrictions: prohibit dredge gear

Dredge gear to prevent damage to soft bottom substrates and sensitive invertebrate communities. (This gear is currently not allowed in California.)

C.9.6: Gear restrictions: prohibit beam trawl gear

Beam trawl except for San Francisco Bay bait shrimp fishery – long established fishery in highly altered habitat. Prevents damage to soft bottom communities, low relief rocky substrates, and sensitive attached invertebrates.

C.9.8: Gear restrictions: prohibit dingle bar gear

Dingle-bar gear to prevent damage to rocky reefs and sensitive attached invertebrates

C.10: Central California no-trawl zones

Support the most up to date collaborative version of the agreement between the Nature Conservancy and Industry areas 1,2,and 3 off central California between Point Sur and Point Conception including Davidson seamount.

C.12: Close ecologically important areas to bottom trawl

Trawl gear prohibition - Oceana revision maps including the Trawl industry maps (version 8 am 6/15/2005) as follows: (N to S)

Areas of agreement – In federal waters accept all areas of agreement between the Oceana/ Industry proposals and any other areas of agreement in state waters (e.g. Monterey Bay, state waters extend 3 miles seaward of a line between Pt. Santa Cruz and Pt. Pinos in this area). This would provide protection to areas of known or expected sensitive habitats while limiting the economic impacts to those acceptable to the fishery.

These include the areas of substantial overlap between the Oceana and Industry proposals for:

Northern and Southern California -
Crescent City Deep Biogenic Area (32)
Eel River Canyon (34) with state modification
Blunts Reef (35)
Mendocino Ridge (36)
Delgado Canyon (37)
Tolo Bank (0)
Point Arena Offshore (39)
Biogenic Area 12 (40)
Cordell Bank (41)
Farallon Is./Fanny Shoal (42)
Half Moon Bay (42) with state modification
Monterey Bay/Canyon (45) with state modification
Point Sur Deep (44)
TNC/ED areas between Pt. Sur and Pt. Conception

Southern California - California proposes fishing gear closures for the areas designated as MPAs in state and federal waters in the CINMS, trawl gear closures in three sub areas in the Cowcod Conservation Area West (CCA) and the CCA East based on their designation as HAPC, and an area surrounding Catalina Island (51) proposed by Oceana. This would protect large areas of rocky habitat, a submarine canyon and occurrences of some deep water invertebrates.

CCA West Sub-Areas (from 50):
  Potato Bank (50-1)
  Cherry Bank (50-2)
  Hidden Reef/Kidney Bank (50-3)
Catalina Island (51)
CCA East (52)

<u>C.13: Close ecologically important areas to bottom-contacting gear</u>
Davidson Seamount – Support prohibiting all bottom contact fishing gear to prevent damage from future fishing or other resource exploitation activities.
Cordell Bank - Support prohibiting all bottom contact fishing gear in depths shallower than 50 fm.

C.14: Close ecologically important areas to fishing
Implement federal waters portions of Channel Islands MPAs.

The Channel Islands MPAs are a proportional representation of habitat types that occur in a unique area of high productivity, biodiversity and biogeographic and oceanographic mixing. This would be the completion of the federal waters phase of the Channel Islands MPA process which implemented MPAs in state waters that were designed to protect habitat and resources in that region. This was a six-year partnership process between the state and the CINMS involving extensive stakeholder input and involvement and continues as a multi-party collaborative effort. All MPAs except the western Anacapa Island marine protected area would be complete no take areas. With the exception of the proposed “Foot Print” MPA in Federal waters all others would be contiguous with existing state MPAs.

Alternative D.1: No Action
California supports the no action alternative which continues to collect fishery monitoring data through a trawl logbook program, the groundfish observer program, and vessel monitoring systems. California does support continued identification of important data gaps for effective management of the groundfish fisheries and efforts to identify and commit funding to adequately address those research needs.

Alternative D.2: Expanded logbook program
California has concerns about the practicality, logistical requirements, and funding needed to implement an industry-wide logbook program and ability to productively use the data generated from such a program.

Alternative D.4: Research Reserve System
A separate research reserve system is not be needed since the proposed MPAs in the CINMS and other proposed gear closures which may be implemented could serve that function, especially on issues of fished and non-fished habitat comparisons.

CDFG-proposed modifications to four areas proposed for closure under C.12

The following provide descriptions of modifications proposed by CDFG in Figure 1 (depicted by an asterisk (*)) to address areas where discrepancies occur between Oceana and Trawl Industry proposals under C.12.

Crescent City Deep Biogenic Area (32):
Modification: Adopt Oceana Area boundaries westward of Trawl Industry-proposed western boundary.
Concerns addressed: The eastern portion proposed for removal is frequently trawled and would make compliance with the closure boundary difficult.

Eel River Canyon (34):
Modification: Adopt Trawl Industry proposal seaward of the deep RCA boundary and adopt Oceana proposal shoreward of the deep RCA boundary.
Concerns addressed: Provide enforceable size closure in shoreward area and extend habitat protection along canyon and into deeper waters.

Half Moon Bay (42):
Modification: remove area shoreward of line proposed by Oceana (see figure)
Concerns addressed: Eastern section is sandy habitat that is needed for a trawl corridor. Easternmost tip offers rocky habitat that may be too small to enforce as a separate closure.

Monterey Canyon (45):
Modification: Adopt Oceana proposed boundaries in western half of area; adopt Trawl Industry proposed boundaries in eastern half along canyon and southeast.
Concerns addressed: Trawling for California halibut occurs along areas that would otherwise be closed if the entire Oceana area was adopted.

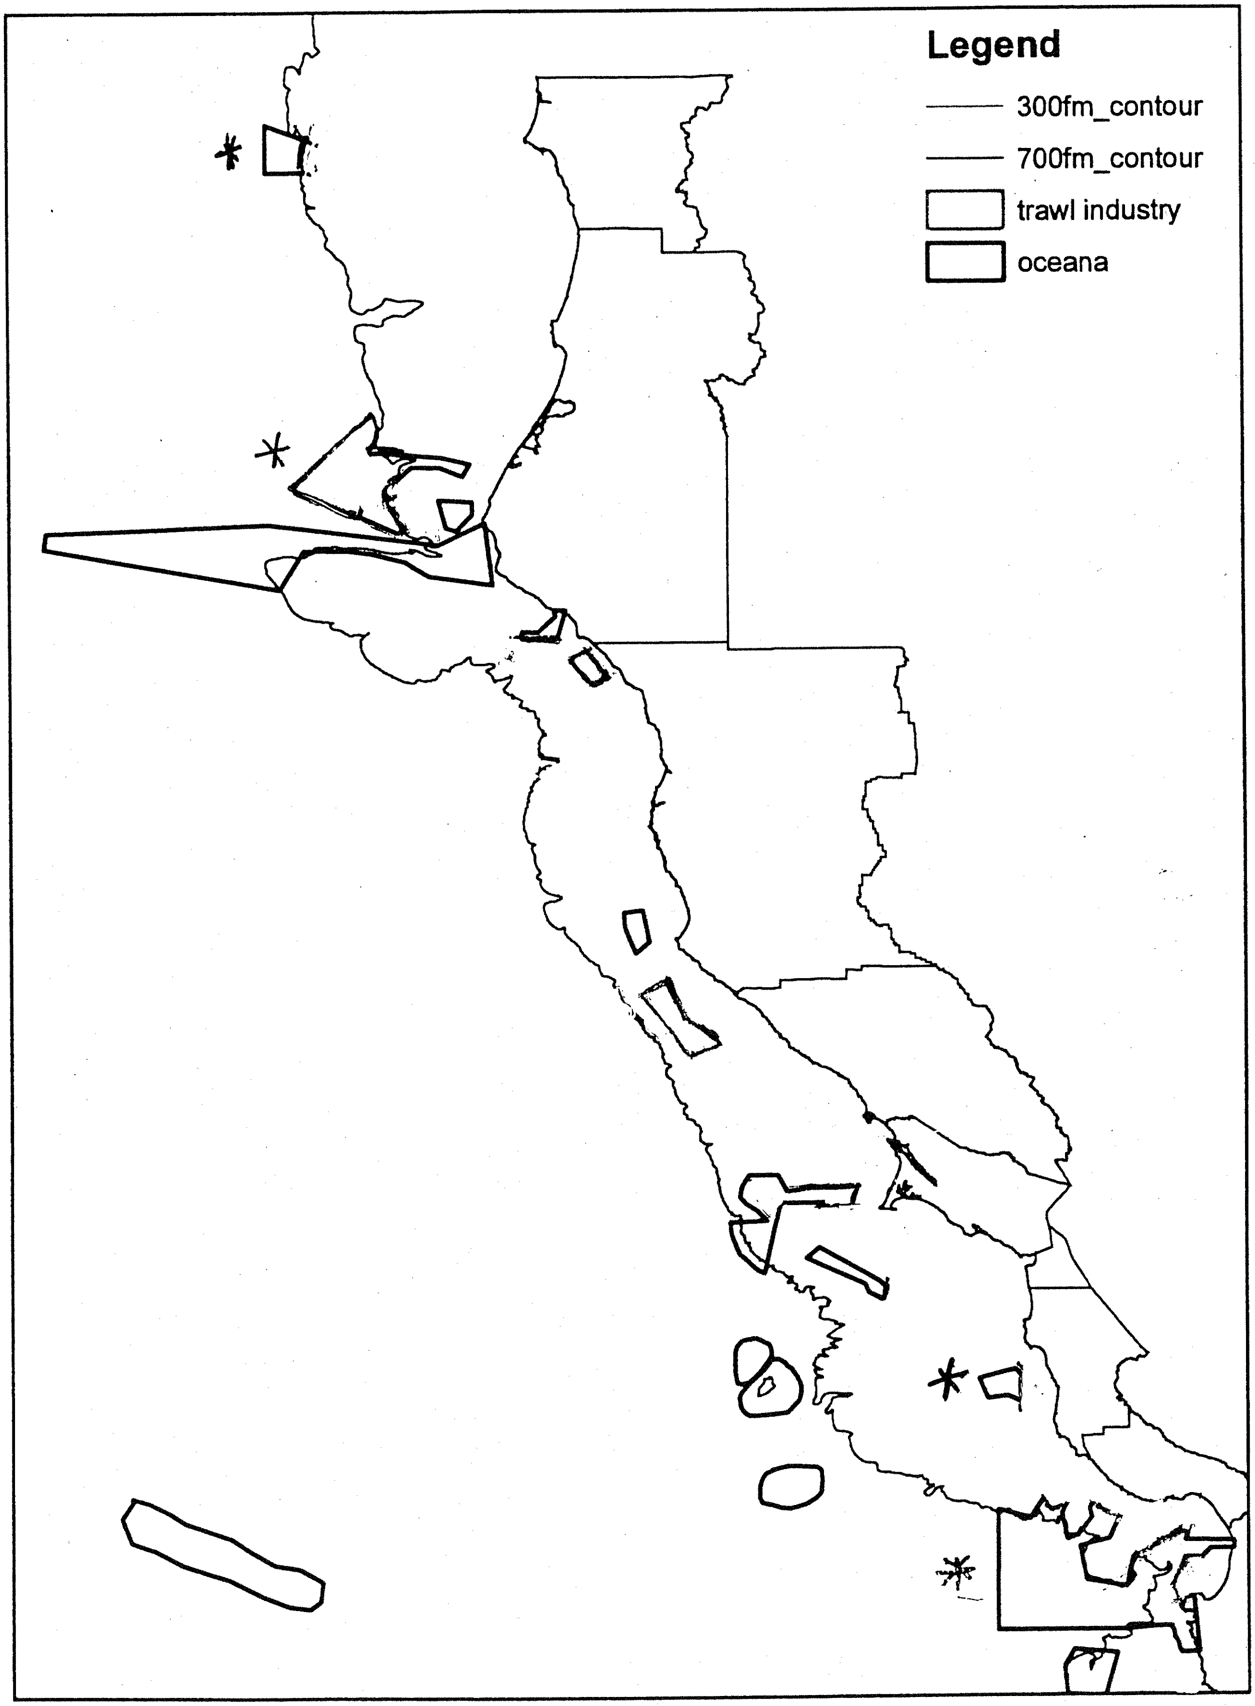

Figure 1: CDFG-supported proposed trawl closure areas under C.12
Boundaries represent areas agreed upon by Oceana and the Trawl Industry.
Areas with an asterisk (*) represent CDFG-modified proposed boundaries where discrepancies occur.

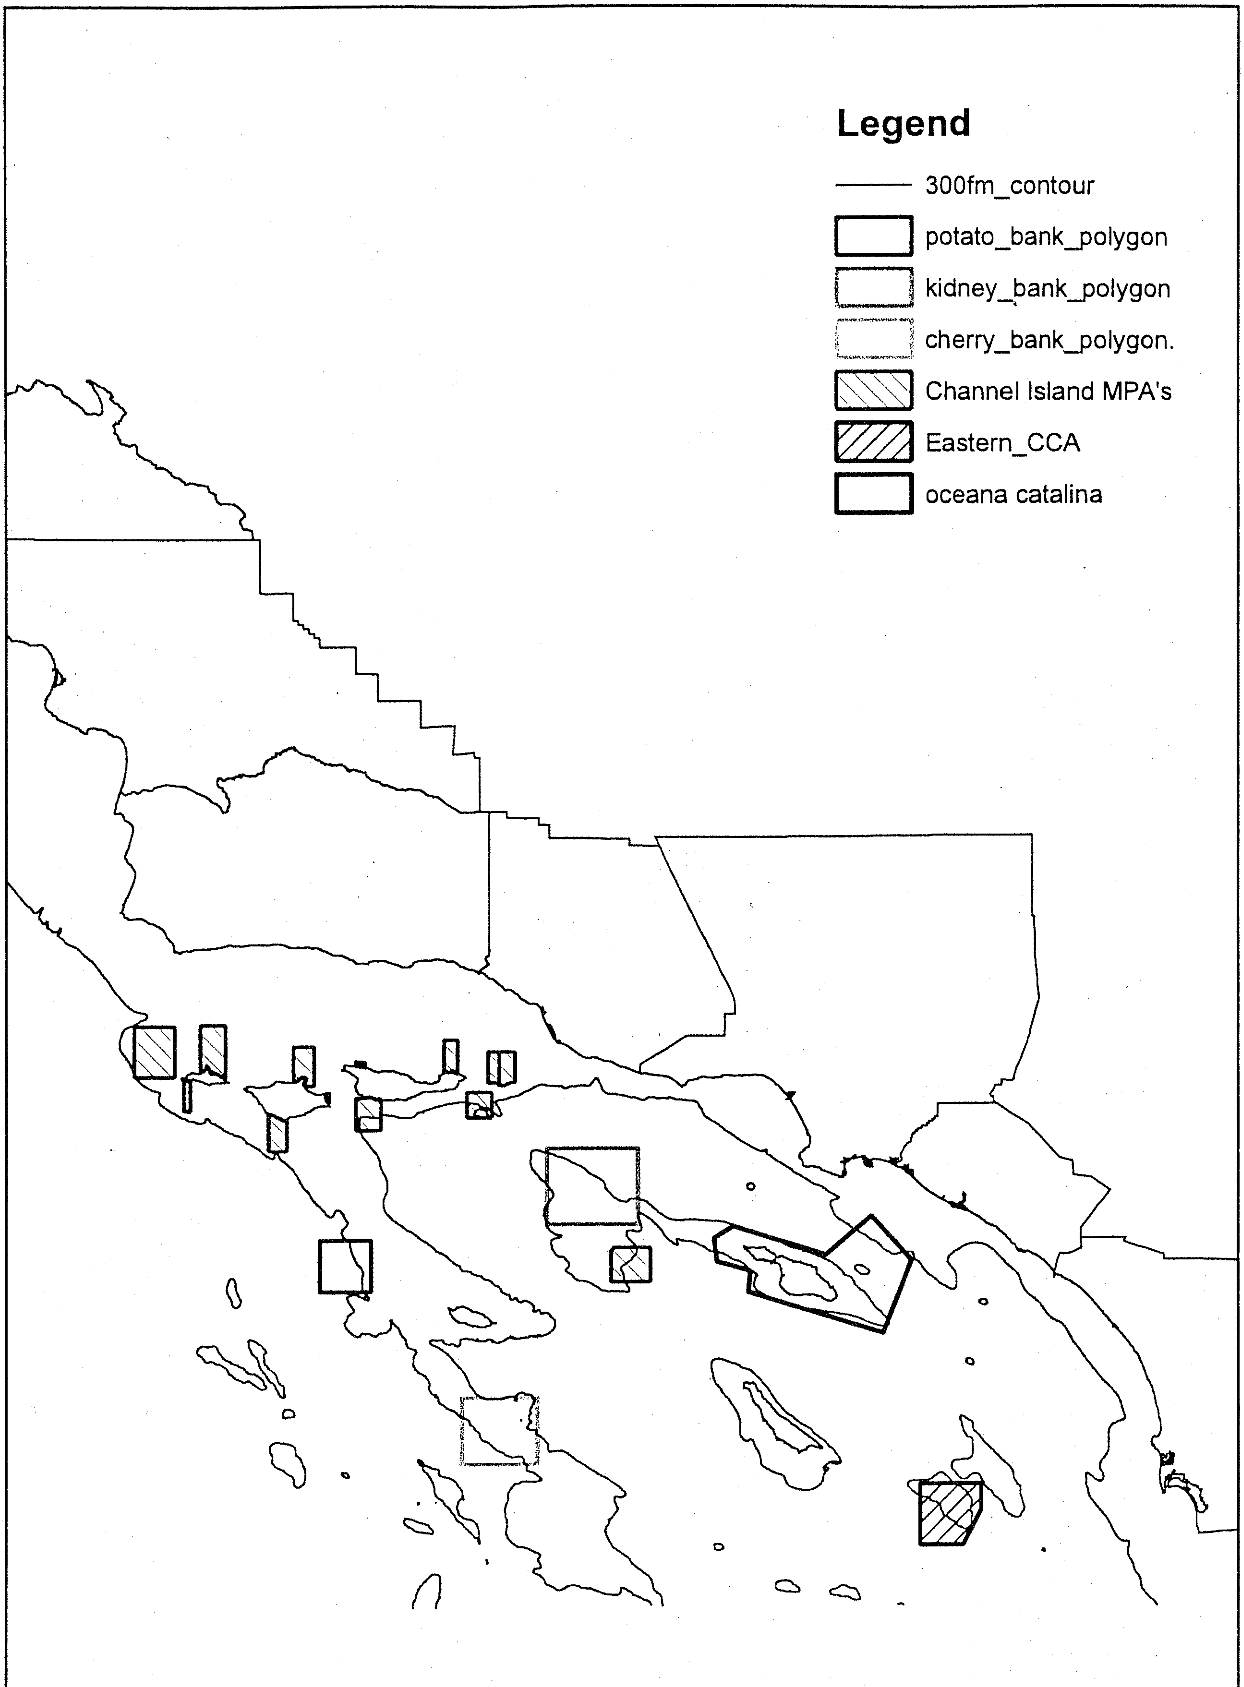

Figure 2: CDFG-supported proposed trawl closure areas under C.12
Boundaries represent areas agreed upon by Oceana and the Trawl Industry.
Areas with an asterisk (*) represent CDFG-modified proposed boundaries where discrepancies occur.

**OREGON DEPARTMENT OF FISH AND WILDLIFE
GROUNDFISH ESSENTIAL FISH HABITAT (EFH) ENVIRONMENTAL IMPACT STATEMENT : FINAL PREFERRED ALTERNATIVES**:

The Oregon Department of Fish and Wildlife (ODFW) has conducted significant public outreach and analysis of the various Essential Fish Habitat (EFH) options for review and selection at the June 2005 Pacific Fishery Management Commission (PFMC) meeting. Efforts were made to provide analysis and review public comment on as many of the options feasible within the time constraints of this process.

ODFW conducted initial technical review sessions with various interested entities, including commercial trawlers, commercial fixed gear and recreational fishery representatives. Because of concerns regarding state fisheries, the options were discussed and reviewed with the Oregon Dungeness Crab Commission, and analysis of pink shrimp tows vs. various geographical options were conducted in consultation with representatives of the pink shrimp fishery. In partnership with the Oregon Sea Grant Extension, ODFW conducted three public meetings in Mid-April (Astoria, Newport and Bandon). The meetings were attended by commercial and sport fishers as well as conservation group representatives and the general public. National Marine Fisheries Service (NMFS) staff were in attendance and provided information at these public meetings. Follow up meetings were held with representatives of the commercial and sport sectors to discuss additional alternatives which were received from Oceana and the trawl industry after the above-referenced public meetings.

The public was concerned about the lack of ongoing education and public outreach regarding this federal process and the fact that options were continuing to be drafted for consideration after the draft environmental impact statement was released for comment on February 11, 2005.

ODFW and the public share the concern that the states have had difficulty adequately analyzing options (to back-up/ground truth federal analysis) which were submitted during and after the DEIS comment period. As a result, ODFW has focused on options that have had adequate public review and analysis wherever possible.

With those caveats, ODFW has, in this exhibit, recommended some criteria for the selection of options. We believe that this is a first step. A formal and timely review process is critical so that final alternatives selected by the PFMC at this June 2005 meeting. Additionally, a system for adequate review of future additions/deletions and changes to these final alternatives is essential.

A. Essential Fish Habitat (EFH): ODFW supports the combination of alternative A2 (waters in depths < or = to 3500 meters/1914 fm) and A3 (100% of habitat suitability profiling). These options were recommended by the PFMC Habitat Committee and the Groundfish Management Team. This designation is reasonable, given data uncertainties and the scope of these options provides a precautionary coverage for EFH consultation. A combination of these two mutually exclusive options provides the wide breadth of habitat designation which is appropriate and necessary for the productivity of groundfish life stages, given current limitations to our information base (biological and habitat). ODFW recommends that any HAPC or fishing mitigation measure not included in this definition of EFH be included as EFH at the time of adoption.

B. Habitat Areas of Particular Concern (HAPC): Within Alternative B7 (Areas of interest), there are distinct locations that can be clearly defined in waters off of the coast of Oregon. The following areas, as currently understood, are likely to be important ecological systems for groundfish life stages, may be sensitive to human-induced impacts, may be at risk should ocean development options take place and are significant habitats for groundfish.

The following areas are appropriate for initial designation as HAPC: Daisy Bank/Nelson Island, Thompson Seamount, President Jackson Seamount. Other option-B7 areas of interest may be included as HAPC as defined geographically under the Oregon option for C-12 below (Rogue Canyon, Heceta Bank and Astoria Canyon).

ODFW's position is that estuaries (B2), canopy kelp (B3), sea grass (B4) and rocky reefs (B6) also meet the criteria for consideration as habitat areas of particular concern and should be designated as HAPC.

Because HAPC designation is a subset of EFH and is primarily a consultation trigger (vs. regulatory), specific locational information is relevant only if HAPC areas are included in specific regulatory actions. In order to identify these habitat types locationally (defining borders), additional information and definitions are necessary. Kelp beds and sea grass locations are not static and there may be problems with designating a living, moving habitat type. Mapping of these areas is not at a level of detail that allow for accurate designation geographically. Rocky reefs, as mapped in the DEIS, are general and there are known reefs missing from the maps currently in the EIS. Since these habitat types occur primarily in state waters, we recommend a state/federal specification/review process by which these will be more specifically defined geographically in the event of regulatory action in these areas. This process should be conducted in a timely manner in collaboration with the states.

C. Alternatives to Minimize Adverse Impacts on EFH Due to Fishing:

ODFW has reviewed and analyzed options within this set of alternatives. This is in addition to the analysis done by NMFS in the DEIS. State/ODFW analysis included:

* Trawl start points (2000-2003) were mapped on options that were relevant to those data: C-2 (options 1 and 2), C-3 options 1-4, C-6, C-7 and C-12.
* Ex- vessel landed value associated with each option: C-2, C-3, C-6, C-7 and C-12 (as proposed in the February 2005 DEIS)
* Ex-vessel landed value of the C-12 options prepared after the DEIS was released for comment: (i.e., the second Oceana option and the trawl industry option).
* All trawl related impact minimization options were analyzed for catch per unit effort in the trawl fishery (2000-2003 logbook information).
* Alternative C-4 (trawl footprint) was analyzed against historic (1993-1996) trawl data in the area west of the RCA.
* Historic trawl data from "no footprint" areas nearshore in Oregon waters (Option C-12, Oceana #2) was not able to be analyzed adequately for decision-making at this time.

* 2003-2004 trawl tow line/landed catch analysis in areas within the second Oceana and trawl industry proposals.
* Maps of historical shrimp tow starts (1980, 1989, 1992) off of Oregon and Southern Washington.
* Maps that overlay the C-12 Oceana and Trawl Industry alternatives as well as rocky substrate data base (NMFS), the bottom trawl RCA, 2003 tow line data (for a sample view of the trawl routes), areas of interest and Oceana no-trawl history footprint option.

A black and white copy of these overlay maps is attached to this statement. Colored maps and additional data/summary charts mentioned above are available from ODFW.

Criteria ODFW used to evaluate options to minimize fishing input include:

* Focus on documented habitat areas of value to groundfish life stages.
* Emphasize locations with unique/high relief topographic features with best available data
* Support balanced use of data sets: e.g., for biogenic/corals need both presence <u>and absence</u> analysis per SSC advice.
* Geographic sites chosen to minimize adverse fishing practices must be selected and regulations designed for enforcement practicability (see Enforcement Consultants' Statement on EFH) and are cost feasible to implement/enforce.
* Fishing impact minimization alternatives should focus on fisheries with adequate locational and economic impact data bases/analysis (e.g., logbook information).
* Data must allow for adequate analysis of impacts/economic value of displaced Fisheries balanced with EFH habitat protection.
* Designate unique habitats as no-trawl areas within the current bottom trawl RCA as priority areas for research on the results of reduced bottom trawl impacts.
* Accommodate/do not pre-empt ongoing state habitat preservation/designation processes in state waters.
* Use both scientific and fisher knowledge of no-trawl site habitat area dimensions when various sitting options overlap.

A critical component of this process:

* Establish a 'star panel'-like review process to review and fine-tune these initial locations/fishing practices and to establish criteria and recommendations on future additions/modifications.

ODFW recommends the inclusion of the following locations in waters off of the Oregon coast for inclusion as no-bottom-trawl areas in the final EIS as a modification to option C-12. These locations are described with the provision that exact and appropriate lat/long information shall be established in the regulatory implementation phase of this process.

I. 'No-trawl' sites within the 75 fm to 200 fm bottom trawl RCA which should serve as priority locations for ongoing research into the results of removal of bottom trawl gear from ecological/habitat areas of interest (numbers preceded by "O" are Oceana-described option C-12 areas; numbers preceded by "T" are trawl industry described option C-12 areas)

* O-11 [11] (Nahelem Bank/Shale Pile) 100% within the bottom trawl RCA
* O-18 [18] (Daisy Bank/Nelson Island): 100% within the bottom trawl RCA
* O-28 [28] (Bandon High Spot), area that is within the bottom trawl RCA only

II. No-trawl sites outside of the bottom trawl RCA:

* T-5 (Portion of Astoria Canyon)
* T-6 (Siletz-deepwater)
* T-7 (Siletz Bay nearshore)
* T-8: (Newport Rockpile/Stonewall Bank)
* T-9: (Portion of Heceta Bank)
* T-10 (Deepwater off Coos Bay)
* T-12 (Portion of Rogue Canyon)

III. Gear-types prohibited:

* Bottom Trawl roller gear larger than 19" in diameter (C-9-1)
* Beam trawl gear (Option C-9-6)

D. Alternatives for Research and Monitoring

* ODFW supports the establishment of a NMFS-State-Fishery "star-panel"-like process (or similar entity that may exist currently) which would convene to review and refine the June 2005 PFMC/NMFS approved alternatives for EFH, HAPC and fishing impact minimization. This process would also serve to review and prepare updates to the Groundfish EFH for the mandatory 5 year review in 2010.

* Research on the impact/results of trawl closures is recommended. The ODFW-priority areas within the RCA serve to provide excellent research opportunities to analyze the impact of the new EFH-related regulations. This is supported by the Habitat Committee report/recommendations.

* Support the expansion of logbook programs to non-trawl fisheries.

Mr. Chairman,

The EFH DEIS currently contains language stating that, "NMFS does not intend for any of the alternatives described below to apply to tribal fisheries in U&A grounds described in 50 C.F.R. 660.324(c)." The tribes would like to reiterate that treaty fisheries be recognized as exempt from any alternative going forward in the EFH FEIS that would negatively impact treaty fishing rights. We will continue working with NOAA Northwest Region Staff to develop and/or specify appropriate habitat protections within usual and accustomed areas (U&As).

The tribes also note that NOAA has a procedural duty to consult with us on matters affecting our interests in U&A areas (Executive Order 13175)[1]. As such no closure should be established in a U&A area without consultation and agreement of the affected tribe(s). Finally, we recognize the importance of assessment and monitoring programs developed in conjunction with the tribes to measure the appropriateness and effectiveness of habitat protections within U&As.

1 Consultation and Coordination with Indian Tribes, American Indian and Alaska Native Policy of the U.S. Department of Commerce, dated March 30, 1995

Highlights by Phil anderson

WASHINGTON DEPARTMENT OF FISH AND WILDLIFE REPORT ON ESSENTIAL FISH HABITAT ALTERNATIVE C.12

The Washington Department of Fish and Wildlife (WDFW) has reviewed and analyzed Alternative C.12, which includes a proposal to close specific areas to bottom trawling as a measure to minimize adverse impacts to essential fish habitat (EFH). WDFW staff used coastal groundfish trawl logbook tow location and catch data from 2003 and 2004 to analyze the effects of closing the proposed areas in waters adjacent to the Washington consistent with the approach described in Exhibit C.3.b, WDFW Report.

WDFW staff analyzed the proposed closed areas off Washington which were contained in the original Oceana alternative, the trawl industry proposal, the revised Oceana alternative, and a WDFW proposal. The results of this analysis are presented in Attachment 1.

As Council is well aware, it is not easy to determine which choices to make that provide adequate habitat protection while minimizing impacts to the fishing industry. We realize the importance of setting aside areas that represent a diversity of habitat types, areas that are particularly susceptible to human disturbance, and areas that are currently undisturbed. We recognize the National Marine Fisheries Service's effort to collate and present the available information to aid this decision-making process; however, we struggled with the sparseness of the information with which to identify all of the areas needing protection and evaluate the impacts to the trawl fishery resulting from closing those areas.

Essentially, the WDFW proposal includes those areas contained in the revised Oceana alternative that have < 5% of the catch of any target species category (e.g., DTS, petrale, dogfish). These areas are: Olympic 2, and Biogenic Areas 1, 2, and 3. The WDFW proposal also includes a modified Grays Canyon area, which closes the majority of the canyon between 100 and 200 fms (see attached map).

We believe our recommended closures represent an important first step in protecting the essential habitat of the groundfish resource while maintaining access for the Washington fishing industry to healthy groundfish stocks, and we offer the following rationale for our proposal:

Olympic 2

- EFH Protection – This proposed closed area contains the only known location in the Northwest Pacific of *Lophelia pertusa,* a reef-forming deep-sea coral. A total of 18 records of habitat-forming invertebrates have been recorded in the revised closed area by NOAA trawl surveys. These include *Alcyonacea* soft corals, other gorgonian corals, scleractinian corals, and Hexactinellid sponges.

- Impacts to Trawlers – The revised boundaries of Olympic 2 are similar to the trawl industry proposal, which avoid important arrowtooth flounder and petrale sole fishing grounds in the northern and southern ends of the original Oceana alternative.

Biogenic 1

- EFH Protection – Every NOAA trawl survey haul performed in the proposed area has recorded the presence of habitat-forming invertebrates, including black corals, scleractinian corals, Hexactinellid sponges, bamboo corals, and sea whips.

- Impacts to Trawlers – The revised boundaries exclude a heavily fished area in the eastern portion of the previously proposed closure, which accounted for much of the estimated economic impact to the trawl industry.

Biogenic 2

- EFH Protection – Every NOAA trawl survey haul performed in the proposed area has documented the presence of habitat-forming invertebrates, including black corals, gorgonians, Hexactinellid sponges, and sea pens.

- Impacts to Trawlers – The revised boundaries exclude a small, but important, fishing area along the eastern edge, and extend the area north and south into unfished and lightly fished areas, as well as deeper waters.

Biogenic 3

- EFH Protection – Every NOAA trawl survey haul performed within the proposed area has documented habitat-forming invertebrates, including black corals, gorgonian corals, sea whips, and sponges.

- Impacts to Trawlers – The revised boundaries encompass the area proposed by the trawl industry (Willapa area), and also include area not recently trawled.

WDFW Grays Canyon

- EFH Protection – The proposed area contains underwater obstructions, trawl hangs and "untrawlable" areas. Most NOAA trawl survey hauls in the proposed closed area documented habitat-forming invertebrates, including records of black corals, gorgonian corals, scleractinian corals, and Hexactinellid sponges.

- Impacts to Trawlers – WDFW is specifically excluding portions of the Oceana revised Grays Canyon alternative because that larger area to the east is primarily soft bottom habitat and contains important pink shrimp grounds. The WDFW-proposed Grays Canyon falls within the boundaries of the current trawl rockfish conservation area (i.e., between 100 fms and 200 fms), so the impacts to the trawl industry are expected to be negligible.

Seattle, WA 98115-0070

Dear Mr. Lohn:

The U.S. Environmental Protection Agency (EPA) has reviewed the draft Environmental Impact Statement (EIS) for **Essential Fish Habitat Designation and Minimization of Adverse Impacts** (CEQ No. 20050049) in accordance with our responsibilities under the National Environmental Policy Act (NEPA) and Section 309 of the Clean Air Act. Section 309, independent of NEPA, specifically directs EPA to review and comment in writing on the environmental impacts associated with all major federal actions and the document=s adequacy in meeting NEPA requirements.

The draft EIS evaluates the effects of a strategy to conserve and enhance essential fish habitat (EFH) for fish managed under the Pacific Coast Groundfish Fishery Management Plan (FMP). The EIS includes alternatives for identification of EFH and Habitat Areas of Particular Concern (HAPC), measures to minimize adverse impacts to EFH from fishing activities, and research and monitoring actions to encourage the conservation and enhancement of EFH. The proposed action is to ensure compliance with section 303(a)(7) of the Magnuson-Stevens Act and will amend the Pacific Coast Groundfish FMP.

The EIS provides six alternatives for identifying and designating EFH, nine alternatives for designating HAPC, fourteen alternatives with various options for minimizing adverse fishing impacts to EFH and four alternatives with two expanded logbook program options for research and monitoring. The following tables provide ratings for each of the alternatives and options provided in the EIS.

An overall rating of EC-2 (Environmental Concerns - Insufficient Information) along with a summary of our comments will be published in the *Federal Register*. A copy of the rating system used in conducting our review is enclosed for your reference.

*LO – Lack of Objection
EC-2 Environmental Concerns – Insufficient Information

Our concerns with the EIS focus on data limitations and inaccuracies, the roles of NOAA-Fisheries and the Pacific Fisheries Management Council in the development and selection of alternatives, and the need for additional information on the Fisheries Economic Assessment Model and the Environmental Justice analysis. Detailed comments discussing our concerns and the alternatives are provided in the enclosure. EPA recognizes it might not be possible to address all data limitations prior to completion of the final EIS. Consequently, our ratings of the alternatives presented in the EIS reflect our concerns and recommend a protective approach to identifying and minimizing impacts to EFH in light of the stated uncertainties.

Thank you for the opportunity to review this draft EIS. If you would like to discuss these comments in detail, please contact Mike Letourneau at (206) 553-6382.

Sincerely,

/S/ Peter Contreras for

Christine Reichgott, Manager
NEPA Review Unit

Draft Environmental Impact Statement

General Comments

We support the Habitat Suitability Probability (HSP) approach utilized in the EIS for identifying Essential Fish Habitat (EFH) and the associated sensitivity index approach used for identifying habitat for closure under Alternative C.3. However, due to the current data limitations and reported inaccuracies in some of the data used in the HSP and sensitivity indices, we have concerns about selecting alternatives that utilize these approaches.

We support your efforts to obtain additional high quality data and correct inaccuracies. In addition to expanding the logbook, vessel monitoring system (VMS) and research reserve programs, we support increasing observer coverage and manned and remote sensing devices that are nondestructive to marine habitats. We agree that combining VMS, logbook and observer data would result in a more complete picture of fishing activities and that VMS data with a higher resolution track line of trawl and fixed gear sets would be a significant benefit. We also support efforts to develop new fishing gear that is less destructive of EFH.

We appreciate the discussion on the non-fisheries related activities in the EIS. These activities described in the upland, riverine, estuarine, coastal and marine sections provide good information for evaluating cumulative impacts to EFH. While the suite of groundfish does not include anadromous species, like krill, they are prey species of groundfish and are impacted by the groundfish fishing activities. Consequently, the EIS would benefit from evaluating the extent to which freshwater habitats should be considered essential groundfish habitat and techniques and opportunities for identifying freshwater HAPC.

The EIS states that EFH recommendations from the National Marine Fisheries Service (NMFS) or a Fisheries Management Council (Council) to federal or state agencies are non-binding. The EIS needs to clarify that only the NMFS, not the Council, can provide EFH recommendations to federal or state agencies. In addition, the EIS should discuss how EFH recommendations from NMFS will impact the Council and its processes.

Alternatives for Identification and Description of Essential Fish Habitat (EFH)

As discussed above, we support the HSP approach utilized for identifying EFH, however, the limitations and inaccuracies of the data utilized in this approach could leave some essential habitat for groundfish species unprotected. Therefore, we support the No Action alternative that designates all waters from the mean higher high water line, and upriver extent of saltwater intrusion in river mouths, along the coasts of Washington, Oregon and California to the seaward boundary to the U.S. Exclusive Economic Zone (EEZ) as EFH.

The EIS states that some of the essential fish habitat maps generated from the information collected on the managed species and utilized in some of the Identification and Description EFH alternatives were incorrect. The final EIS should discuss if the essential fish habitat maps generated from the information collected on the managed species inaccuracies have been corrected and if so, the results of those corrections.

The EIS states that the Council and NMFS will attempt to have the methodology for calculating “biogenic areas” peer-reviewed by the Council’s Scientific and Statistical Committee (SSC) during the draft EIS review period, and that the methodology may be incorporated into the formal adoption of a Fisheries Management Plan (FMP) amendment and regulatory action. The EIS should clarify if such an action would require the development of a supplemental EIS.

The EIS discusses how the Scientific and Statistical Committee (SSC) approved the methodology for developing the indices used in the HSP model, but did not approve the impact function component of the model used for developing the alternatives. The EIS needs to explain why the SSC did not approve the impact function component of the model and if there are plans to obtain their approval prior to the selection of preferred alternatives by the NMFS.

Alternatives for Habitat Areas of Particular Concern (HAPC)

The EIS states that the HAPC alternatives are not mutually exclusive and that all of the action alternatives could be included in a final preferred alternative, even if some of the designated areas were to overlap. While the EIS is clear that HAPC must be a subset of EFH, it must also be clear that if all of the HAPC action alternatives (Alternatives B.2 through B.9) were selected, selection of a preferred EFH alternative would be limited. While the discussion and figures in Chapter 4 of the EIS provide information on what HAPC areas would be excluded under each EFH alternative, it is not clear which EFH alternatives would be excluded by selecting all of the HAPC alternatives. This needs to be clarified in the EIS.

While we support the approach of combining alternatives into a final preferred alternative, we have concerns with Alternatives B.5 (Core Habitat) and B.8 (Oil Production Platforms). The Core Habitat under Alternative B.5 is defined as the upper 10% area of an HSP greater than 0%, for the juvenile and adult life history stages of overfished and precautionary zone groundfish species. Because of the limitations and inaccuracies of the data utilized in the HSP analyses, there is a potential that some HAPC for some of the overfished and precautionary zone groundfish might not be protected under this alternative. Consequently, we have environmental concerns with this proposed alternative.

While there have been high concentrations of groundfish observed in association with many of the oil platforms off the coast of California, including overfished species, it is uncertain if this is a net benefit to the ecosystem. These unnatural structures may be attracting fish populations away from natural reefs, exposing fish to mercury contamination, attracting predators resulting in a net loss to the fish populations, and increasing fishing effort in the area. We recommend that Alternative B.8 be modified to address these concerns. Once it is determined that decommissioned platforms scheduled for removal do not pose a mercury contamination threat, we recommend that the platforms remain in place until such time that it is demonstrated that adequate natural habitat exists and overfished species meet maximum sustainable yield (MSY). Such an alternative would include the benefits these platforms provide to the groundfish species, address the mercury contamination and the potential attraction of fish from natural reefs, and protect the species from increased effort by fishers.

We support a process for new HAPC designations such as the one proposed in Alternative B.9. As additional information is obtained there is the potential for identifying new areas that are important to the survival and sustainability of a species. This information should undergo a technical and public review for consideration as HAPC. Alternative B.9 provides for such reviews in a streamlined process for designating new HAPC.

Alternatives to Minimize Adverse Fishing Impacts to EFH

The proposed alternatives for minimizing adverse fishing impacts on EFH include gear modifications, area closures and fishing effort reductions. Alternative C.2 includes three options for

Depth-based Gear Restrictions. Alternative C.2.2 would prohibit the use of large footrope trawl gear throughout the EEZ and prohibit all fixed gear shoreward of 100 fm north of 40°10' N latitude and 150 fm south of 40°10' N and consequently would be the most protective of EFH. We recommend that Alternative C.2.2 be selected as the preferred alternative.

Alternative C.3 (Close Sensitive Habitat) includes four options all based on sensitivity and recovery indices developed as part of the fishing impact model component of the comprehensive risk assessment. Of the four options, Alternative C.3.4 would provide the most protection, however, because of the limitations and inaccuracies of the data utilized in this modeling effort, there is a potential that some sensitive habitats might not be protected under this alternative. Therefore, we have concerns with these proposed alternatives.

Alternative C.4 (Prohibit Geographic Expansion of Fishing) has two options which generally cover the same geographic area. However, Alternative C.4.1 prohibits fishing in areas that were not trawled between 2000 and 2002, leaving some 10 minute blocks westward of the 2000m contour vulnerable to fisheries impacts. In addition, Alternative C.4.2 accounts for all bottom-tending gear and addresses the lack of geo-referenced fishing effort data for fixed-gear fisheries. Therefore, we recommend that that Alternative C.4.2 be selected as the preferred alternative.

Despite the prohibition of krill fishing in Washington, Oregon and California waters and the lack of a krill fishery in Council managed waters, we believe Alternative C.5 (Prohibit a Krill Fishery) would be a good preventative measure to protect this important prey species and its habitat. We understand that the Council has elected to address this issue by incorporating krill as a management unit species in the Coastal Pelagic Species FMP, potentially eliminating the need for Alternative C.5. The EIS should discuss if incorporating krill as a Coastal Pelagic Species in the FMP would be as effective as Alternative C.5 and which process could be implemented in the shortest amount of time. If both processes are equally protective of krill, the least time consuming process should be implemented.

Alternative C.6 (Close Hotspots) would prohibit trawling in habitat that has a high probability of being EFH for a large number of groundfish based on the HSP modeling analyses. Because of the limitations and inaccuracies of the data utilized in the HSP modeling, there is a potential that some EFH might not be protected under this alternative. Alternative C.2.2 would prohibit trawling and all fixed gear over a larger geographic area including the area that would be protected by Alternative C.6. Therefore, we recommend selecting Alternative C.2.2 as the preferred alternative instead of Alternative C.6.

Alternative C.7 (Close Areas of Interest) calls for closing the areas of interest designated under Alternative B.7 to fishing either to bottom trawling (Alternative C.7.1) or to all bottom-contacting activities (Alternative C.7.2). These areas of interest would be based on various HSP sensitivity values depending on gear types. While we recommend that Alternative C.7.2 be given preference above C.7.1 as it would protect more EFH from impacts by fishing gear, we have concerns that some areas might not be protected due to the limitations and inaccuracies in the data utilized in the HSP analyses.

Alternative C.8 (Zoning Fishing Activities) would limit the use of bottom-tending gear to specified zones where the agency determines that such activities can be conducted without altering or destroying a significant amount of habitat. Bottom tending fishing gear would be prohibited in all areas deeper than the 2,000 m contour along the continental slope extending to the maximum westward range of groundfish EFH. There would be a five-year transition period to gear specific zones for the remaining area inside the 2,000 m contour, which would remain open to bottom-tending fishing gear.

During the five-year transition period, NMFS would conduct research to delineate zones where specified fishing activities would be permitted. Alternative Option C.8.1 would establish fishing zones for bottom-contact trawls, dredges, and similar bottom-tending mobile fishing gear. Other bottom-contacting gear including bottom longlines, traps, and pots would not be restricted. Alternative Option C.8.2 would establish fishing zones for all bottom-contacting gear types including bottom longlines, traps, and pots. This alternative would include a gear modification and substitution program that cooperatively involves fishers in the design and testing of new gear. The western boundary of the geographic area covered by Alternative C.8 would be dependent on the Identification and Description EFH alternative selected. If the Alternative A.1 (No Action) Identification and Description EFH were selected, the western boundary of Alternative C.8 would be the boundary of the EEZ.

Alternative C.8 in combination with Alternative A.1 would provide a protective approach westward of the 2000 m contour and control fishing activities within the 2000 m through the establishment of fishing zones that would not be significantly impacted by various bottom contact gear types. While we support the adaptive management approach and the inclusion of fishers in the gear research aspects of the program, the EIS does not provide information on how the NMFS will define 'significant' when determining the amount of habitat that can be altered or destroyed under this alternative. The EIS states that the best scientific information available will be utilized for determining whether unavoidable adverse impacts would be minimal and temporary, however, it does not discuss if the HSP model inputs or other information will be used to make these determinations. It is recommended that the EIS provide additional information on potential approaches for determining the significance of habitat impacts under this alternative.

We support the selection of Gear Restriction Alternative C.9 (all options) as a preferred alternative and believe that all the options should be combined into a single alternative. We also support Alternatives C.10 (Central California No-Trawl Zones), and C.11 (Relax Gear Endorsement Requirements). Alternatives C.12 (Close Ecological Important Areas to Bottom Trawl), C.13 (Close Ecological Important Areas to Bottom-Contacting Gear), and C.14 (Close Ecologically Important Areas to Fishing) are variations of the Comprehensive Collaborative Mitigation Alternative. While Alternatives C.12 and C.13 would restrict trawl fishing and bottom contact gear fishing in these ecologically important areas, they would be left vulnerable to some fisheries impacts. Therefore, we recommend that Alternative C.14 be selected as the preferred alternative.

Research and Monitoring Alternatives

Currently, there is limited data on the distribution of groundfish species and their associated habitats, and habitat-specific productivity. In addition, habitat-specific densities are only available for a few species. We agree that there is a critical need for comprehensive, detailed and accurate information on benthic habitats and associated groundfish assemblages on spatial scales relevant to fisheries management and habitat production. Core nursery grounds and spawning areas need to be identified and protected and there is a need to better understand the relationship between climatic events and abundance, growth, spawning success and survival of groundfish species.

We support the Research and Monitoring alternatives that will obtain information that will better define and minimize impacts to EFH. Including all fishing vessels in the Expanded Logbook Program Alternative (Alternative D.2.1) would provide the largest amount of data for updating and increasing the precision and accuracy of the model inputs used for identifying and minimizing EFH. We acknowledge the added economic impacts expanding the Vessel Monitoring System (VMS) Program (Alternative D.3) would have on fishers. However, the EIS is clear that minimizing impacts to EFH will increase enforcement needs and the VMS program could be utilized to address some of these needs. In addition, combining VMS, logbook and observer data would result in a more complete picture of fishing activities and VMS data with a higher resolution track line of trawl and fixed gear sets would be a significant benefit. Finally, we support the Research Reserve System (Alternative D.4) as a means of better understanding the effects of fishing on habitat. The EIS is clear that additional information is needed regarding the length of time needed for habitat features and functions to cover from fisheries impacts. Alternative D.4 provides a mechanism to obtain such information.

Fisheries Economic Assessment Model

The EIS needs to provide additional information on the Fisheries Economic Assessment Model. Specifically, the EIS should include a detailed description of the model, the assumptions used in the model and the process that was utilized to rectify the model with groundfish fishery economic data. While the EIS discusses potential economic impacts to fishers, processors and fishing communities based on this model, it also needs to discuss the uncertainty of these predicted economic impacts and how the model, originally developed for the limited entry trawl sector, has been adapted to project economic impacts in all groundfish fisheries.

Environmental Justice

While we agree that the geographic scope of the EIS results in some difficulties in identifying and determining if low income or minority populations will be disproportionately impacted by the proposed actions, we believe that the EIS would benefit from additional discussion on how it obtained meaningful public participation from low income and minority populations that may be impacted by the proposed action. The information presented in Appendix E demonstrates that some areas have higher minority and low income populations than others. For example, The Hispanic Population by State, Port Group, County and Port data presented in Appendix E shows that the percentage of the population in Santa Barbara that is Hispanic (54.28%) is higher than any other area. The EIS should discuss what measures were taken to assure that the Hispanic population in the Santa Barbara area was afforded the opportunity for meaningful participation in the process for the proposed action. In particular, the EIS should describe what was done to target the Hispanic communities of Santa Barbara, whether materials regarding the proposed action were translated into Spanish, and if there were translators present during public meetings held in the Santa Barbara area. In addition, the EIS should describe what feedback was received from the Santa Barbara Hispanic communities and how that was incorporated into the decisions for the proposed action.

The EIS should describe what was done to inform all low income and minority communities about the proposed action and the potential impacts in will have on their communities (notices, mailings, fact sheets, briefings, presentations, exhibits, tours, news releases, translations, newsletters, reports, community interviews, surveys, canvassing, telephone hotlines, question and answer sessions, stakeholder meetings, and on scene information), what input was received from the communities, and how that input was utilized in the decisions that were made regarding the proposed action.

U.S. Environmental Protection Agency Rating System for Draft Environmental Impact Statements Definitions and Follow-Up Action*

Environmental Impact of the Action

LO – Lack of Objections
The U.S. Environmental Protection Agency (EPA) review has not identified any potential environmental impacts requiring substantive changes to the proposal. The review may have disclosed opportunities for application of mitigation measures that could be accomplished with no more than minor changes to the proposal.

EC – Environmental Concerns
EPA review has identified environmental impacts that should be avoided in order to fully protect the environment. Corrective measures may require changes to the preferred alternative or application of mitigation measures that can reduce these impacts.

EO – Environmental Objections
EPA review has identified significant environmental impacts that should be avoided in order to provide adequate protection for the environment. Corrective measures may require substantial changes to the preferred alternative or consideration of some other project alternative (including the no-action alternative or a new alternative). EPA intends to work with the lead agency to reduce these impacts.

EU – Environmentally Unsatisfactory
EPA review has identified adverse environmental impacts that are of sufficient magnitude that they are unsatisfactory from the standpoint of public health or welfare or environmental quality. EPA intends to work with the lead agency to reduce these impacts. If the potential unsatisfactory impacts are not corrected at the final EIS stage, this proposal will be recommended for referral to the Council on Environmental Quality (CEQ).

Adequacy of the Impact Statement

Category 1 – Adequate
EPA believes the draft EIS adequately sets forth the environmental impact(s) of the preferred alternative and those of the alternatives reasonably available to the project or action. No further analysis of data collection is necessary, but the reviewer may suggest the addition of clarifying language or information.

Category 2 – Insufficient Information
The draft EIS does not contain sufficient information for EPA to fully assess environmental impacts that should be avoided in order to fully protect the environment, or the EPA reviewer has identified new reasonably available alternatives that are within the spectrum of alternatives analyzed in the draft EIS, which could reduce the environmental impacts of the action. The identified additional information, data, analyses or discussion should be included in the final EIS.

Category 3 – Inadequate
EPA does not believe that the draft EIS adequately assesses potentially significant environmental impacts of the action, or the EPA reviewer has identified new, reasonably available alternatives that are outside of the spectrum of alternatives analyzed in the draft EIS, which should be analyzed in order to reduce the potentially significant environmental impacts. EPA believes that the identified additional information, data, analyses, or discussions are of such a magnitude that they should have full public review at a draft stage. EPA does not believe that the draft EIS is adequate for the purposes of the National Environmental Policy Act and or Section 309 review, and thus should be formally revised and made available for public comment in a supplemental or revised draft EIS. On the basis of the potential significant impacts involved, this proposal could be a candidate for referral to the CEQ.

Agenda Item C.3.b
WDFW Report
June 2005

WASHINGTON DEPARTMENT OF FISH AND WILDLIFE SUMMARY ANALYSIS OF TRAWLER-PROPOSED AND OCEANA-PROPOSED BOTTOM TRAWL CLOSED AREAS USING 2003 WEST COAST TRAWL LOGBOOK DATA

The Washington Department of Fish and Wildlife has reviewed and analyzed the potential impacts to fishers by closing areas proposed by the trawl fishing industry and by Oceana to bottom trawling, based on trawl logbook data. Washington Department of Fish and Wildlife staff used West Coast groundfish trawl logbook data from 2003, extracted from PacFIN in March 2005, to plot the locations of trawl tows relative to the closed areas proposed by the trawl fishing industry and under the Oceana alternative (EFH EIS Alternative C.12), for the areas off Washington state (i.e., north of the Columbia River).

Set points and haul-out points were plotted when available; however, in some instances, only set points were available. Because haul-out data were incomplete, the resulting catch data analysis was based on set point locations only (i.e., if a tow began within the proposed closed area, then the catch data associated with that tow is described as coming from within that area; if a tow began outside of the closed area, then the catch data associated with that tow is excluded from the area). We realize that tows set outside the closed area may have traversed and/or ended within the proposed closed area, particularly tows set adjacent to or near the closed area; conversely, catches associated with tows set within the area may have occurred outside the area and, to some extent, these conditions could offset one another. As mentioned above, haul-out data are incomplete and we wanted to use the available data to evaluate potential fishing impacts.

The trawl tows were plotted on maps relative to the proposed closed areas, and the trawl rockfish conservation area (RCA) boundaries for 2005 are also overlaid, for reference purposes. As the RCA boundaries change between fishing periods, the boundaries for the majority of the fishing year (March-October) were plotted. It is important to note that the trawl RCA boundaries were first implemented in September 2002; however, trawl activity shown to occur within the RCA are likely the result of changes in the RCA boundaries and/or are associated with exempted fishing permits (EFPs). The RCA boundaries have also changed from year-to-year; however, the 2005 boundaries are relatively comparable to the 2003 boundaries.

Department staff produced a set of tables that summarizes the amount of area covered under the trawl proposal and the Oceana proposal, number of tows that occurred in each area, and the amount of catch by area, based on logbook data. Catch data were summarized for the following species categories—petrale, DTS (Dover sole/ thornyheads/sablefish), rockfish, arrowtooth flounder, spiny dogfish, and Pacific cod. A blank cell represents no trawl activity, and a value of 0.0% indicates a value of < 0.1%.

Based on our discussions with groundfish fishery representatives, the Department is willing to include the state waters off the Washington coast (i.e., the area from the shoreline to three miles) as a HAPC alternative. This area represents key habitat for juvenile rockfish and other groundfish species, and adult nearshore species (e.g., black rockfish). This area is currently closed under Washington State regulations to trawl (since 2001) and groundfish-directed fixed gear (since 1996) fisheries and we are proposing that this area be closed to these activities through federal essential fish habitat regulations as well. Inclusion of Washington's coastal state waters would add a significant amount of overall area, which would be closed to trawl and groundfish-directed fixed gear, without additional impact to fishing.

Agenda Item C.3.c
GMT Report
June 2005

GROUNDFISH MANAGEMENT TEAM REPORT ON ESSENTIAL FISH HABITAT ENVIRONMENTAL IMPACT STATEMENT

At the May Groundfish Management Team (GMT) meeting, the GMT had conversations with Eileen Cooney and Steve Copps from NOAA Fisheries regarding the timeline for Essential Fish Habitat (EFH) implementation and clarification of joint state/federal management; and received presentations from the trawl industry and Oceana regarding their new and revised alternatives to C.12. The GMT believes the current Draft Environmental Impact Statement (DEIS) contains sufficient information for the Council to take final action at this meeting. This is a preliminary GMT report on the EFH EIS. The GMT anticipates having further discussions and presenting a supplemental report at the June Council meeting.

To facilitate the development of regulations for implementing EFH, the GMT believes Council action in June should be as specific as possible relative to the action that will be taken, provided there is flexibility to address overlaps and gaps with existing regulations (e.g., Rockfish Conservation Areas [RCAs]) for management and the ease of enforcement. The GMT cautions the Council against selecting alternatives that are difficult to translate into regulations, such as selecting depth contours instead of coordinates to define areas.

The GMT recommends the results of Council action in June (i.e., the impacts of the preferred alternative) be presented at the September Council meeting to facilitate Council action on the draft plan amendment and implementing regulations. The GMT requests that the resulting habitat protection, trawl impact, and economic impacts of the preferred action be included. Additionally, the GMT recommends NMFS dedicate resources to conduct Geographic Information System (GIS) analyses of the preferred alternative and implementing regulations and that development and review of implementing regulations would be jointly developed by the GMT, Groundfish Advisory Subpanel, and Enforcement Consultants at the September and November Council meetings.

The GMT also recommends that EFH and Habitat Areas of Particular Concern (HAPC) designations be included in the Groundfish Fishery Management Plan (FMP) and then be specified in regulations.

Alternatives for Designation of EFH

The GMT understands that designating EFH results in a definition of the area in which consultation requirements would apply (i.e., consultation on fishing and non-fishing activities which may adversely affect EFH). The GMT notes that, while the DEIS is a thorough compilation of existing groundfish habitat data, the quantity of data in many instances is sparse and the level of resolution is coarse. The GMT believes that habitat for all groundfish species in the FMP needs to be protected, regardless of status (i.e., overfished and non-overfished stocks); therefore the GMT supports the Council's preferred alternatives (Alt. A.2 and Alt. A.3) for the designation of EFH.

Alternatives to Designate Habitat Areas of Particular Concern

The GMT supports the Council's preferred alternatives (Alts. B.2, B.3, B.4, and B.6) for designation of HAPC (estuaries, canopy kelp, seagrass, and rocky reefs). The habitat areas which have been determined to need the most protection at this time are covered within the current suite of preferred alternatives. The GMT understands the need for the Council to have maximum flexibility in regards to HAPC designation, as habitat and stock information becomes available that may guide future designations as well as adjustments to current HAPC areas.

The GMT recommends that the Council consider selecting a combination of HAPC alternatives, even if the resulting maps of the areas overlap one another. This is because, as more stock information becomes available and species move in and out of the overfished and/or precautionary categories, the additional designation of nearshore rocky reef areas would still afford protection to the current area of overlap.

As stated previously in November 2004, the GMT also recommends that a consistent approach be applied to HAPC alternatives. Specifically, with regard to HAPC alternative B.7 (designating certain areas of interest as HAPCs), the criteria for these areas is not apparent, and their selection appears random. It appears these areas were not selected by a pre-determined set of criteria, but were chosen and then justified based on the results.

The GMT understands that the process to adjust EFH designations and components such as HAPCs would require an amendment to the Groundfish FMP. The GMT recommends a four-year review period that aligns with the biennial management and specifications process. This gives the Council flexibility to adjust EFH and HAPC designations as new and improved habitat data become available. However, it is unclear as to whether the maps depicting the areas designated as HAPCs would automatically be updated as more habitat data become available. If the maps are automatically revised with new data, then the GMT does not believe that alternative B.9 (a process to consider proposals for HAPC designation outside the review period) would be necessary.

Alternatives to Minimize Adverse Impacts to EFH

In November 2004, the GMT clarified that the commercial and most of the recreational area closures that are currently in place are for the purposes of protecting overfished species. In recommending those area closures, the GMT did not consciously propose them as habitat protection measures. The depth contours chosen for RCA boundaries—both trawl and non-trawl—are proxies for the areas in which specific rockfish species occur and are most abundant in their adult life stage (based on fishing and survey data), and are used in conjunction with available NMFS observer data (stratified by depth of fishing activity) to assist the Council in estimating impacts to overfished species. As new stock status information becomes available and/or as more information becomes available to further refine the closed area (e.g., through the use of "hotspots" or "coldspots"), areas which were previously closed may become accessible in the future. Therefore, the GMT does not believe the RCA boundaries should form the bases for habitat protection measures, such as those specified in C.2.

However, the GMT does note that, until sufficient information is collected to manage the groundfish fisheries through the use of hotspots, the current RCAs (or some form of them) will likely remain in place to achieve rebuilding strategies for overfished rockfish. In order to adequately manage fisheries by strictly using hotspots (as a replacement for RCAs), the GMT would need spatial data on habitat types and information on the relationship between different habitat types and groundfish stocks. It is anticipated that, given the long-lived nature of most of the overfished species and the length of time needed for those stocks to rebuild, and the lack of data needed for hotspot management, the RCAs will likely remain in place for an extended period of time, and the cumulative economic impact of these trawl closures should be considered in conjunction with any additional measures related to habitat protection.

In reviewing the draft EIS, there was little to no discussion about how proposed measures to mitigate fishing impacts on EFH would be implemented in conjunction with current management. The GMT recommends that a discussion of how the proposed closed areas would mesh with current closed areas, such as RCAs, from a management (and enforcement) perspective be included in the final EIS.

Also, the GMT does not support alternative C.3 (close 25% of representative habitat to all fishing) as the GMT does not believe that sufficient data are available to demonstrate that areas need to be closed to all fishing for the purposes of habitat protection; this alternative would be better addressed in the Council's discussions on marine reserves.

With regard to "hotspots" (alternative C.6), as described above, the GMT believes this management tool should be used to address species-and-gear-specific areas based on fishing and/or research data (such as those data collected through exempted fishing permits). The use of "hotspots" is currently available to the Council and should be considered as part of the broader biennial management process. However, the GMT notes that the use of the term "hotspots" in alternative C.6, and in the EFH EIS in general, is different because it refers to areas of high biodiversity.

The GMT does not support alternative C.7 as it is linked with HAPC alternative B.7 for the reasons described above.

With regard to alternative C.8 (zoning), the GMT recommends that fishing restriction alternatives be limited to the area within the HAPC-designated area (i.e., not be broader than the HAPC area). This alternative would require zoning to be considered within the entire EFH-designated area. Secondly, the zoning and evaluation criteria are undefined making it difficult to predict (and subsequently analyze) the possible outcomes of this effort. As with alternative C.3, this alternative may be better addressed as part of the Council's consideration of marine reserve initiatives.

The GMT understands that legally the Council does have the ability to take mitigation measures outside of whatever is designated as EFH and that re-evaluation is for designation of EFH as well as the management measures associated.

The GMT anticipates having further discussions in June on alternatives to minimize adverse impacts to EFH and may include further recommendations in a supplemental statement.

The GMT believes that the preferred alternatives to minimize adverse impacts to EFH all have merit from a habitat perspective; however, the GMT does not support alternative C.11 (relax gear endorsements) in it's present form, but we would support a modification to alternative C.11 which only permits fishers with a trawl gear endorsement to switch to fixed gear. The GMT believes alternative C.14 (close ecologically important areas to all fishing) is better addressed through the Council's marine reserves initiatives.

Alternatives for Research and Monitoring

The GMT believes that alternatives D.2 (expanded logbook program), D.3 (expanded Vessel Monitoring System [VMS]), and D.4 (research reserve system) all have merit and would enhance the understanding of spatial fishing effort, habitat condition, and the relationship of habitat to stock productivity.

Spatial data on fisheries other than Limited Entry (LE) trawl are currently not collected or are not made available in a database to managers. Given that non-trawl fisheries occur in locations that often differ from trawl fisheries and given a lack of information on the location of other fisheries, it is difficult to identify the non-trawl footprint, and to identify areas that are economically critical to the continued survival of fisheries other than LE trawl. While systems like VMS are necessary for enforcement and would certainly enhance the understanding of spatial effort, the GMT believes that spatial data systems linking catch to fishing location – such as logbooks – would prove more useful for research as these systems could be used to a) establish the current footprint for those fisheries, b) enhance knowledge regarding fishing within certain areas by collecting information such as catch per unit of effort, and c) identify areas that are economically critical for those fisheries to better address practicability considerations under EFH management. However, it is the GMT's understanding that current agency resources may not be adequate to expand logbook systems. Therefore, the GMT recommends that logbook systems be expanded to the extent feasible as resources become available. In addition, in order to adequately analyze existing and future spatial information, the GMT requests that NMFS increase its GIS capabilities for use in groundfish management.

The current understanding of habitat recovery and habitat's relationship to groundfish management is not well understood. A system of research reserves would prove valuable in furthering this understanding. The GMT believes that a well designed research reserve system would take into account existing reserves, encompass a variety of habitat types across depths and latitudes, and would exclude certain bottom impacting gear types from those areas–to varying degrees–in order to assess the impact specific gears have on habitat. Some of those reserves may prohibit all gears that interact with groundfish, others may exclude all bottom-tending gear, and some may exclude or include individual gear types. In addition, any research system should correspond to fishing impact mitigation measures in order to assess the success of those measures.

Finally, the GMT believes that existing programs would prove valuable in increasing the understanding of habitat and location of fishing effort. The GMT believes that VMS and observer data should be made readily available so that managers are better able to assess issues such as coral catch and location of fishing effort to assist in meeting the multiple mandates of the groundfish FMP and Magnuson-Stevens Act.

HABITAT COMMITTEE REPORT ON THE GROUNDFISH ESSENTIAL FISH HABITAT ENVIRONMENTAL IMPACT STATEMENT

The Habitat Committee (HC) developed this statement on the Groundfish Essential Fish Habitat Draft Environmental Impact Statement (DEIS) through email communication. We reiterate some of the HC's earlier statements, particularly on description of Essential Fish Habitat (EFH), designation of habitat areas of particular concern (HAPC), and research and monitoring, but also have refined our thinking on measures to minimize adverse impacts to EFH due to fishing, after review of the DEIS (February 11, 2005).

Summary of Recommendations of Habitat Committee

A. Designation of EFH: Adopt Alternative A2
B. Designation of HAPC: Adopt B2, B3, B4, B6, B7 and B.9.
C. Measures to Minimize Impacts of Fishing:
Adopt <u>elements of</u> C4.2, C7.2, C9.5, C9.6, C.10, and C.12, 13 and 14.
D. Research and Monitoring: Adopt a combination of D.2. and D.4.

The HC believes that the designation, description and protection of EFH, as mandated by the 1996 Sustainable Fisheries Act, is a helpful tool for the Pacific Fishery Management Council. It helps moves fishery management into a broader ecological context and is a step forward in the incorporation of the principles of ecosystem-based management as called for by the U.S. Commission on Ocean Policy (2004), the Pew Ocean Commission (2003) and the U.S. Department of Commerce report to Congress on Ecosystem-based Management (1999).

The preparation of the DEIS to support the Council's upcoming decisions on EFH has focused a great deal of effort and has brought information together that would not otherwise have been available to managers in a usable format. While there are significant gaps and uncertainties in our understanding of marine habitat and the specifics of how changes in habitat condition lead to changes in fishery resource productivity, the process of compiling the available information has been integral in bringing these gaps and uncertainties to light. This, in turn, suggests priority areas for future monitoring and research efforts. The authors of the DEIS have done a remarkable job assembling and depicting alternatives and supporting information with very limited time and resources; they cannot be faulted for the data gaps and uncertainties that remain. Consequently, the DEIS represents a comprehensive compilation of the best information currently available, and is an adequate basis for decision-making by the Council.

The HC understands that industry and environmental groups are likely to come forward with new alternative formulations as refinements to those already presented in the draft DEIS for fishing impact minimization. While we are unable to comment on these hypothetical and unseen alternatives, we offer recommendations on the four decision areas based on the existing published alternatives. We provide a rationale for these recommendations and have prepared a matrix (attached) showing how the existing alternatives help to meet some of these principles.

We hope this is a useful tool that the Council can use to review new alternatives against. In arriving at our recommendations, we considered how each alternative would help achieve the following six principles or objectives:

General Principles

1. **Understand impacts of fishing**

All habitats, whether marine or terrestrial, experience natural disturbances. Fishing can also represent a disturbance to habitat, and management and conservation attention should be most concerned with disturbances that are quantitatively and/or qualitatively unlike the natural disturbances that marine habitats and constituent organisms experience and are presumably better able to withstand.

We must act with precaution as we seek improved understanding of fishing impacts to habitat of various types and under differing energy regimes. Study of impacts and recovery require areas where specific fishing disturbances can be studied experimentally as well as two types of control areas that are not impacted by any fishing and areas that are open to fishing impacts of all kinds.

As noted in the DEIS, most studies of fishing gear impacts on habitat have been conducted outside of the West Coast region. The HC supports the concept that ecological principles can be applied to data collected during studies of fishing gear impacts on marine habitats in other areas. However, specific studies conducted in this region will strengthen our understanding, particularly in the context of the unique and complex assemblage of species managed under the Council's groundfish FMP.

Areas chosen for study should be broadly representative of all habitat types in which PFMC managed groundfish occur. In particular, they should represent this diversity based on depth, substrate type, latitude and ecoregion (e.g. both above and below Pt. Conception). Many areas in the West Coast Exclusive Economic Zone (EEZ) are not currently fished. We recommend that unfished study areas be selected in collaboration with fishermen from all gear sectors in order to take advantage of these unfished areas and to minimize additional areas closed by regulation (see #6, below).

2. Focus on Priority Habitats

The HC feels that priority habitats that are vulnerable to disturbance by fishing gear, and that warrant protective measures include canopy kelp, seagrasses, seapens, and biogenic structure forming organisms such as corals and sponges that are associated with high relief rocky habitats, canyons, and seamounts.

As noted in the Scientific and Statistical Committee report to the Council in March 2005, the distribution and abundance of priority habitats is poorly understood and warrants further investigation.

3. Protect undisturbed areas

There may be other areas that hold unique habitats that are as yet undiscovered or poorly understood and potentially fragile. These areas should be candidates for future protection. As a precautionary step, the HC recommends that areas that are presently undisturbed should remain that way until better mapping information is available. A number of recent discoveries along the West Coast of unique and poorly studied habitats with associated species support this principle, including: a common, conspicuous, and previously undescribed species of black coral living in the Southern California Bight; multispecies aggregations of a deep-dwelling sculpin and a deep-sea octopod brooding eggs in a fluid seep area on the Gorda Escarpment off California; and methane seeps with associated carbonate rock structures and chemosynthetic communities along the shelf break off Oregon. These recent observations suggest that there are undiscovered unique areas scattered along the West Coast that warrant protection by limiting the expansion of existing fisheries.

4. Protect the forage base

The HC understands that prohibiting a directed krill fishery will take place through another management approach by the Council. The HC is very supportive of this action and encourages the Council to expand protection to all of the currently non-managed forage species as well. Preservation of a healthy forage base that is relied upon by managed groundfish species is an important element in the broader context of habitat protection and ecosystem-based management.

5. Timely implementation of protection measures

While there is substantial learning to be done on this topic, the HC feels that action on EFH protection proceed with a plan for effectiveness monitoring. This would be a precautionary approach with adjustments expected during each 5-year review period.

6. Utilize existing restricted areas to also achieve habitat objectives.

In working to select areas for habitat protection, we encourage the consideration of areas that have already received some protection for other purposes (e.g., bycatch reduction and stock rebuilding) so as to both realize the benefits that are already accruing to habitat from these measures, and to minimize the imposition of new regulatory restrictions on the fishing industry.

The HC understands that the Council has the flexibility to adopt any alternative, or blend of alternatives, provided that it is within the scope of the analyses contained in the draft DEIS. We note how helpful the GIS tool has been in dealing with the habitat-based management options in the DEIS and encourage the Council to use this tool during deliberations considering the various new and existing options. Our recommendations are explained below and accompanied by an attached table.

HC Recommendations on the Alternatives

A. Designation of EFH: Adopt Alternative A.2

The HC recommends adopting EFH Alternative A.2 (identified as 100% of the area where habitat suitability probability (HSP) is greater than zero for all species and any additional area in depths less than or equal to 3,500 m or 1914 fathoms) as its final Preferred Alternative. This recommendation reflects our belief that the maximum probabilistic approach to determining EFH, as is represented in this alternative, is reasonable given data uncertainties, and that the added precaution of including some areas beyond depths where data become particularly uncertain is also wise. It is our understanding that the proposed EFH designation includes not only substrate, but also the water column above that substrate, including surface waters.

B. Designation of HAPC: Adopt B.2, B.3, B.4, B.6, B.7. and B.9

The purpose of HAPC is to identify areas that 1) possess important ecological functions for groundfish, 2) are sensitive to human-induced environmental degradation, 3) are at risk of stress due to development actions, and/or 4) are rare habitat types for groundfish. We are aware that designating HAPC serves to concentrate attention on potential threats to these habitats, but provides no explicit protection.

The HC recommends that the Council adopt as its final alternative an amalgamation of Alternatives B.2, B.3, B.4, and B.6 (estuaries, canopy kelp, seagrass beds, and rocky reef areas). We also note that areas identified under Alternative B.7.(areas of interest) that are not already encompassed in the previous four draft alternatives have unique geological and ecological features of special value to fisheries and accordingly, many of these are also currently being used as research areas. As such, the HC believes that these areas merit the special attention afforded HAPC designation and deserve incorporation into the Council's final alternative. In addition, the HC recommends that the Council include Alternative 9 in its final alternatives as a mechanism to streamline future HAPC designations based on new information.

C. Measures to Minimize Impacts of Fishing to EFH: Adopt elements of C4.2, C7.2, C9.5, C.10, and C.12, 13 and 14.

The HC notes that while the importance of habitat to marine fishery resources is increasingly recognized, detailed understanding of the relationship of habitat condition to fishery resource productivity on the one hand, and to the individual and cumulative impacts of fishing activities on the other, is still being developed.

In light of the principles and considerations outlined above, the HC recommends adopting some elements of:

Alternative C.4.2 limits expansion of fisheries for all bottom tending gear

Alternative C.7.2 protects areas of interest as identified by HAPC alternative B.7 from all bottom tending gear. We note that this alternative specifically takes advantage of the cowcod closure area and we recommend identification of a subset of the RCAs also to be identified for closure to encompass all habitat types, depths, and latitudes.

Alternative C.9.5 prohibits the use of dredge gear. Dredge gear is little used, has been or is being phased out, and is known to be destructive to habitat.

Alternative C.10 (Central California buyout and closure) has merit and is very progressive in its approach, but is limited in geographic scope. However, if the private parties involved (fishermen and the Nature Conservancy) jointly agree that this is a productive proposal, we believe that there are habitat benefits that deserve support.

Alternative C.12 is the Oceana alternative relating only to bottom trawl gear, while Alternatives C.13 contains the same areas but closes them to all bottom contacting gear and C.14 closes these areas to all fishing. (The HC thinks that all three approaches should be used in various combinations to meet its principles of allowing protection and research).

Discussion

It is clear that the Council, the scientific community, and the public are developing an increasing awareness that complex habitats of relief, including biogenic habitats such as seagrasses, kelp, corals, sponges and sea-pens are important to the growth and survival of managed species. Consequently, we recommend that the Council's Final Alternative include measures that will afford protection to these priority habitat types. The most direct method to protect these habitat types would be to identify measures that would prohibit fishing with mobile bottom tending gear in these areas. Because many of these features are associated with rocky substrate, the Council may prefer to focus its primary attention on this substrate type.

A comprehensive alternative that addresses specific habitat protection goals and criteria would be useful. One of the Council's most difficult decisions will be whether and how to apply habitat protection measures to only trawl gear or to other bottom-contacting fisheries as well. Our base of information on the spatial distribution and intensity of fixed gear commercial and recreational fisheries, as well as of the habitat impacts of these fisheries, is much less robust than it is for mobile, bottom-tending gear.

The HC recognizes that the Council has been placed in an extraordinarily difficult position of balancing the benefits of habitat protection against the costs of displaced fisheries, in the face of this uncertainty. Fixed gear and recreational fisheries target different species occupying different habitats than many trawl fisheries. However, we understand that fixed gear can impact habitat features through contact of gear, and shearing of lines as gear is retrieved. The HC recommends that the Council take initial measures in a precautionary fashion to protect priority habitat types. The Council should also assure that there is some full and on-going protection of areas that represent a full suite of habitat types, depth and latitude ranges to reflect uncertainty. However, all-encompassing depth-based measures that may have negative consequences to fisheries may be overly broad.

While we think Alternative C.8 to zone fishing activities is an interesting idea, it requires NOAA to do extensive research to demonstrate that any unavoidable adverse impacts would be minimal and temporary. Lack of available funds makes this option impractical. Further, it is silent on criteria to be employed to determine whether an area should be open or closed and much of its protective force would be deferred to the future.

The HC believes that habitat protection through new gear restrictions (Alternative C.9) can be appropriate, particularly if they are readily enforceable and accepted by the fishing industry. The HC recognizes that the Council's action to reduce catch of overfished species, using restrictions on large footrope trawl gear, has also seemed to have had the added benefit of protecting habitat by moving trawl effort off of high relief habitat.

In general, the HC cannot speak to the habitat benefits of the several options under this alternative. Much depends on where the gear is fished, and how it is fished. For example, in high relief areas with abundant emergent invertebrates (e.g. sponges or corals), or low energy environments with little disturbance, infrequent bottom contact by any gear may have a significant habitat impact.

We note that fishing gear is constantly evolving; development of habitat friendly fishing gear should be encouraged. While gear restrictions may act to protect habitat under present conditions and configurations, there are no assurances that the habitat protections envisioned will be maintained through time as gear configurations change. Much will depend on how legal and prohibited gear is defined in future regulations.

D. Research and Monitoring : Adopt a combination of D.2. and D.4.

The HC recommends that the Council adopt a combination of Alternative D.2, option 1 (mandatory logbooks for all groundfish operations) and Alternative D.4 (a system of research closures to provide areas for experimentation and observation of habitat condition in open and closed areas) as its final alternative for research and monitoring.

The HC believes that it is essential that the mandatory five year review of the Council's measures to identify and protect EFH be conducted with a much better understanding of the spatial distribution of habitat types and functions, the spatial distribution fishing activities, and the relationship of habitat condition to fishing activities and the productivity of fishery resources.

Collection of accurate spatial information on non-trawl fisheries is a significant need for the next EFH update. This information needs to provide a comprehensive picture of activity showing seasonal and interannual variability, effort and catch across a wide representation of the fleet. We believe a logbook program provides the best vehicle to collect the needed comprehensive information linking effort, harvest and location, Additionally we suggest the Council retain the option of requiring vessel monitoring systems (VMS) for circumstances where automated collection of precise locational information addresses management or enforcement questions. As the technology becomes available and affordable, adoption of an electronic logbook format should be encouraged to facilitate more broad and rapid use of logbook data.

Evaluation of the Council's measures to protect habitat from adverse effects of fishing, and of fishing impacts to habitat are essential to understanding whether any restrictions to fishing activities are warranted and justified. Developing these evaluations through carefully structured comparisons of open, closed and experimental areas that are matched for habitat type (substrate, depth and latitude) is necessary in order to clearly differentiate changes that are the result of Council management and conservation actions, as opposed to changes that may result from broader changes in oceanographic conditions and recruitment events. Clearly, implementation of research or conservation closures requires that goals and objectives be identified, as well as mechanisms for siting and monitoring. This is a topic the Council has endorsed in its MPA policy white paper. The HC encourages the Council to actively support funding to the participating agencies and universities for the necessary research to meet this goal.

Additionally, a specific plan for monitoring the effectiveness of the adopted EFH measures should be identified and funded so we can evaluate their effectiveness during the mandatory 5 year EFH review.

Habitat Committee Analysis of
Groundfish EFH DEIS Fishing Impact Minimization Alternatives

(alternatives shown in bold outline are Council preliminary preferred Alternatives)

Principles → **Fishing Impact Minimization Alternatives↓**	Provides on-going protection of sensitive or special habitats from gear with bottom contact		Areas with little disturbance remain undisturbed		Utilizes existing closed or unfished areas		Considers prey base (other food chain interactions?)	Implementation to begin near-term
	all bottom contacting gear	all bottom trawl gear	all bottom contacting gear	all bottom trawl gear	all bottom contacting gear	all bottom trawl gear		
C.1 No action								X
Depth Based								X
C.2. 1. No large footrope trawl shoreward of 200 fm and no fixed gear shoreward of 100 fm								X
C.2.2. no large footrope trawl throughout the EEZ and no fixed gear shoreward of 100 fm								X
C.2.3. no large footrope trawl gear shoreward of 200 fm and no fixed gear shoreward of 60 fm								X
Close Sensitive Habitat								X
C.3.1. sensitive areas with low existing trawling efforts (higher threshold) closed to all fishing (all gear types)	X	X	X	X				X
C.3.2. sensitive areas (lower threshold) with low existing trawl effort closed to all fishing (all gear types)	X	X	X	X				X
C.3.3.same as .1 except no adjustment made for trawl effort	X	X	X	X				X
C.3.4. same as .2 except no adjustment made for trawl effort	X	X	X	X				X

Principles → Fishing Impact Minimization Alternatives↓	Provides on-going protection of sensitive or special habitats from gear with bottom contact		Areas with little disturbance remain undisturbed		Utilizes existing closed or unfished areas		Considers prey base (other food chain interactions?)	Implementation to begin near-term
	all bottom contacting gear	all bottom trawl gear	all bottom contacting gear	all bottom trawl gear	all bottom contacting gear	all bottom trawl gear		
Prohibit Geographic Expansion of Fishing								
C.4.1. Trawl fisheries would be prohibited from fishing in areas that were untrawled during 2000-2002		X		X		X		X
C.4.2. All bottom tending gear types prohibited from fishing west from the 1094 fm contour	X	X	X	X	X	X		X
Prohibit a Krill Fishery								
C.5.Designate krill as a component of EFH and prohibit fisheries that target it.							X	X
Close Hotspots								
C.6. Prohibit bottom trawling in areas that have high habitat suitability (great then 20%) for more than 50 species or life stages (results in most waters shallower than 200 m being closed to bottom trawling)		X						X
Close Areas of Interest								
C.7.1 close certain HAPC areas (Alt. B.7 areas) to bottom trawling		X				X (cowcod closure area)		X
C.7.2. close certain HAPC areas (Alt. B.7) to all bottom contacting fisheries	X	X			X (cowcod closure)	X (cowcod closure)		X

Principles → **Fishing Impact Minimization Alternatives↓**	Provides on-going protection of sensitive or special habitats from gear with bottom contact		Areas with little disturbance remain undisturbed (limits expansion of fisheries)		Utilizes existing closed or unfished areas		Considers prey base (other food chain interactions?)	Implementation to begin near-term
	all bottom contacting gear	all bottom trawl gear	all bottom contacting gear	all bottom trawl gear	all bottom contacting gear	all bottom trawl gear		
Zoning Fishing Activities								
C.8.1. Fishing zones established for bottom tending mobile gear within 5 years where research shows unavoidable impacts would be minimal and temporary; no fishing outside 2000 m contour immediately		?		X (outside of 2000 m only)		?		outside of 2000 m only
C.8.2 Fishing zones established for all bottom contacting gears within 5 years where research shows unavoidable impacts would be minimal and temporary; no fishing outside 2000 m for all bottom contacting gear immediately	?	?	X (outside of 2000 m only)	X (outside of 2000 m only)	?	?		outside of 2000 m only
Gear Restrictions in areas identified as EFH for groundfish								
C.9.1. prohibit roller gear larger than 15 inches								X
C.9.2. prohibit the use of flat trawl doors								X
C.9.3. Limit the length of a single longline groundline to 3 nm								X
C.9.4. employ habitat friendly anchoring								X
C.9.5. prohibit dredge gear	dredge gear only							X
C.9.6. prohibit beam trawl gear	beam trawl gear only							X
C.9.7. prohibit set gillnets beyond 60 fm	set net gear only							X
C.9.8. prohibit dingle bar gear	dingle bar							X

(troll groundfish gear)	gear only							
Principles → **Fishing Impact Minimization Alternatives↓**	Provides on-going protection of sensitive or special habitats from gear with bottom contact		Areas with little disturbance remain undisturbed (limits expansion of fisheries)		Utilizes existing closed or unfished areas		Considers prey base	Implementation to begin near-term

Agenda Item C.3.c
Habitat Committee Report
June 2005

Habitat Committee Report

on the

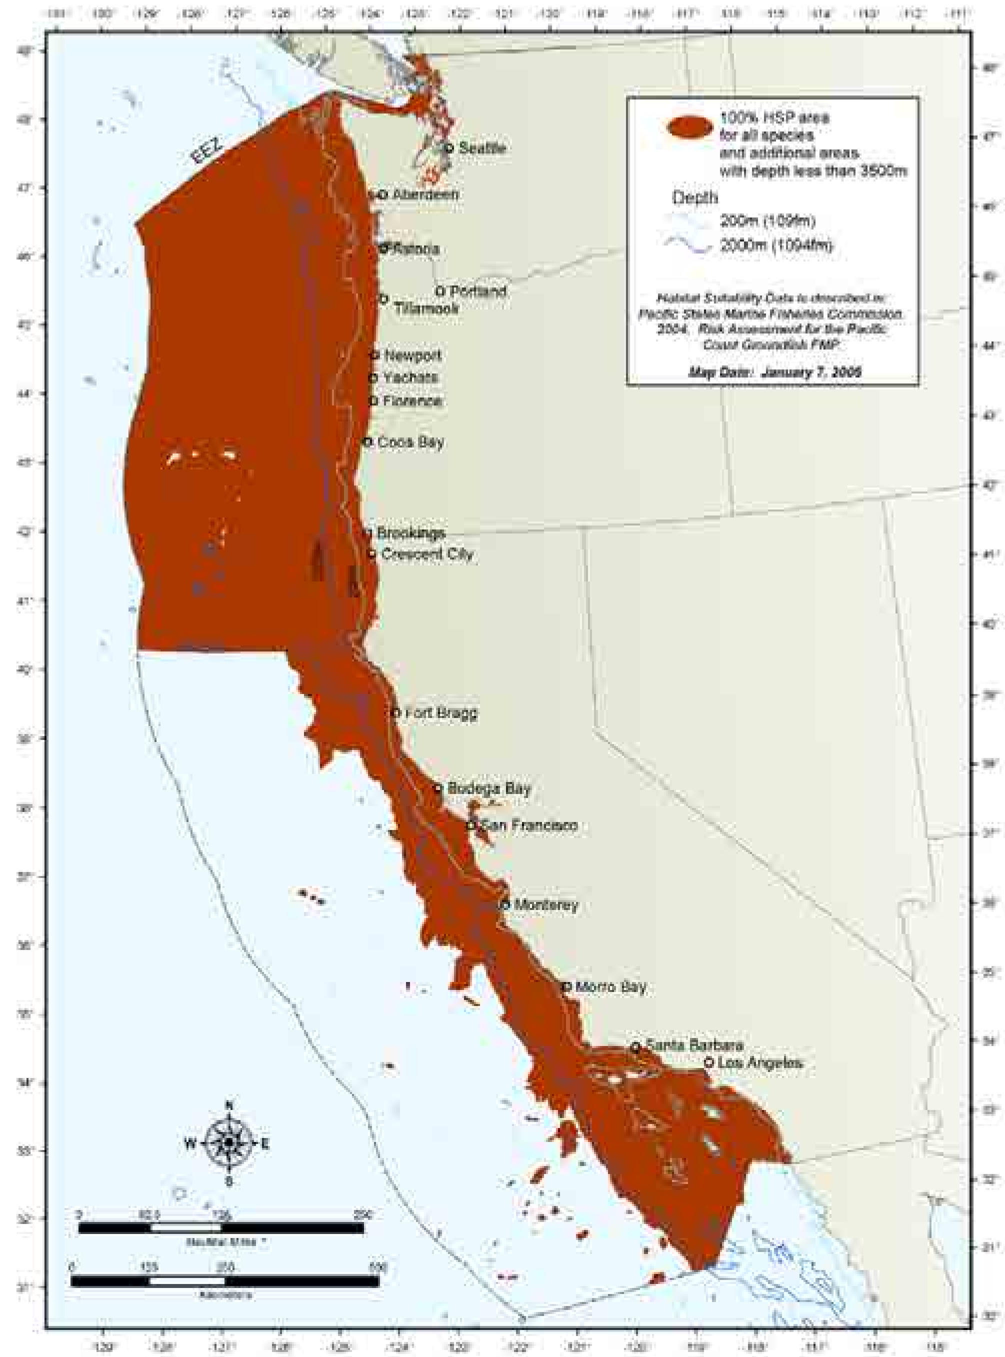
Groundfish Essential Fish Habitat Environmental Impact Statement

Olympic Coast National Marine Sanctuary

Habitat Committee Recommendations

EFH Designation

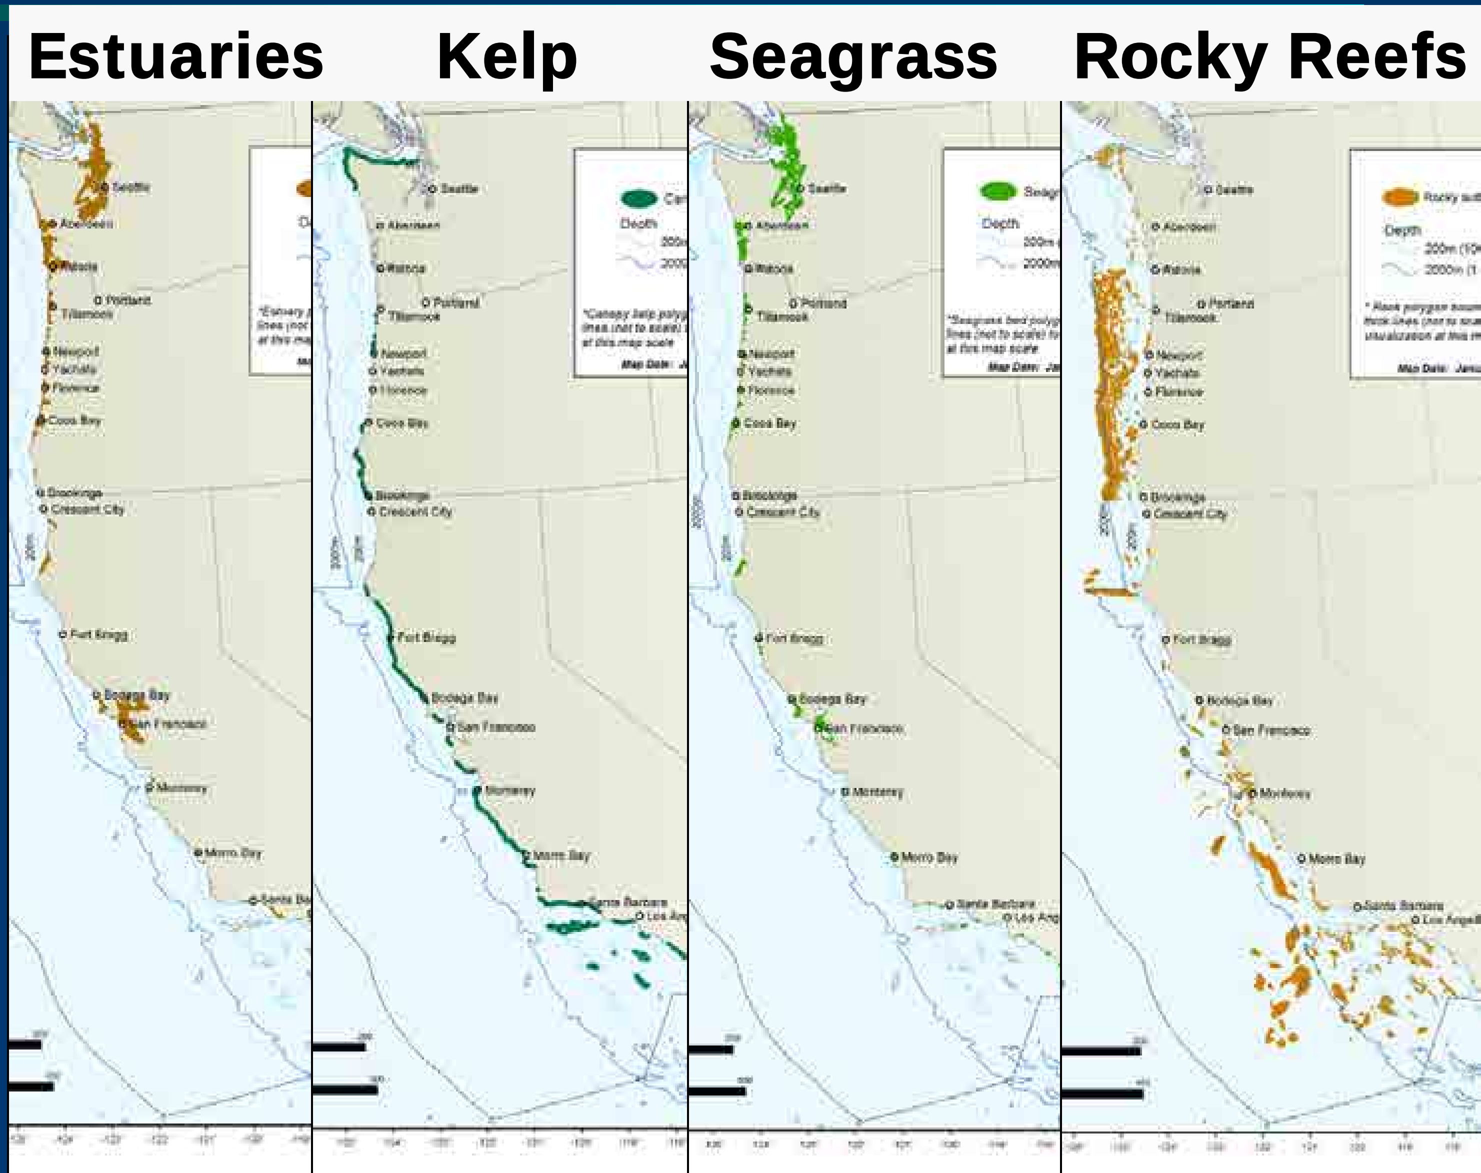
- A.2: Depths less that 3,500 m



Habitat Committee Recommendations

HAPC

- Alts. B.2,3,4,6: Estuaries Kelp Seagrass Rocky Reefs
- Alt B.7: Areas of Interest
- Alt B.9: HAPC Process



Habitat Committee Recommendations

Minimize Adverse Impacts

- C.4.2: no expansion all bottom-tending gear
- C.7.2: close Areas of Interest to bottom-contacting gear
- C.9.5: Prohibit dredge gear
- C.10: Central Calif. No-Trawl Zones

Habitat Committee Recommendations

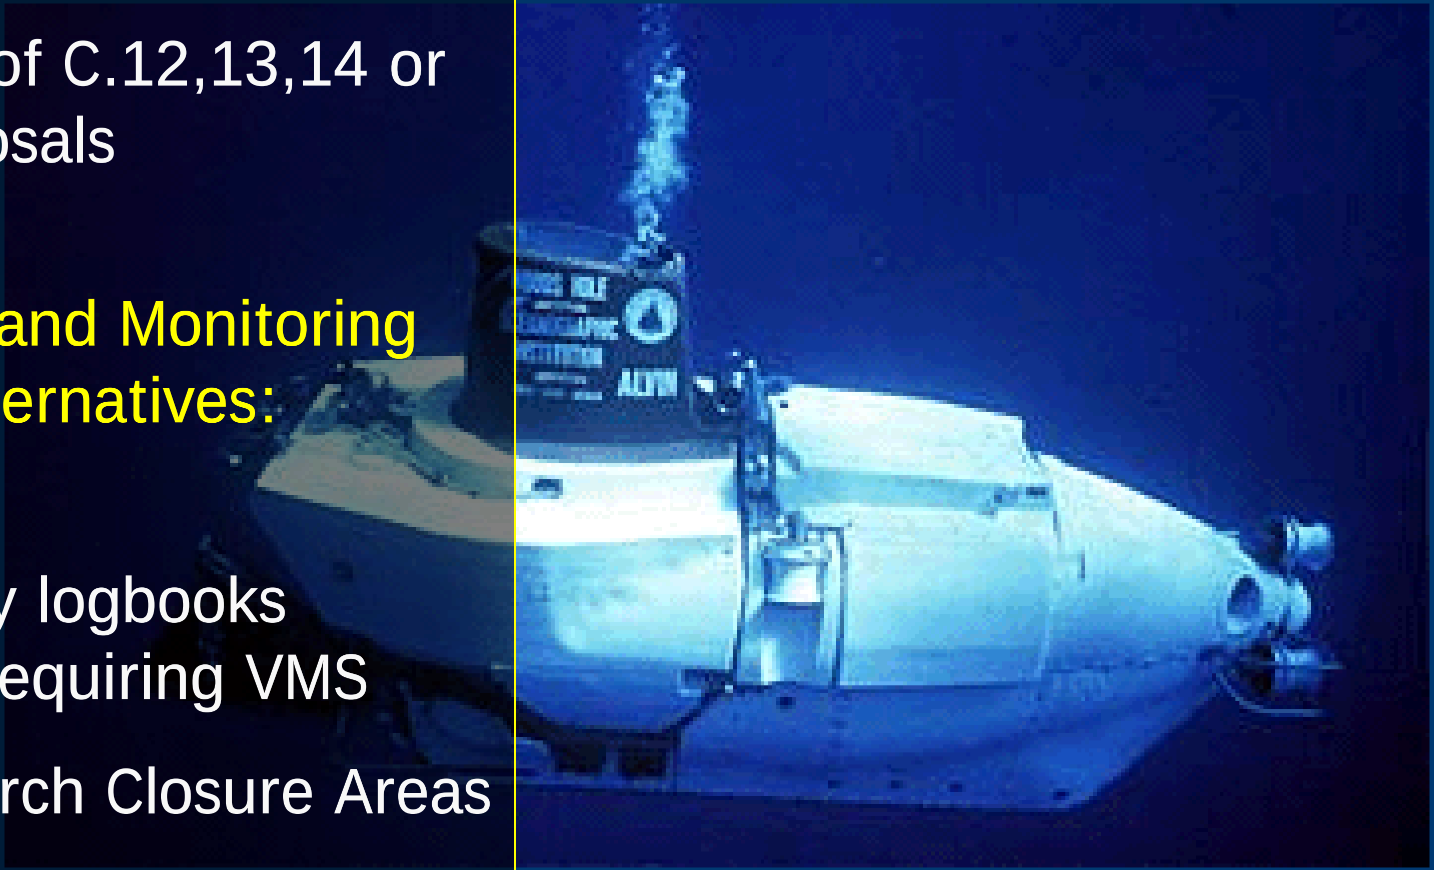
Close Ecologically Important Areas:

- Elements of C.12,13,14 or new proposals

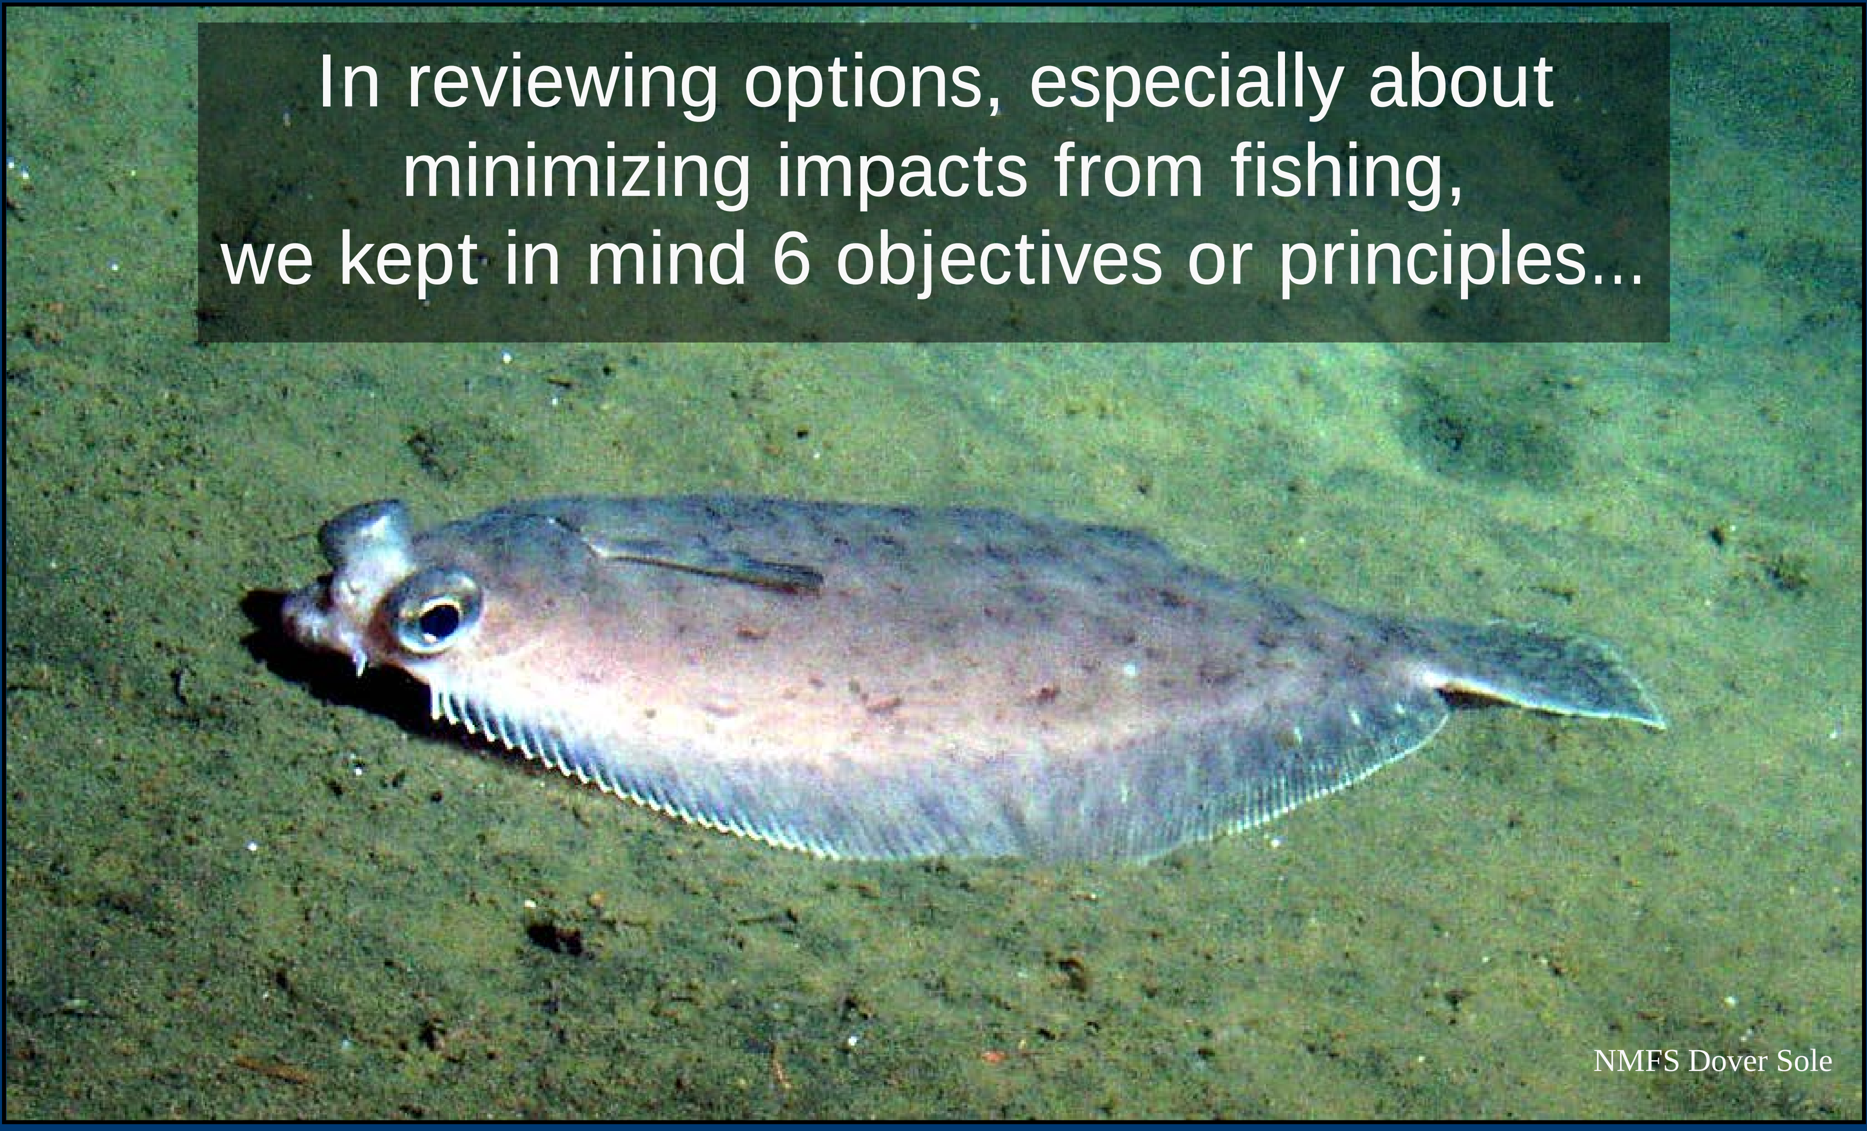
Research and Monitoring Alternatives:

- D.2.1

  Mandatory logbooks
  Consider requiring VMS
- D.4 Research Closure Areas



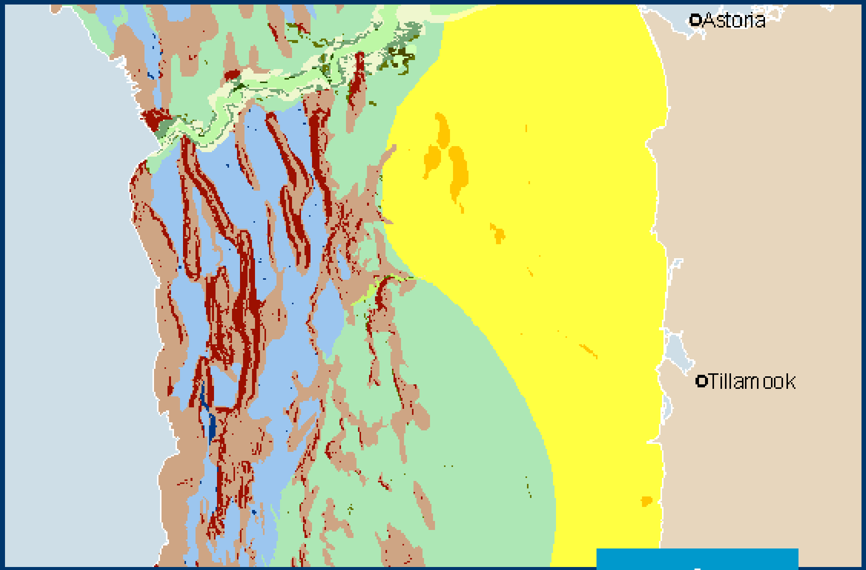
Principles to Assist Decision Making



1. Understand Impacts of Fishing

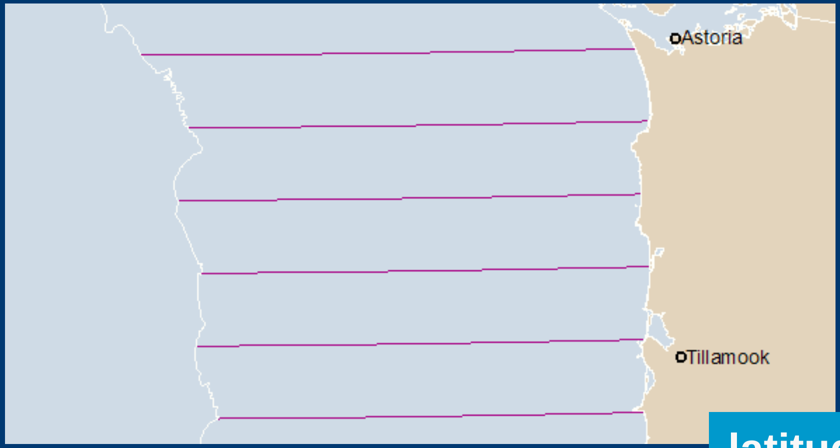
- Focus where fishing impacts differ from natural disturbances
- Precaution; seek improved understanding
- Comparative study – fished vs. unfished
- West coast-specific studies needed

Study fishing impacts over a broad representation of habitat types & locations



geology

depth



latitude

2. Prioritize Vulnerable Habitats

- Canopy kelp
- Seagrasses
- Seapens
- Structure-forming organisms
  - High-relief rocky habitats
  - Canyons
  - Seamounts

Steve Fisher OCNMS

Gorgonian coral; Channel Islands NMS

3. Protect Undisturbed Areas

NMFS rosethorn rockfish

May contain habitats that are:

- Unique and undiscovered
- Poorly understood
- Potentially fragile

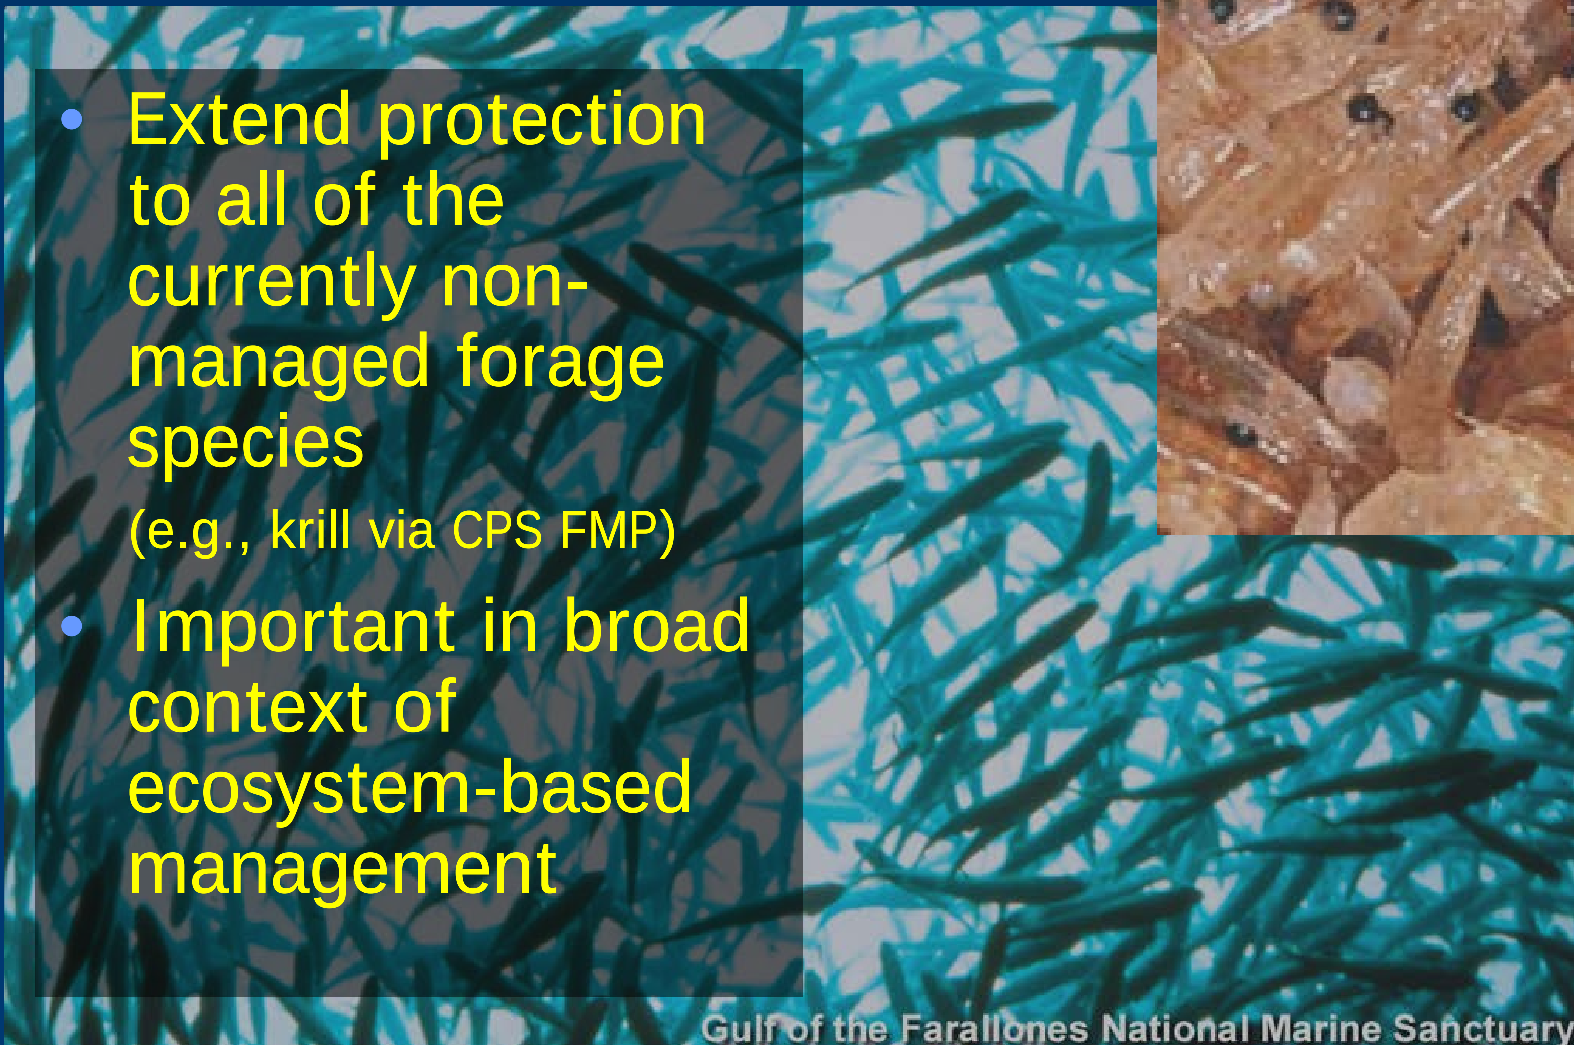
Precautionary approach:

Undisturbed areas should remain undisturbed until better information is available.

4. Protect Forage Base

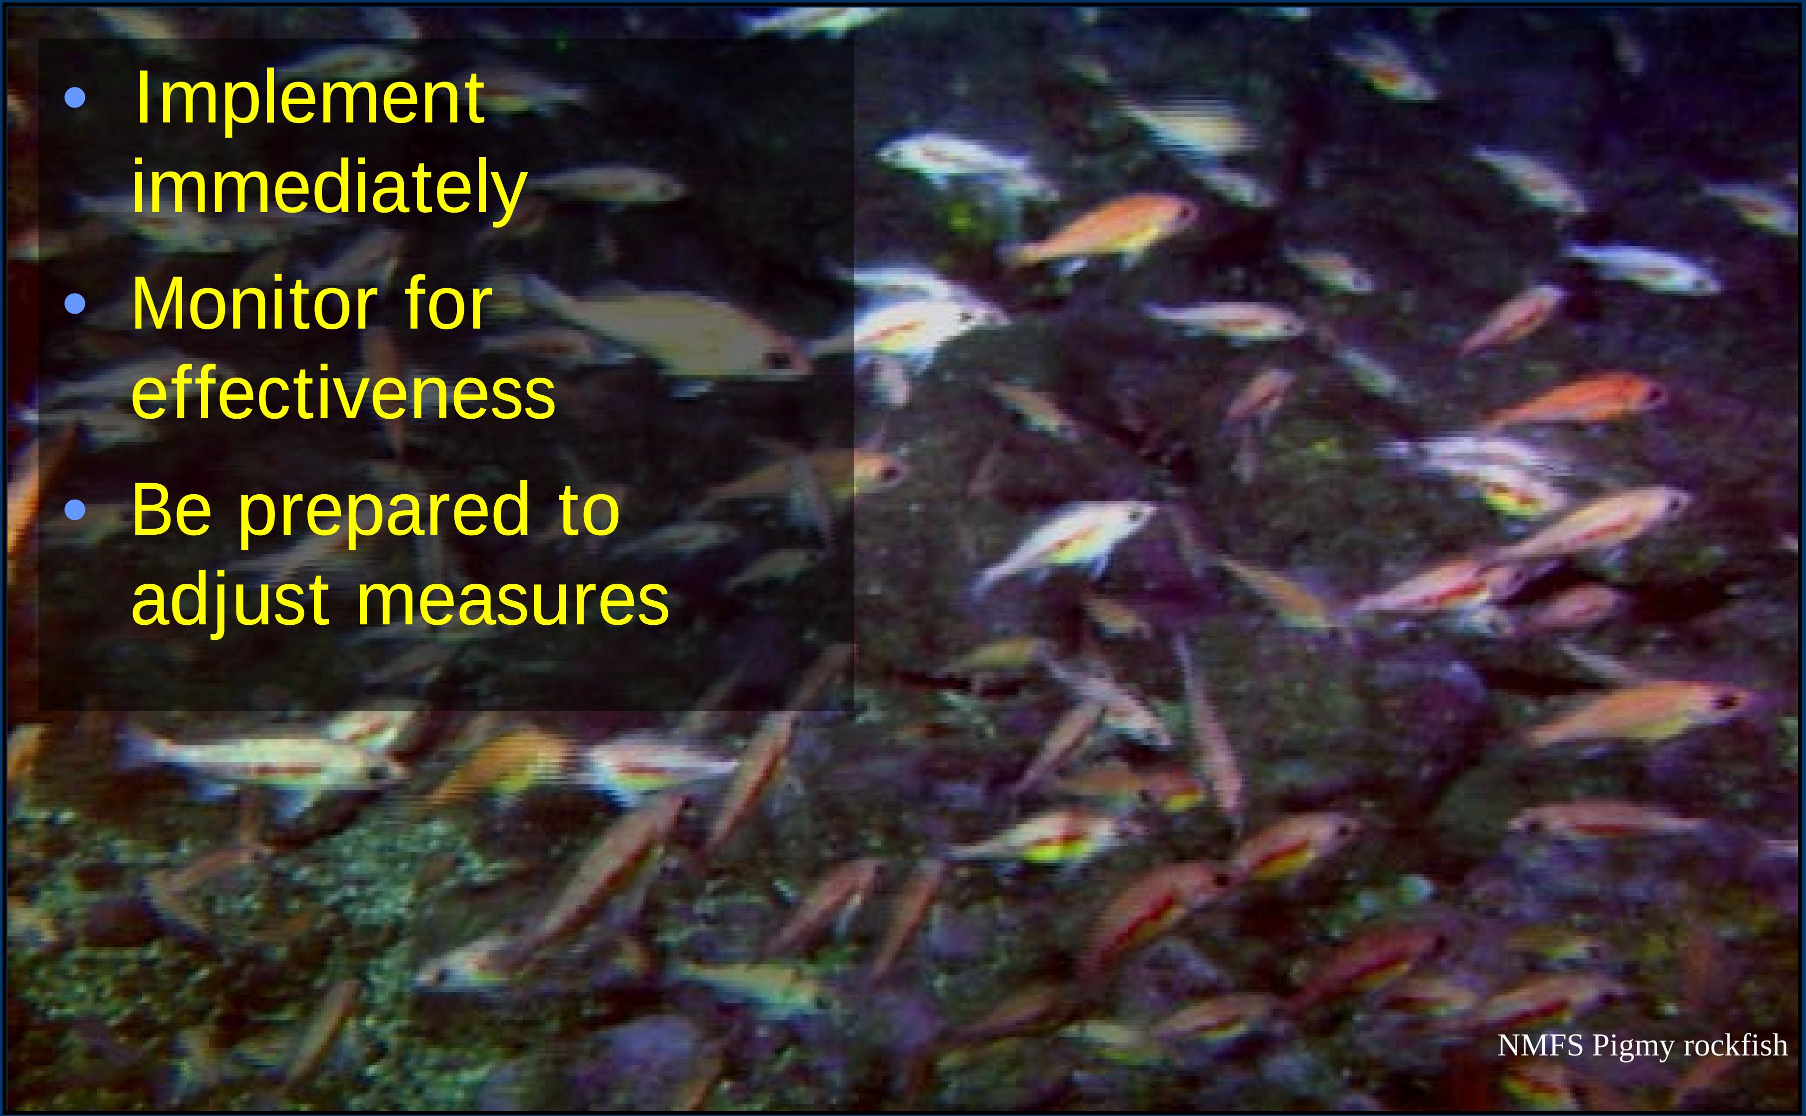
- Extend protection to all of the currently non-managed forage species

  (e.g., krill via CPS FMP)
- Important in broad context of ecosystem-based management



5. Timely implementation of protection

- Implement immediately
- Monitor for effectiveness
- Be prepared to adjust measures



NMFS Pigmy rockfish

6. Use Existing Restricted Areas

- Minimize imposition on fishers
- Optimize benefits
- Take advantage of habitat recovery that may be already occurring

Black rockfish; Monterey Bay NMS; Kip Evans

Application of Principles

Does the alternative:

1. Help understand the impacts of fishing?
2. Focus on priority habitats?
3. Protect undisturbed areas?
4. Protect forage base?
5. Provide timely implementation?
6. Build upon existing restricted areas?

When in Doubt:

- Is it precautionary in favor of habitat protection?
- Is the habitat type involved currently under- or over-represented?
- Is there opportunity for comparative study?
- How will it be evaluated for effectiveness? (clear goals and objectives)

Agenda Item C.3.c
SSC Report
June 2005

SCIENTIFIC AND STATISTICAL COMMITTEE REPORT ON GROUNDFISH ESSENTIAL FISH HABITAT ENVIRONMENTAL IMPACT STATEMENT – FINAL PREFERRED ALTERNATIVE

At the March 2005 meeting, the SSC heard an update from Mr. Steve Copps (NMFS) on recent progress in preparing the groundfish EIS for EFH. The updated draft EIS document was distributed in March for further consideration at the April Council meeting. He noted that the present draft of the EIS is substantially changed and addresses many of the concerns expressed previously by the SSC.

Also at the March 2005 meeting, the SSC reviewed the Oceana Methodology for identifying areas of EFH that would be closed to bottom trawling and listened to presentations by Jim Ayers and Jon Warrenchuck (Oceana), and Geoff Shester (Stanford). Oceana's stated objective for EFH is to protect habitat while maintaining vibrant fisheries. The Oceana alternative is included as one of the alternatives in the draft EIS. The Council included the Oceana alternative as preliminary preferred Alternative number 12.

The Oceana approach considers coral and sponge habitats to be of particular importance to groundfish and referred to the EFH final rule, which states that it is not appropriate to require definitive proof of a link between fishing impacts to EFH and reduced stock productivity before Councils can take action to minimize adverse fishing impacts to EFH to the extent practicable.

The Oceana alternative seeks to establish an open trawling area by subtracting the area to be protected from the total fishing area, effectively freezing the bottom trawl footprint. Trawl logbook data from 2000-2003 were used to establish the proposed bottom trawl footprint. Areas within the proposed bottom trawl footprint were identified as areas of EFH that would be closed to bottom trawling based on 5 criteria. Observer data were not explicitly used to identify biogenic habitat, rather they were used to corroborate determinations from other sources. Approximately 14,000 km^2 of 90,000 km^2 within the bottom trawl footprint were identified as areas of EFH that would be closed to bottom trawling.

Oceana used multiple criteria to evaluate areas for closure, not just records of structure-forming invertebrates from trawl and submersible surveys. These additional criteria included; 1) a database of areas considered untrawlable during the shelf survey, 2) substrate characteristics (hard bottom habitat, including rocky ridges and rocky slopes), 3) bathymetric features (canyons, gullies and seamounts), and 4) areas with high habitat suitability from the EFH analysis. Areas labeled biogenic in the Ocean alternative were identified primarily from records of structure-forming invertebrates.

At the March meeting a considerable amount of SSC discussion focused on what criteria were used to define areas to be closed to fishing. The SSC noted that trawl survey data are not adequate to formulate a comprehensive model of coral and sponge distribution. An analysis of the density of positive trawl samples (for invertebrates) was used as a basis for drawing polygons enclosing discrete areas. The SSC noted that the analysis, because it is an analysis of positive tows only, is probably not the best metric of habitat forming invertebrate distribution; a presence/absence analysis may be more robust. It is clear that groundfish trawl surveys are not the ideal tool for sampling invertebrate distribution and abundance.

Observer data from bottom trawl fishing vessels, aggregated in blocks, were also analyzed as a secondary data source. Oceana reported that these data corroborated the trawl survey analysis and recommended increased observer coverage to document invertebrate distribution. The SSC noted that increased observer coverage may not be the solution. Special studies are essential to further understand the biogenic structure and its linkage to groundfish production.

Oceana indicated to the SSC its expectation that the Council would provide an analysis of long-term economic benefits of their alternative in the Draft EFH EIS. The SSC notes that such analysis is not feasible without more definitive information on long-term effects of habitat protection on fishery yield.

At the April meeting of the SSC, discussion on EFH again focused on the Oceana methodology. The SSC noted that, while Oceana's work is a good start in beginning the process to identify locations where biogenic habitats may exist, much work is needed to produce reliable and detailed maps showing the spatial distribution of biogenic habitats.

The SSC recommends new, scientifically designed surveys be developed to explicitly assess EFH. Such surveys could employ new technologies utilizing undersea quantitative video deployed on Autonomous Underwater Vehicles (AUV's), Remote Operated Vehicles (ROV's), and manned submersibles.

The SSC recommends that the Council explore an adaptive approach as it enters into the realm of spatial fisheries management. If planned carefully, incremental gains in knowledge could follow from studies designed to evaluate the effects of fishing (and not fishing) on a habitat-specific basis.

In conclusion:

1. There remains scientific uncertainty as to whether or not sponge and corals are essential fish habitat for the species in the groundfish FMP, but they are longlived and undoubtedly easily damaged by bottom trawling.

2. Trawls were not designed to sample sponge and coral organisms.

3. The NMFS groundfish trawl survey was not designed to identify or sample sponge and coral habitat.

4. Trawl fishery data may not adequately identify biogenic habitat.

5. Given these caveats and data limitations, the SSC considers the Oceana methodology to be a reasonable first attempt at identifying invertebrate distributions. However, the SSC cautions that if this approach is used to designate EFH these designations should be reviewed and modified, if necessary, as data from more appropriate surveys become available.

6. The SSC will incorporate research and data needs with regard to groundfish EFH into the next update of the Council's Research and Data Needs document.

ENFORCEMENT CONSULTANTS REPORT ON GROUNDFISH ESSENTAIL FISH HABITAT ENVIRONMENTAL IMPACT STATEMENT – FINAL PREFERRED ALTERNATIVE

The Enforcement Consultants (EC) have reviewed the proposals and have the following comments. I will be referring to Agenda Item C.3, Attachment 1, June 2005, Summary of the Alternatives in the Groundfish Essential Fish Habitat DEIS.

1. Close sensitive habitat. We would repeat our long-standing comments about describing areas.
   a. Use latitude and longitude.
   b. Avoid numerous small areas; keep areas at a minimum.
   c. If identified areas are very small, additional restrictions, such as no transit required, might be necessary to protect the integrity of the area.

Alternatives C.2.1, C.2.2, and C.2.3 have a large number of vessels impacted that currently do not carry vessel monitoring systems (VMS) (i.e., open access line gear, Dungeness crab pot). Creating numerous areas that restrict these vessels, while not including VMS requirements, will exceed enforcement capabilities.

Option C.4.2 Currently, there is no definition of **bottom tending gear** in the regulations.

Option C.7.2 Currently there is no definition in the regulations for **bottom contacting** fishing activities.

C.8.1 Currently, there is no definition in the regulations for **Mobile bottom contacting gear**.

The EC would encourage somebody to work through the above gear types to describe or define them. We would hope that definitions be kept to a minimum and be very specific to avoid confusion.

C.9.3 is unenforceable. We are unable to measure the length of a 3 NM longline groundline. At best, we may be able to measure the distance between terminal ends, but this would not result in the actual groundline length.

C.9.4 Employ habitat friendly anchor system. We need more information and definition. Additionally, our concern is how a habitat-friendly anchoring system is used or deployed versus a legal description of a specific anchor. There may be safety issues if this a break-a-way type anchor. This may be something to recommend or use as a guideline, but this may not be enforceable.

C.9.8 Definition issue. We need more information on how dingle bar gear is defined.

D.3 Expanded VMS. The EC would recommend VMS be selected as a preferred alternative to be evaluated. Many of these alternatives would impact vessels that currently are not required to carry VMS. This would create enforcement issues, as we would be limited to at sea enforcement.

It would not take many areas being designated to exceed enforcements ability to maintain the integrity of these areas if people had an incentive to violate regulations.

PFMC

GROUNDFISH ADVISORY SUBPANEL STATEMENT ON GROUNDFISH ESSENTIAL FISH HABITAT ENVIRONMENTAL IMPACT STATEMENT - PREFERRED ALTERNATIVE

The Groundfish Advisory Subpanel (GAP) spent several hours over the course of two days reviewing the available material on groundfish essential fish habitat (EFH). We appreciate the time taken by Mr. Steve Copps of NMFS, the staff of Oceana, Mr. Pete Leipzig of Fishermen's Marketing Association, and Ms. Michele Culver of the Washington Department of Fish and Wildlife (WDFW) to provide us with information on the various options.

Because there are numerous options and alternatives to consider, the GAP used Agenda Item C.3, Attachment 1 - "Summary of the Alternatives in the Groundfish Essential Fish Habitat EIS" - as a checklist to work through decisions. Our comments will follow the list laid out in that document.

<u>Alternatives to identify and describe EFH</u>

The GAP recommends Alternative A.2 - depths less than 3,500 meters - as the preferred alternative, with the understanding that this area includes both bottom habitat and the water column. The GAP rejected alternatives based on habitat suitability potential (HSP) because the data on habitat is extremely uncertain in much of the area on the West Coast. By using a depth-based line that covers all known observations of Pacific groundfish, we are better assured that we include sufficient area. The GAP notes that the area included in this alternative is larger than in all other proposed alternatives except "no action."

<u>Alternatives to designate habitat areas of particular concern (HAPC)</u>

The GAP recommends that four habitat types - Estuaries (Alternative B.2), Canopy Kelp (Alternative B.3), Seagrass (Alternative B.4), and Rocky Reefs (Alternative B.6) - generally be considered for inclusion as HAPCs. However, because the exact locations of these types are uncertain (two GAP members from two states noted that well-known rocky reefs were missing from the maps provided in the draft environmental impact statement [EIS]), because there may be additional types or areas that should be included based on future scientific research, and because there might be areas that should be de-designated based on future research, the GAP recommends a designation process, such as the one described in Alternative B.9, be included in the FMP amendment. The GAP believes that the EFH Technical Review Group established by NMFS and the Council would be an excellent body to review areas and make specific site determinations. The GAP urges the Council and NMFS to maintain the Technical Review Group for this purpose.

A majority of the GAP also recommended including certain oil production platforms (Alternative B.8) in HAPC designation. The majority believes that scientific studies have demonstrated the value of existing platforms to increasing availability of habitat and productivity of various rockfish species.

A minority of the GAP believes that oil production platforms should not be included at this time, but should be candidates for future designation under the process available under Alternative B.9.

A sub-minority of the GAP believes it is inappropriate to include oil production platforms or other man-made structures in HAPC designation.

Finally, the GAP notes that it had recommended, in March 2005, that certain specific areas in Channel Islands, Cordell Banks, and Monterey Bay National Marine Sanctuaries be included as HAPCs.

The GAP rejected alternative B.5 because it is based on the uncertain data used to develop HSP. The GAP rejected Alternative B.7 because it has a long and not well-defined list of areas to be designated without regard as to what habitat types may or may not be present in those areas.

<u>Alternatives to minimize adverse impacts to EFH</u>
As a way of narrowing the process, the GAP rejected all alternatives that had not been identified by the Council as "preliminary preferred" alternatives (Alternatives C.1, C.2, C.3, C.5, C.6, C.7, C.8) based on the reasoning they had been given sufficient discussion by the Council at the November 2004 meeting, and the remaining alternatives provided a sufficient range for consideration.

The GAP rejected Alternative C.4 because the alternative for prohibiting the expansion of bottom trawl fishing is included as part of the GAP recommendations under Alternative C.12.

The GAP recommends inclusion of a modified Alternative C.9 that would have individual gear type decisions made after a review by Council advisory bodies and approval by the Council. The GAP notes that several of the specific gear type recommendations made under this alternative do not necessarily provide additional protection for habitat, but do result in economic losses. For example, roller gear larger than 15 inches can safely be used in many bottom habitats, and there is little difference in protection between 15 inch and 14 inch roller gear. One experienced trawler noted that extremely small diameter footropes, if used in some habitat, could actually cause more damage than larger roller gear. Similar arguments could be made about flat trawl doors, longline groundlines, and depth restrictions on gillnets. The GAP strongly believes that any gear restrictions of this type need to be carefully and expertly examined on a case-by-case basis through a formal process.

The GAP believes Alternative C.10 should be examined in the overall context of the GAP recommendation on Alternative C.12. There was no way the GAP could correlate this alternative with other closed areas under Alternative C.12. The GAP reserves final comment on this alternative until it can be examined comprehensively with other proposed areas.

The GAP rejected Alternative C.11 because it is a management measure that should be examined in the context of the ongoing groundfish management process, including the development of trawl individual quotas (IQs). Although there might be some ancillary habitat benefits to this alternative, the GAP believes it should more properly be examined as a management option.

The GAP rejected Alternatives C.13 and C.14 because the ecologically important areas where closures would occur were designed specifically under Alternative C.12 to apply to bottom trawl impacts. If the Council at a later date wishes to close areas to other gear types, those areas should be identified in relation to those gears using the same processes (identification of ecological features, examination of fishing history, extensive consultation with users, and utilization of fishermen's knowledge and experience) as were used in developing the GAP recommendations for Alternative C.12.

In examining Alternative C.12, the GAP looked at two comprehensive options (Oceana and the Trawl Industry) and two sub-options (WDFW and tribal usual and accustomed (U&A) areas), as well as potentially combining elements of Alternatives C.4 and C.10. Both of the comprehensive options were based on the same general premise: balancing the protection of physical and biogenic habitat features with the economic livelihood of the bottom-trawl fishery. How this balance was accomplished, and what resources were utilized to achieve the balance, were the main differences between the proposals.

All but one member of the GAP recommended using the Trawl Industry option as the base model for identifying closed areas and the depth line beyond which no future bottom trawling may occur. In rejecting the Oceana option, the majority of the GAP noted that one of the studies used to identify sensitive habitat was used improperly (the Zimmermann paper cited was written to demonstrate why swept area trawl surveys are of questionable value in surveying rockfish abundance, not as a means of identifying specific habitat features), that the trawl track data used was not ground-truthed with working trawlers, but instead, relied on logbook start and stop points, that the consultation with industry did not involve a significant coastwide sampling of working trawl fishermen, and that the Oceana option would prevent any modification to existing trawl location or practices, regardless of whether any essential habitat protection occurred. In contrast, the Trawl Industry option - while using the same identification of ecological features, with the same possible incorrect results - did look at actual trawl tow data from working bottom trawl fishermen and resulted from a series of meetings with working trawl fishermen all along the coast.

Regarding the depth beyond which no bottom trawling should expand, the GAP believes the 1,000 fathom contour in the Trawl Industry option better reflects the depth beyond which no trawling presently occurs. The GAP also notes that fathom lines plotted on a chart do not necessarily represent the limits of fishing areas. As a practical matter, most vessels allow themselves a buffer to avoid drifting over a line while fishing or retrieving gear. Thus, a 650 fathom line becomes a 550 fathom line in terms of actual operations. Using the 1,000 fathom contour will still provide substantial protection.

Regarding the WDFW sub-option for areas of the coast of Washington, the GAP believes the proposed refinements should be examined in the context of the base option of the Trawl Industry proposal. Unfortunately, the GAP had no means readily available to overlay the coordinates of the WDFW proposal with other options.

In regard to closed areas within the tribal U&A areas, the GAP recommends that none be established unless they have the concurrence of the appropriate tribal government. The GAP encourages treaty tribes to examine habitat within their U&A areas for habitat protection.

Although the GAP is recommending the Trawl Industry option as the basis for this alternative, the GAP notes that there may be time for the Trawl Industry, Oceana, WDFW, and proponents of Alternative C.10 to meet and potentially develop a combined option in time for final Council action in September. Regardless of whether or not this occurs, the GAP strongly encourages

NMFS to develop a single chart which can be used to accurately delineate and compare the various options prior to final Council action.

Although the Trawl Industry proposal is silent on the subject, there no doubt will be an effort to consider modifications to closed areas or to establish new areas, perhaps based on other gear types. At such time as these changes are considered, the GAP believes that they need to be reviewed by Council advisory bodies and that meaningful consultation occur with states and affected fishermen who possess local knowledge.

<u>Alternatives for research and monitoring</u>
A majority of the GAP supports Alternative D.2 requiring an expanded logbook program to cover all commercial and charterboat fisheries. While logbooks have their limitations, the majority believes that they can be a useful secondary source of data for future management and habitat protection measures.

A minority of the GAP rejected this alternative, suggesting that in the absence of ample observer coverage and shore-side sampling, logbooks can be helpful, but in areas where sampling and observer programs are strong logbook data becomes redundant.

The GAP rejected Alternatives D.3 and D.4. Both vessel monitoring systems and marine reserves are already being considered by the Council under separate management actions. Since these efforts are on-going and involve a wide range of affected parties, the GAP believes these alternatives should be considered under more appropriate processes.

Finally, the GAP notes that whatever set of alternatives is adopted by the Council, significant additional research will need to be conducted. The GAP urges NMFS to send money in order to fully carry out the final Council recommendations.

SUMMARY OF GAP RECOMMENDATIONS ON EFH PREFERRED ALTERNATIVE

Identify and describe EFH -	**Alternative A.2**
Designate HAPC -	**Alternatives B.2, B.3, B.4, B.6, B.8 (majority); B.9 to create a designation and review process**
Minimize impacts -	**Revised Alternative C.9 (process for examining future gear restrictions on a case-by-case basis); Alternative C.12 using the Trawl Industry proposal with potential modifications based on WDFW concerns and Alternative C.10; no closed areas in tribal U&A areas without the concurrence of the affected tribal governments**
Research and Monitoring -	**Alternative D.2 applying to all commercial fishing vessels and charterboats.**
In general -	**NMFS: send money!**

GROUNDFISH MANGEMENT TEAM REPORT ON GROUNDFISH ESSENTAIL FISH HABITAT ENVIRONMENTAL IMPACT STATEMENT - FINAL PREFERRED ALTERNATIVE

In the June Briefing Book, the GMT provided a report on the Essential Fish Habitat (EFH) Environmental Impact Statement (EIS), including recommendations for the designation of EFH and Habitat Areas of Particular Concern (HAPC), some of the alternatives to minimize adverse impacts to EFH, and alternatives for research and monitoring. During the current June meeting, the GMT has had further discussions on the EFH EIS. These discussions have focused on management issues and the feasibility of alternatives to minimize adverse impacts to EFH. This statement outlines the key points generated from these discussions and builds on the statement provided in the briefing book.

<u>EFH General Comments:</u>

The GMT is concerned that the current inadequacy of spatial data for many fisheries limits our ability to fully evaluate the impact of many of these alternatives.

The GMT is not clear where there is flexibility in the implementation and future evaluation of EFH habitat designations and area closures when new information becomes available. We believe that the Council and Council community need to be made cognizant of this as they make their decisions.

The GMT supports provisions that would allow for changes in habitat protection measures in response to new information on potential impacts of different gear types.

The GMT also would appreciate clarification on the exact areas (e.g. state versus federal waters) in which these measures may or may not apply, particularly as concerns state jurisdictions.

<u>Alternatives to Minimize Adverse Impacts to EFH</u>

The GMT does not support using broad coastwide area and depth closures such as decribed in Alternative C.2. for protection of habitat. Rather, such closures (e.g. RCAs), are used for managing the take of overfished species and should continue to be used in this manner.

As efforts are made to streamline RCAs, the GMT recognizes that it may be possible to configure RCAs to serve joint purposes. However, doing so would require an analysis of both dimensions, bycatch and habitat. This analysis is currently not available. The GMT long term objective is to minimize area closures while still meeting our bycatch and EFH objectives.

The GMT notes that Alternative C.4.1 uses federal groundfish trawl logbook data (and does not include state trawl logbook data) from the years 2000-2002 to separate trawled areas (referred to as a trawl footprint) from untrawled areas. However, this time period does not include years, such as during the mid-1990s, when catches of deeper trawl species such as sablefish and thornyheads were higher. From a review of coastwide trawl logs from 1993-1996, over 99% of the tows off Oregon and California occurred inside of 700 fathoms. If the Council decides to adopt Alternative C.4., and thus freeze a trawl footprint, then the GMT recommends only freezing the westward boundary for trawl fishing to 700 fathoms from Point Conception (34°27' N Latitude) to the U.S./Canada border and to 300 fathoms from the U.S./Mexico border to Point Conception to prevent expansion of directed groundfish bottom trawl fishing into deeper waters. Any boundaries eastward of this line, however, may not capture the actual footprint since we do not have comprehensive trawl location data from state fisheries.

With respect to non-trawl gear (Alternative C. 4.2.), the GMT is supportive of the concept of a non-trawl footprint, but is concerned that the analysis of spatial effort patterns has focused almost exclusively on trawl gear, and there has been little or no analysis or inventory of available spatial data for non-trawl bottom-contacting gear.

Regarding Alternative C.6., the GMT sees great value in closing areas of high groundfish diversity (defined within the draft EIS as "hotspots"); however, the GMT believes that data are insufficient at this time to identify these areas of high diversity and recommends that this be an area for future research.

Regarding Alternative C.9., the GMT notes the following:

Several of the gear restrictions have the probability of severely impacting or even eliminating state trawl fisheries, most notably C.9.2 prohibiting flat trawl doors, C.9.5 prohibiting dredge gear, C.9.6 prohibiting beam trawl gear, and C.9.7 prohibiting set gill nets in waters deeper than 60 fathoms.

Flat trawl doors are used coastwide to take pink shrimp over sediment habitat. Other trawl door types have been found to be ineffective at catching pink shrimp within this habitat. Also, fishermen targeting pink shrimp are not currently aware of this proposed restriction to their fishery. Dredge gear is currently used in Washington to target oysters in Grays Harbor and Willapa Bay while beam trawl gear is used in both Puget Sound and San Francisco Bay to target shrimp. In regards to the beam trawl gear, it is possible that this gear could be modified to reduce impacts to EFH. Set gill nets are prohibited within California state waters, but are used outside of 3 miles in waters deeper than 60 fathoms to take state species such as California halibut and groundfish species such as blackgill rockfish. As a consequence, Alternative C.9.7 essentially eliminates this fishery.

The GMT also notes that these minimization measures would apply to fisheries within EFH which could include state waters. If these measures are adopted by the Council, then states would have to notice and adopt compliance regulations through their state regulatory processes before implementing them within state waters.

In regard to Alternative C.9.1., restricting large roller gear would impact the coastwide DTS fishery. Trawling over continental slope sediments requires larger roller gear. Smaller roller gear tends to dig into the soft sediment resulting in a greater impact and creating a safety issue for fishermen using this gear.

The GMT believes that Alternative C.11 could have habitat benefits only if it were modified to allow trawl vessels to switch to fixed gear. However, the GMT is concerned that such an alternative would be initially difficult to implement with current administration and management systems, and believes that relaxing the gear endorsement would likely function better under an

IFQ program. For example, anticipating when trawl vessels would switch to fixed gear without a declaration mechanism would be difficult, and predicting the fishing success of those vessels would initially be complicated. In addition, allocations for sablefish, trawl, DTL, and tier fisheries may need to be adjusted and tracking catches against allocations would add another layer of complexity to an already complex tracking system.

With respect to Alternative C.12 and the conservation areas recommended in both the Oceana Alternative and the Trawl Industry Alternative, the GMT recognizes that the states have spent considerable time and expertise evaluating fisheries trawl data in the federal waters fished by their state's vessels. The GMT believes that this is the appropriate way to evaluate these data and to adjust area boundaries to minimize impacts to fisheries while ensuring that multiple habitat types are covered in closed areas. Thus, the GMT recommends consideration of state proposals for modification of closed areas based on state fishery data.

The GMT recommends an exemption for Scottish seine from trawl closures south of 40˚10' that target sanddabs. This gear is used by a small number of vessels and has less impact on bottom habitat and low bycatch rates of rockfish.

The GMT also recommends requiring VMS on all bottom trawl vessels for enforcement purposes, noting that there are currently state trawl fisheries without VMS.

The GMT would like to commend Oceana on their efforts to incorporate fishery-specific location data and adjust areas to reduce impacts while not compromising their objectives under EFH. We also appreciate the efforts by the industry to balance their need to maintain fishing opportunities with Oceana's proposals for protecting habitat. We believe that both Oceana and the trawl industry's efforts represent movement in the appropriate direction for considering alternative configurations of protected areas under C.12.

With respect to action on deepwater structures (seamounts, atolls), the GMT recognizes that closing these regions to bottom-contacting gear would have no foreseeable impact on current fishing activities.

The GMT recognizes that the main focus of the current impact minimization effort is on the impacts of bottom trawling on essential groundfish habitat, as trawling impacts have the most habitat-impact related research available. The GMT would like to avoid inadvertently restricting other gears by closing areas without evaluating both the impacts to these fisheries, and the cumulative impacts of other gears on EFH.

The GMT believes that there is a need in the future to direct more NMFS resources and contributions in the process of evaluating alternatives such as C.12.

In regard to Alternative C.13, the GMT recommends that this measure apply only to the Davidson Seamount Area and Cordell Bank as discussed by the Council under the National Marine Sanctuaries. Area included is within the coordinates of the Davidson Seamount Area, and at Cordell Bank, this is depths less than a 50 fm isobath as approximated by series of waypoints. (not the way Oceana drew out Cordell). Prohibit bottom-tending gear (with exceptions noted in Cordell Bank NMS language). For consistency recommend that this also be adopted for the federal portion of the Channel Islands National Marine Sanctuary.

Recommend that could incorporate various fishing provisions that have already been agreed upon between the State of California and the Sanctuary and public process.

GMT RECOMMENDATIONS:

A. Designation of EFH: Adopt one of the Council's preliminary preferred alternatives (Alt. A.2 A.3)
B. Designation of Habitat Areas of Particular Concern (HAPC):
   Adopt Council's preliminary preferred alternatives (Alts B.2, B.3, B.4 and B.5) to designate HAPC (estuaries, canopy kelp, seagrass, and rocky reefs), and Alt. B.9 to review and modify HAPC (4-year period)
C. Measures to Minimize Impacts of Fishing on EFH:

- Adopt Alternative C.4.1 as modified in the statement (westward boundary at 700 fathoms north of Point Conception and 300 fathoms south of Point Conceptions with no eastward boundary)
- Adopt elements of Alternative C.12 based on recommendations from states. Include:
    - Scottish seine exemption
    - Requirement for VMS on all bottom trawl vessels
- Adopt Alternative C.13: Close ecologically important areas to bottom-contacting gear for
    - Davidson Seamount Area
    - Cordell Bank to 50 fm (vertical hook and line exempted)
    - Federal portion of Channel Islands National Marine Sanctuary with allowances for state-sanctuary agreements

D. Research and Monitoring: Adopt elements of alternatives D.2, D.3, and D.4 as far as practicable.
E. Address C.6, C.7, C.8, and C.14 under Council discussion of Marine Reserves; C.11 under an IFQ program

Re: Comments on Pacific Coast Groundfish Fishery Management Plan Essential Fish Habitat Designation and Minimization of Adverse Impacts Draft Environmental Impact Statement

Dear Mr. Lohn and Mr. Hansen:

Thank you for the opportunity to comment on the Essential Fish Habitat Draft Environmental Impact Statement for Pacific Coast groundfish. We urge the National Marine Fisheries Service (Fisheries Service) to adopt and implement designation Alternative A.2 plus seamounts. We further urge adoption and implementation of Revised Alternative C.12 as the minimization alternative. Revised Alternative C.12 is thoroughly documented and discussed in Attachment 1: Detailed Description, Discussion, and Comparison of Original Alternative C.12 and Revised Alternative C.12. This attachment includes detailed maps of Revised Alternative C.12. We will fax and mail copies to your office since the file size exceeds the capacity for many email systems to accommodate.

The National Environmental Policy Act ("NEPA") is the "basic national charter for protection of the environment." 40 C.F.R. 1500.1. Congress' goal in enacting the statute was "to help public officials make decisions that are based on understanding of environmental consequences, and take actions that protect, restore and enhance the environment." Id. To meet this purpose, NEPA requires that agencies prepare an Environmental Impact Statement (EIS) for all "major Federal actions significantly affecting the quality of the human environment." 42 U.S.C. 4332(C); see also American Oceans Campaign v. Daley, 183 F.Supp.2d 1 (D.D.C. 2000). One of the cornerstones of NEPA is the solicitation and consideration of informed public views of agency decisionmaking.

Since the original development of Alternative C.12, we have gathered and analyzed more data and information to refine the alternative to better reflect the current bottom trawl footprint, decrease potential displacement to bottom trawl fishermen, and provide practicable protection for Essential Fish Habitat on the West Coast. We have ensured that the alternative is based on the best available information and protects sensitive habitats while maintaining vibrant fisheries. As part of our public comments on the Essential Fish Habitat Draft Environmental Impact Statement ("EFH DEIS"), Oceana is submitting an updated, revised Alternative C.12. Revised Alternative C.12 is well within the scope of the original Alternative 12 as described in the EFH DEIS, and is fully consistent with NEPA's purposes in soliciting public comment. 40 C.F.R. 1503.4. Inclusion, selection and implementation of Revised Alternative C.12 in the Final EFH EIS does not require a supplemental Environmental Impact Statement.

The changes reflected in Revised Alternative C.12 are the result of recommendations by the Scientific and Statistical Committee to pay closer attention to the presence of corals, sponges, and other living seafloor substrates in NOAA trawl survey and other data; analysis of spatial distribution of trawl track information from logbooks; and information provided by the bottom trawlers on areas they suggest be open or closed. By adopting the Revised Alternative C.12, the Fisheries Service and Pacific Fishery Management Council (Council) are able to maintain vibrant fisheries and provide important practicable mitigation measures for protecting Essential Fish Habitat.

The Revised Alternative C.12 is based on the Oceana Approach and is substantially similar to the version submitted in 2004 with some boundary changes which accommodate information referenced above. Though some boundaries have been modified to accommodate commercial trawlers and protect habitat, all management provisions proposed in the original Alternative C.12 remain intact in the Revised Alternative C.12.

As a steward for public resources, the Fisheries Service has an obligation to conserve, protect, and manage living marine resources responsibly. In the Sustainable Fisheries Act of 1996, Congress amended the federal statute governing fishing in the waters off of America's coasts by adding conservation provisions. The Magnuson-Stevens Act requires that the Fisheries Service describe and identify Essential Fish Habitat, and minimize the adverse effects of fishing on that habitat to the extent practicable. It was the Fisheries Service's non-compliance with the law that resulted in a court order to conduct the EFH EIS process now in progress. In particular, the Court noted, "There is no substantive discussion of how fishing practices and gear may damage corals, disrupt fish habitat, and destroy benthic life that helps support healthy fish populations." (District Court Order at 41).

The Fisheries Service has acknowledged the importance of living benthic substrates in a variety of fora. In addition, numerous scientific papers, including those published by Fisheries Service scientists, describe the importance of corals, sponges, and other living substrates to both commercial and noncommercial fish species and marine life. Further, over the past several years, the body of science concerning both the importance of intact marine habitat and the effects of fishing gear on habitat has grown substantially. The National Academy of Sciences (2002) clearly identifies the adverse impacts of bottom trawling on corals, sponges, and other living seafloor animals. The Academy recommends fishing effort reduction, gear modifications, and area closures to mitigate the adverse impacts of bottom trawling on seafloor habitats.

Despite the recognition of the importance of corals, sponges, and other living substrates as keystones of the ocean ecosystem and Essential Fish Habitat; and the clear scientific reports of threats of bottom trawling to this sensitive long-lived habitat, the Fisheries Service still has not adopted or implemented measures for mitigation to stop this destruction. Revised Alternative C.12 provides a strong, viable, practicable action to do so.

The Fisheries Service and the Pacific Fishery Management Council urged Oceana privately and criticized us publicly to move away from litigation and become more involved in the EFH EIS process by helping develop viable and practicable alternatives. We have done so in good faith. Over the past three years, we have developed a viable and practicable management alternative for the Pacific by working with the Fisheries Service, the Pacific Fishery Management Council, other conservation organizations, commercial fishermen, recreational fishermen, state officials from Washington, Oregon, and California, scientists, local residents, and critics. Revised Alternative C.12 recognizes both the importance of corals, sponges, and other living seafloor animals as essential fish habitat, and the importance of maintaining healthy vibrant fisheries in the Pacific.

As the Fisheries Service and the Pacific Fishery Management Council consider adoption and implementation of minimization alternatives, we ask that you keep in mind that bottom trawling is a privilege granted by the American people through the Secretary of Commerce and the Council. It is not the right of a few to risk unmitigated destruction with long-term consequences to ocean ecosystems simply to achieve a short-term financial gain. We request the agency and Council adopt Revised Alternative C.12 as the preferred alternative in the Final EIS and implement it through regulations.

Sincerely,

Jim Ayers

Revised Alternative C.12 **May 11, 2005**

Table of Contents

Revised Comprehensive Alternative C.12

Preface: Overview of Modifications to the November 2004 original Alternative C.12 proposal

Modifications based on Washington, Oregon, and California Trawl Logbook Analysis

The Washington Department of Fish and Wildlife (WDF&W) generated maps of the areas closed to bottom trawling proposed in original Alternative C.12 overlaid with all 2003 bottom trawl logbook data, which mostly consisted of set points and haul out points, however in some cases, only the set points were available. WDF&W also performed an economic analysis using the set points only of the trawl logbook data, which attributed catch to a closed area when the set point fell within that closed area. It is interesting to note that the displaced 2003 revenue estimated by WDF&W with the set point method was higher than Oceana's estimate using the proportional overlap method using the mean revenue from 2000 to 2003 in 10 by 10 minute blocks. For original Alternative C.12, WDF&W estimated the 2003 displaced bottom trawl revenue represented by the proposed bottom trawl closures at $5,463,659 and Oceana estimated the annual displaced revenue at $4,810,730. The Oregon Department of Fish and Wildlife (ODF&W) provided tables with an economic analysis of the 2000-2003 trawl logbook set points contained within the closed areas proposed in original Alternative C.12. The California Department of Fish and Game (CDF&G) provided maps of the entire California coast that displayed all bottom trawl logbook data, including set points and haul points. Also displayed were the state fisheries for California halibut, and some shrimp and sea cucumber trawl information.

The information provided above was used to modify the boundaries of the proposed closed areas, and to improve the accuracy of the existing bottom trawl footprint. Modifications to the boundaries of closed areas where made by visually comparing the spatial pattern of the 2000-2004 trawl set points to the existing boundaries. With the finer level of detail, it was possible to identify specific important fishing areas within the 10 by 10 minute blocks and modify boundaries as appropriate to reopen areas containing clusters of set points and to exclude additional untrawled areas from the trawl footprint. The finer level of detail also allowed for greater refinement of the bottom trawl footprint, particularly in California. The result is Revised Alternative C.12, a practicable, comprehensive conservation alternative that protects essential fish habitat while maintaining vibrant fisheries.

Modifications based on greater incorporation of presence/absence information on habitat forming invertebrates (Scientific and Statistical Committee suggestion)

At the March Pacific Fishery Management Council (PFMC) meeting, the Scientific and Statistical Committee suggested paying greater attention to presence/absence data from the National Marine Fisheries Service (NMFS) trawl survey information that was used in the identification of biogenic areas. As such, a few additional closure areas were identified using information on habitat-forming invertebrates as the primary criterion.

Other modifications

- An additional seamount (located outside of the trawl footprint), Rodriguez Seamount, is included in Alternative C.12.
- Some proposed closed areas were split into parts by reopening high value trawl areas.
- Several nearshore rocky reefs were added to the proposed closed areas.
- Canyons in Northern California were added to the suite of trawl closures based on additional habitat information.
- Based on input from trawl fishermen at the March PFMC meeting in Tacoma, an area of rugged bottom terrain with pinnacles outside of the Rogue Canyon area was added.
- Based on input from trawl fishermen at the April 29 Morro Bay EFH Meeting, a significant area in the northern area of the proposed Monterey Bay trawl closure was reopened, as well as a section of the "Morro Ridge" proposed closure.
- The trawl industry also suggested some areas for closure in April 2005, and we attempted to include consideration of those boundaries.
- Some of the previously proposed areas were renamed to better describe the habitat features in question.

Introduction

Revised Alternative C.12, the Comprehensive Collaborative Alternative seeks to maintain vibrant fisheries while protecting habitat and biodiversity. The Alternative focuses on reducing the impacts of bottom trawling on Essential Fish Habitat (EFH). Using the mandate of the Sustainable Fisheries Act of 1996 to identify and protect EFH, Oceana developed this science-based alternative using all available data and information which included a comprehensive literature review of fish habitat studies, habitat-fishery linkages, and fishing impacts. This approach was recently used by the North Pacific Fishery Management Council to minimize adverse impacts to EFH in Alaska's Aleutian Islands region. The currently available fisheries data, habitat data, and economic data from the U.S. West Coast, while not perfect, allowed us to design a cost-effective Alternative that is precautionary yet practicable.

According to the National Academy of Sciences (2002), bottom trawling reduces habitat complexity, causes shifts in benthic (bottom-dwelling) communities, and reduces productivity of benthic habitats. The Academy recommends three management measures to reduce the effects of bottom trawling: area closures, gear modifications, and effort reduction. Revised Alternative C.12 employs all three of these management measures while maintaining commercial fishing opportunities.

Specifically, the Revised Alternative C.12 includes the following management measures:

1. Prohibit bottom trawling outside the current trawl footprint (defined by using spatially explicit trawl logbook data from 2000-2004 with methodology to draw boundaries as described in this document).
2. Implement 61 year-round bottom trawl area closures in known sensitive habitat areas (identified in maps appended to this document).
3. Extend the 8 inch maximum roller size trawl footrope restriction to all bottom trawling. throughout the U.S. West Coast EEZ. The footrope restriction is made permanent instead of re-authorized on an annual basis.
4. Bottom trawl effort reductions as developed by the Pacific Fisheries Management Council ("PFMC").
5. Consideration by the PFMC of gear conversion opportunities for bottom trawlers.
6. Comprehensive monitoring of individual vessel performance and habitat damage including:
    a. Increase onboard observer coverage on bottom trawl vessels to a level determined to be necessary by NOAA to estimate annual bycatch of habitat-forming invertebrates and quantify habitat interactions with fishing gear;
    b. Require vessel Monitoring Systems (VMS) on all vessels using bottom trawl gear to catch groundfish in the U.S. West Coast EEZ with positions recorded at a time stamp of every 5 minutes (time);
    c. Improve electronic logbooks to provide better fishing effort information to NOAA and state authorities;
    d. Annual publication of a NMFS *West Coast Groundfish Habitat Status Report* to make habitat impact and bycatch data available to the Council, the public and the fleet at as high a spatial and temporal resolution as possible; and
    e. Establish baseline data and a process for setting and implementing bycatch limits on structure-forming invertebrates and/or other habitat performance standards.
7. Comprehensive research and benthic mapping program to improve EFH information levels.

a. Funding for additional gear impacts research;
b. Coastwide biogenic seafloor mapping project; and
c. Ecological and behavioral studies of habitat use by commercial fish and invertebrate species.

This document provides a summary of the approach, science, methodology, and data used to develop and modify Alternative C.12.

The Precautionary Approach

Revised Alternative C.12 is a precautionary approach to mitigate the effects of fishing on habitat. When undertaking the task of identifying and protecting EFH in Alaska, NMFS contracted the Center for Independent Experts (CIE) to review their assessment of fishing effects on EFH in the North Pacific Region (Drinkwater 2004). The CIE panel repeatedly emphasized the need to be precautionary, both when assessing effects on habitat and when taking management actions.

> *Use the **precautionary approach** especially where the data are unclear, where recovery times are long (e.g. for corals and sponges), or where habitat reduction is high even if the abundance levels are above MSST. Since it is likely difficult to detect an influence on the stock until after the habitat is damaged, perhaps even until much of the habitat is destroyed, the use of the **precautionary approach** is paramount. This is especially true for those habitats with long recovery times, e.g. hard corals and sponges*

(Drinkwater 2004).

On the U.S. West Coast, the recent discovery of a new species of deep-sea coral (*Antipathes dendrochristos*) (Opresko 2005), is an example that highlights the very real possibility that Essential Fish Habitat may be destroyed before researchers know anything about it. Since very little benthic habitat on the U.S. West Coast has been explored to date, the potential for adverse impacts is enormous. The loss of Essential Fish Habitat may have devastating long-terms consequences for U.S. West Coast fisheries. Therefore, the high risk inherent in conducting the groundfish fisheries with bottom trawl gear justifies prescriptive, precautionary management measures to protect EFH.

Spatial Management Measures

The spatial management measures of the Comprehensive Alternative define the areas that are open and closed to bottom trawling. These management measures are in addition to all existing closures in the Pacific Groundfish Fishery Management Plan (“FMP”) and implementing regulations. These areas are determined based on several criteria described in detail in the following sections. Areas closed to bottom trawling are based on the locations of sensitive and complex habitat areas and/or areas with low economic value to the bottom trawl fleet. Boundaries were drawn to minimize overlap with high value fishing areas and to follow closely the sensitive habitat features. The proposed closures incorporate the Pew Oceans Commission (2003) Final Report (Ch 11, Sections 3-4) recommendations to:

- Prohibit bottom trawling on corals, sponges, and seamounts;
- Allow bottom trawling only in designated areas; and

- Close all other areas to bottom trawling.

The overall formulation of the spatial management measures is based on a combination of various data layers provided by NMFS and other data sources.

Summary of Methods

1. Determine the spatial extent of recent bottom trawl effort (setting the existing bottom trawl footprint);
2. Assess the distribution of fishery value within the footprint;
3. Determine where areas containing complex sensitive habitat occur;
4. Close areas of complex sensitive habitat within the footprint with consideration of displaced revenue; and
5. Establish bottom trawl permitted open area.

[Area of bottom trawl footprint] **minus** [Complex sensitive habitats] **minus** [Existing management closures] **equals** [Area open to bottom trawling]

Spatial Management Summary

Delineating the bottom trawl footprint

To define the boundaries of the U.S. West Coast bottom trawl footprint, we examined bottom trawl logbook records from PACFIN of groundfish catch occurring from 2000-2003. We selected this time span to include annual variability of trawl activity, which incorporates transitions that may have resulted from recent management measures. For example, in 2000 a footrope restriction in some areas altered the distribution of trawl effort (Bellman and Heppell, EFH DEIS Appendix 19). Trawl restrictions in the Rockfish Conservation Areas ("RCA") also altered distribution of trawl effort over this period. However, Bellman and Heppell (Appendix A-19) conclude that trawl effort along the U.S. west coast is patchy and has been consistent in its overall distribution over their entire study period (1995-2002). They state (p. 30):

> *Overall, fishing effort exhibited patchy distribution and maintained similar statewide patterns over the entire study period. This consistency is common when fishermen return to areas previously known to harbor high abundances of target species and suitable seafloor for trawling.*
>
> *From a conservation standpoint, this patchiness may be desired if fishing efforts do not also expand into the unaffected areas. Patchy distribution of trawl effort disturbs the same areas of seabed frequently, but in turn leaves large areas unaffected by the impacts of fishing gear. Spatial management measures, such as closed areas, can have the effect*

of shifting fishing activity to areas that were previously lightly fished or very rarely fished.

This provides both rationale and justification for identifying the bottom trawl footprint as accurately as possible to protect "previously lightly fished or very rarely fished" areas. Therefore, the objective of closing all areas outside the trawl footprint is threefold:

1. To prevent further geographic expansion of bottom trawling;
2. To prevent unintended displacement of trawl effort into new areas; and
3. To maintain the trawl industry's ability to harvest their allocated quota in remaining open areas.

Fishing vessels are required to record their catches in electronic logbooks and/or fish tickets which are then gathered and maintained by the Fisheries Service. The agency provided a dataset aggregated in 10 by 10 minute blocks with species or species group resolution, and excluding any information which the Fisheries Service asserted to be confidential. Given these constraints, a spatial resolution of 10-minute blocks was selected to ensure consistency with the analyses performed by Terralogic and MRAG for the Pacific Groundfish EFH EIS, and to minimize data loss due to confidentiality. Data with a finer resolution is preferable and is much more useful for spatial analysis, but the public faces a tradeoff when requesting spatial fishery data from the Fisheries Service. Requesting data on a fine scale results in a significant loss of data, since the Fisheries Service withholds information if fewer than 3 fishing vessels operate in the area for which fishing information is requested.

The footprint was further refined in 2005 by analyzing the spatial arrangement of trawl track information within the blocks. State agencies provided maps of the proposed areas closed to bottom trawling overlaid with set point and haul back points of commercial bottom trawl hauls. This information confirmed that trawl effort is not uniform across a block, but occurs in specific discrete, patchy areas. The footprint was refined by removing portions of blocks where no or very little trawl effort was recorded. The footprint excludes the area within 3 nm of shore in the state waters of Washington and California that are already closed to bottom trawling. The total area of the revised delineated bottom trawl footprint was estimated at 82,000 km^2 using the best available data.

Distribution of bottom trawl fishery ex-vessel revenue

The dataset described above was also used to estimate the distribution of fishery value within the footprint. For each 10 by 10 minute block, we calculated the total catch of each species throughout the four-year period. The dollar value for each unit of catch of each species was determined from the *PFMC INPFC Area Report: Groundfish Estimated Ex-vessel Prices-per-pound for 2004 for all Gears*. We multiplied the total catch of each species in each block over the four year period by each species' respective value per unit, and summed the values for all species in each block. This allowed us to calculate the total ex-vessel value for the total bottom trawl catch in each block for the four year period from 2000-2003.

Due to data limitations, this method inherently assumes an even distribution of trawl effort throughout each entire block. Since the modified closed areas are intentionally drawn to avoid the concentrations of trawl effort within each block, the results of this method will consistently overestimate the actual displaced revenue in the analysis of our proposed closures.

Areas of sensitive habitat

Boundaries of areas of complex sensitive habitat were identified using the best available datasets (see footnotes) and applying the following criteria:

- Hard substrate, including rocky ridges and rocky slopes[1]
- Habitat-forming invertebrates[2]
- Submarine canyons and gullies[1]
- Untrawlable areas (trawl hangs and abandoned trawl survey stations)[3]
- Seamounts[1]
- Highest 20% habitat suitability for overfished groundfish species as defined by NOAA[4]

Boundaries were developed to reflect most precisely the specific habitat features identified, while attempting to minimize the number of way points for the sake of enforceability. The justifications for considering these areas as complex sensitive habitat are discussed below.

Hard substrates

Hard substrates, which include rocky ridges and rocky slopes, are one of the least abundant benthic habitats, yet they are among the most important habitats for fishes (Hixon et al. 1991, Pacific EFH PDEIS 2005). Hard substrates are also the seafloor substrate type most sensitive to bottom trawling and take the longest to recover (NAS 2002, Pacific EFH PDEIS 2005).

The EFH DEIS states:

> *Many managed species are dependent on hard bottom habitat during some portion of their life cycle. Typically, deeper water hard bottom habitats are inhabited by large, mobile, nektobenthic fishes such as rockfish, sablefish, Pacific hake, spotted ratfish, and spiny dogfish (MMS 2002). Cross and Allen (1993) estimated that about 30% of the fish species and 40% of the families occur over hard substrates. Many managed groundfish species use hard bottom habitats during one or more life stages including aurora rockfish, bank rockfish, black rockfish, black-and-yellow rockfish, blackgill rockfish, blue rockfish, bocaccio, bronzespotted rockfish, brown rockfish, cabezon, calico rockfish, California scorpionfish, canary rockfish, chilipepper, China rockfish, copper rockfish, cowcod, dusky rockfish, flag rockfish, gopher rockfish, grass rockfish, greenblotched rockfish, greenspotted rockfish, greenstriped rockfish, harlequin rockfish, honeycomb rockfish, kelp greenling, kelp rockfish, leopard shark, lingcod, Mexican rockfish, olive rockfish, Pacific cod, Pacific ocean perch, pink rockfish, quillback rockfish, redstripe*

Over 10,000 hard substrate polygons from the *Consolidated GIS Data, Volume 1, Physical and Biological Habitat data disk* (PFMC 2003) were plotted in GIS to determine where hard substrate habitat occurred.

Habitat-forming invertebrates

> *The planet's life-support systems are the source of stability for all peoples, all nations. Cold-water coral reefs are emerging as a new piece in this vital web of life which now requires our urgent attention.*
>
> *-Klaus Toepfer, Executive Director, UNEP*

Deep sea corals and sponges provide three dimensional structures that form habitat for commercial groundfish, shellfish, and other marine life in the Pacific (Krieger and Wing 2002; Malecha et al. 2002; Heifetz 2002) and other parts of the world (Costello et al. 2003; Scott and Risk 2003; Sulak et al. 2003; Rocha et al. 2000; Mortensen et al. 1995; Buhl-Mortensen and Mortensen 2004; Husebo et al. 2002; Sainsbury 1987). Structure-forming invertebrates (or biogenic habitat) are sensitive to impacts from bottom trawl gear (NAS 2002, Anderson et al. 2003, Engel and Kvitik 1998, Krieger 2001, Malecha and Stone 2003, MacDonald et al. 1996, Kaiser et al. 2000, Mortensen et al. 2003, Van Santbrink and Bergman 1994). Deep-sea corals and sponges, including species found on the U.S. West Coast, have been shown to be extremely long-lived (Leys and Lauzon 1998, Risk et al. 2002, Roark et al. 2005, Andrews et al. 2003). Recently, more than 1,100 scientists from around the world signed a statement (attached) on protecting deep sea coral and sponge ecosystems:

> "*In short, based on current knowledge, deep-sea coral and sponge communities appear to be as important to the biodiversity of the oceans and the sustainability of fisheries as their analogues in shallow tropical seas.*"

Throughout this DEIS process, perhaps no other criterion has generated as much discussion as the data on habitat-forming invertebrates. Despite the growing global concern for these species evidenced by the United Nations Report on Cold-water corals (Freiwald et al. 2004), consideration of the available data on habitat forming invertebrates has been viewed with trepidation and skepticism during the Pacific EFH process. We recognize that there are some limitations with the coral and sponge data, as with all marine and fisheries databases.

Nevertheless, because of the importance and sensitivities of these habitats, and the recognized need to be precautionary in management decisions in general and with regard to sensitive habitats in particular, we developed a reasonable approach using all available data.

In fact, a repeated criticism of the Alaska Region EFH DEIS by the Center for Independent Experts was that coral, sponge, and bryozoan bycatch from observer records were not analyzed, utilized, or incorporated (Drinkwater 2004). Specifically, the Center for Independent Experts recommended that NMFS "…analyze catch and effort data, observer bycatch data, field studies and consult with the industry to assess the damage done to the long-lived corals and sponges as well as the possible encroachment of fishing trawls into new areas containing corals and sponges" (Drinkwater 2004). It is worth noting that several studies to date have used trawl survey and observer bycatch records to assess distribution of these invertebrates and adverse impacts of trawling (Heifetz 2002, Heifetz et al. 2005, Anderson and Clark 2003).

Due to apparent confidentiality constraints, NMFS has not shared the Pacific observer bycatch dataset with the public. However, an analysis of the data images shows that the observer bycatch records for habitat-forming megafaunal invertebrates corroborates the areas identified for mitigation measures in the Comprehensive Alternative.

The validity of any data source depends on whether the methods used to collect the data are able to meet the objective of its use. Our specific policy objective in using the trawl survey data is to determine areas have high likelihood of containing corals and sponges within "trawlable" areas of the bottom trawl footprint. This is because areas outside the footprint and "untrawlable" areas are already protected in Revised Alternative C.12.

While direct submersible observations are the most accurate source of data for coral and sponge locations, the extremely limited spatial extent of submersible exploration on the U.S. west coast and the need to use the best available data requires the use of additional data sources. The most extensive data source containing records of habitat-forming invertebrates is the trawl survey database. Since sampling effort in the Pacific has not been uniformly distributed across habitat types, our intent in utilizing this data is not to predict the distribution of these animals across unsampled habitats, but merely to focus on regions where repeated samples have occurred. We are aware of the potential limitations in using bottom trawl surveys to identify precise abundances of habitat-forming invertebrates. Therefore, we have been extremely cautious in our use of the data. It stands to reason that an area which contains repeated samples of corals and sponges contains habitat suitable for corals and sponges. In fact, the PFMC's Science and Statistical Committee recommended that a reasonable approach is to focus on areas where corals and sponges have been documented, either from trawl surveys or other sources.

Coral and sponge records from trawl surveys must be considered a conservative estimate of the presence of biogenic habitat. Unfortunately, little information exists to ground-truth the extensive trawl survey databases with seafloor habitat. Of the thousands of NOAA trawl survey hauls that have occurred through the years, only one trawl survey track has been crossed by known submersible dive transects. The survey track, which occurred in 1986, was crossed by three dive transects on Heceta Bank in 2002. That 1986 trawl survey haul recorded 4 kg of an unidentified sponge species, or an estimated CPUE of 1 kg/hr. In 2002, the three dive transects that crossed this survey track recorded high densities of sponge of up to 167 vase sponges/ $100m^2$ (Wakefield, unpublished data). This reflects that a coral or sponge record from a trawl survey is indicative of areas of biogenic habitat. An initial focus on regions where corals and sponges have been documented, either from trawl surveys or other sources, is a reasonable approach, and was specifically recommended by the PFMC Scientific and Statistical Committee in its review of Alternative C.12. Given the importance and sensitivities of these habitats, and the recognized need to be precautionary in management decisions, we developed a responsible and reasonable approach to consider all available data in making management decisions.

We also recognize the trawl survey sampling and statistical design creates a possibility for false negatives. In other words, the data sets may fail to identify habitat-forming invertebrates in many places where they actually occur. We are aware that sampling invertebrates is not the primary goal of trawl surveys. This may result in failing to sample "untrawlable" areas where habitat-forming invertebrates occur and/or failing to record occurrences at sampled sites. The former, as discussed, does not appear to pose a problem since we are only using the data for identifying positive locations. The latter possibility is likely to be reduced significantly by repeated sampling at the same location, which is a sampling strategy used in the trawl survey.

Trawl surveys do not pinpoint exact locations, but rather transects. Therefore a positive record of habitat-forming invertebrates means that the habitat may be found anywhere along the trawl track. Therefore, in drawing boundaries, we attempted to include the entire trawl track inside the closure boundary for each record we used to justify a biogenic area closure. Furthermore, invertebrate identification is recorded at the taxonomic group level rather than at the species level. This does not pose a significant problem because identification to taxonomic group level is sufficient to classify an invertebrate as "habitat-forming".

An extensive database was used to determine "hotspots" where the presence of habitat-forming invertebrates (corals, sea whips, sea pens and sponges) was frequently recorded or large samples of these invertebrates occurred. The database comprised records from Alaska Fisheries Science Center slope and shelf trawl surveys from 1977 to 2001, Northwest Fisheries Science Center slope and shelf trawl surveys from 2001 to 2003, and MCBI's database of deep-sea coral records. MCBI's database was commissioned by NOAA and includes coral records from the California Academy of Sciences, Smithsonian Institution, MBARI, and Scripps compiled from various research cruises and scientific collections (Etnoyer and Morgan 2003).

Two types of point density analyses were performed using the ArcView 9.0 Spatial Analyst Point Density Tool (ESRI 2004) to determine clusters of coral and sponge records. The first analysis explored the density of records, with each point weighted equally. A total of 3,691 coral and sponge records were used in the analysis. For trawl survey data (3,291 records), the start point of the trawl was used to plot points. For other coral and sponge data (400 records from MCBI dataset) the sample location point was plotted. Using a cell size of 2,000 meters and a search radius of 10,000 meters, the point density function outputs the mean density per kilometer of coral and sponge records. This approach identifies areas that have had numerous records of habitat-forming invertebrates.

The second analysis explored clusters of coral and sponge records with high survey catches. Only trawl survey data, with associated records for catch weight and CPUE, were used in the analysis. A total of 3,291 survey start points from NOAA trawl surveys from 1977-2003 were plotted. This density analysis weighted the points by the rounded integer of the catch of coral or sponge. For example, a CPUE of 10 kg/km^2 would be counted ten times. This approach identifies areas with the highest relative weights of coral and sponge sample records. Both analyses were useful for identifying "hotspots" of records of habitat-forming invertebrates.

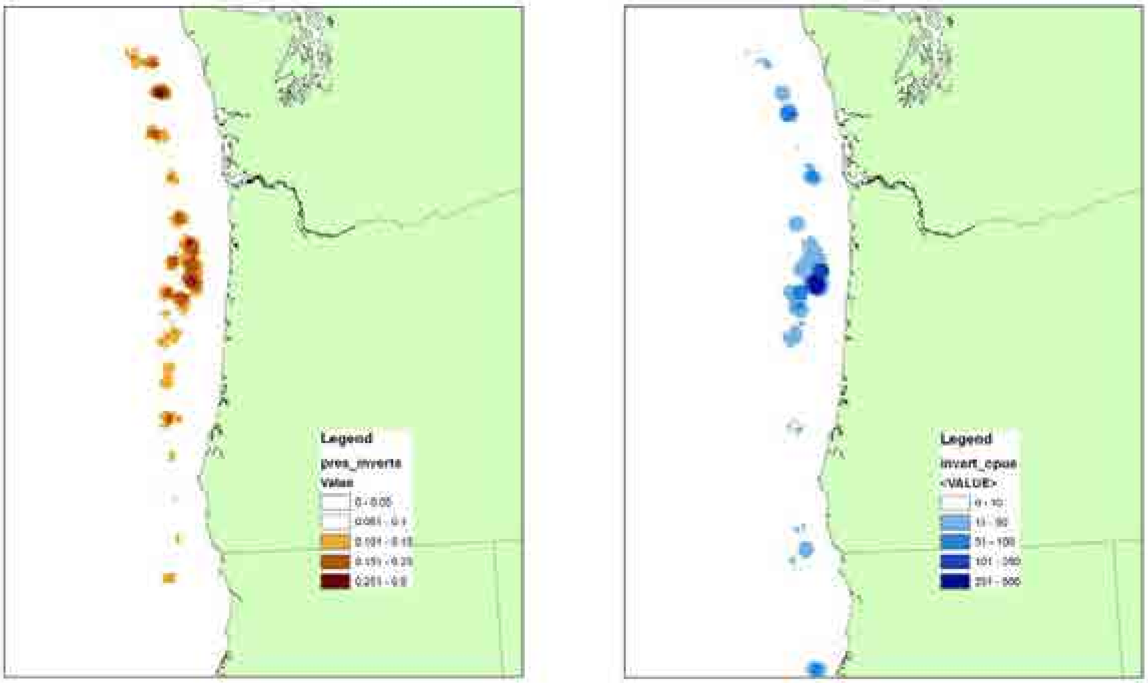

Figure 1: Point density analysis of coral and sponge records. The figure on the left displays output when all points are weighted equally. The legend shows density of points per square kilometer. The figure on the right displays output from point density analysis with points weighted by CPUE. The legend shows mean CPUE per square kilometer.

At the March 2005 PFMC meeting, the Scientific and Statistical Committee suggested paying greater attention to presence data from the NMFS trawl survey information that was used in the identification of biogenic areas. As such, a few additional closure areas were identified using information on habitat-forming invertebrates as the primary criterion.

Submarine canyons and gullies

Submarine canyons are known to be areas of enhanced productivity due to current upwelling zones (Freeland and Denman 1982). For this reason, canyons show enhanced concentrations of benthic invertebrates (Haedrich et al. 1980; Sarda et al. 1994; Vetter and Dayton 1999), plankton (Cartes et al. 1994; Macquart-Moulin and Patriti 1996), demersal fishes (Stefanescu et al. 1994), and whales (Kenney and Winn 1987; Schoenherr 1991) relative to surrounding areas on the slope and shelf. Brodeur (2001) found dense concentrations of Pacific ocean perch (*Sebastes alutus*) and krill associated with biogenic habitats in a Bering Sea submarine canyon, while areas with damaged biogenic structures had far fewer rockfish, and areas in the canyon without biogenic structure had no rockfish. In the North Pacific Ocean, rockfishes in the genus *Sebastes* often inhabit the offshore edges of banks or canyons and are known to capitalize on advected prey resources such as euphausiids (Pereyra et al. 1969; Brodeur and Pearcy 1984; Chess et al. 1988; Genin et al. 1988). Therefore, submarine canyons provide essential habitat for groundfish that is highly vulnerable to fishing impacts.

Vetter and Dayton (2001) found that submarine canyons in Southern California provide large quantities of food in aggregated form on the deep sea floor by acting as conduits for marine macrophyte production produced in the intertidal and shallow subtidal zone. This study also found elevated abundance of Pacific hake and turbot in these canyons. Starr et al. (2002) found evidence for site fidelity in green-spotted rockfish (*S. chlorostictus*) and suggested large-scale reserves for boccacio (*S. paucispinus*) at a canyon in Monterey Bay.

Submarine canyons provide habitat for larger sized rockfish that seem to prefer structures of high relief such as boulders, vertical walls, and ridges. Yoklavich et al. (2000) found high abundance of large rockfish associated with complex structural habitat in Soquel Canyon with lower size and abundance in fished areas. Canyon heads are the upper, shallower portions of submarine canyons where coastal upwelling fronts have been shown to contain high abundance of rockfish larvae (Bjorkstedt 2002). Additionally, Hooker (1999) found higher abundance of cetaceans in a submarine canyon known as “The Gully” off Nova Scotia relative to surrounding areas of the shelf and slope. The cover and protection offered by submarine canyons allow pockets of rockfish populations to flourish, in contrast to more exposed areas where the populations are more easily fished. Because submarine canyons on the U.S. West Coast are typically upwelling zones, they often contain higher abundances of filter feeding invertebrates, such as corals, sponges, tunicates, and bryozoans, which contribute to the structural complexity of the seafloor.

Canyon habitat polygons from the *Consolidated GIS Data, Volume 1, Physical and Biological Habitat data disk* (PFMC 2003) were plotted in GIS.

Untrawlable areas

The Zimmerman (2003) database includes all records from the NMFS West Coast Triennial Trawl Survey where major trawl net hangs and untrawlable survey stations were recorded. These areas are considered unsuitable for trawling due to areas of high structural complexity, such as boulders or rock outcrops (Zimmerman, pers. com.). Substrates or structures that induce a trawl hang provide habitat for juvenile fish (Link and Demarest 2003). The study found that a buffer of 3.7 km (2 nautical miles) around these features would encompass 17-30% of juvenile fish. Since most trawl net hangs are concentrated, these authors recommend a methodology of identifying these concentrations and establishing a no-trawl buffer around them. Other work on this topic suggests that such a methodology would only close 1-4% of the ocean bottom to trawling (Link 1997).

Furthermore, it is expensive to fisherman to replace trawl gear that has been damaged or lost due to contact with benthic structure. Since fishermen wish to avoid hangs, closing areas with high relative densities of areas known to be “untrawlable” will help avoid damage to trawl nets and close areas fishermen probably avoid anyway. Therefore, the economic effects of bottom trawl closures based on the Zimmerman dataset are likely to be negligible.

The GIS data used in the manuscript by Zimmerman (2003) was plotted in GIS.

Seamounts

Seamounts are sites of enriched biological activity relative to the surrounding waters (Mullineaux and Mills 1997, Dower and Perry 2001, Haney et al. 1995). Koslow et al. (2001) conducted a survey of Tasmanian seamounts where 30% of species identified were new to science and 30-60% were found nowhere else on earth. Studies indicate that seamounts function as deep-sea islands of localized species distributions, dominated by suspension feeders like corals and sponges which can be easily damaged by fishing gear that makes contact with the bottom (Monterey Bay National Marine Sanctuary, Sanctuary Integrated Monitoring Network, URL: www.mbnmssimon.org/sections/seamounts/overview.php).

Recent studies conducted by the Monterey Bay Aquarium Research Institute on West Coast seamounts have documented unique and diverse biological communities. (http://www.mbari.org/volcanism/seamounts/seamountsresearchtop.htm). Along the crests and slopes of several seamounts, MBARI scientists observed long-lived coral and sponge habitats. DeVogelaere et al. (2003) found 24 coral taxa on Davidson Seamount off California and described numerous species associations, particularly that *Paragorgia sp*. were found in areas with highest species diversity. Guyots are a type of volcanic seamount with a flat top or plateau. Because the tops are flat, they may be particularly vulnerable to trawling due to the relative ease of setting trawl gear. The rarity, uniqueness, and vulnerability of seamount faunal communities provide strong scientific justification for a highly precautionary approach (de Forges et al. 2000, Stocks 2004, Probert et al. 1997).

Eight seamounts have been identified within the jurisdiction of the PFMC. These are President Jackson, Thompson, San Juan, Guide, Pioneer, Gumdrop, Davidson, and Rodriguez Seamounts. The location and area delineation of most of the seamounts were plotted in GIS from data on the *Consolidated GIS Data, Volume 1, Physical and Biological Habitat data disk* (PFMC 2003). Rodriguez Seamount was not included in the dataset but has been incorporated into the revised alternative.

Highest 20% habitat suitability for overfished groundfish species

Several major groundfish species have been designated as overfished and are currently being fished pursuant to rebuilding plans. Most of these species have been documented to use complex structural habitat. Protecting habitats specifically for these species will aid in their recovery.

Habitat suitability modeling performed in the Habitat Comprehensive Risk Assessment (PFMC 2004) identified areas of the highest suitability for overfished groundfish species. The proposed spatial management measures in Alternative C.12 were selected to ensure protection of habitat important for overfished groundfish species.

Consideration of all available data

With data in hand, we began to construct the spatial management component of Alternative C.12, identifying areas that would be open or closed to bottom trawling. Because we recognized that it was not practicable to close every area of sensitive habitat to bottom trawling, we attempted to reach a reasonable solution that is as cost-effective and equitable as possible. In other words, we attempted to protect as much important habitat as possible while minimizing short-term economic costs. Many factors were carefully considered while drawing boundaries for the open/closed areas to bottom trawling:

- Avoid high fishery value areas when considering closed areas;
- When habitat features overlapped high fishery value areas, minimize the overlap of the resultant boundary;
- Distribute open/closed areas equitably among regions; and
- Draw closed area boundaries that conform to the habitat feature, minimizing closure area

Results

Overview

Table 1: Summary Statistics of Revised Alternative C.12

Area Description	Square kilometers	Square miles (nautical)
Area within Pacific EEZ	826,680	241,021
Area of existing bottom trawl footprint (fished area)	82,000	23,908
Area remaining open to bottom trawling	70,000	20,409
Area to be closed within the existing footprint	12,000	3,499
Area closed outside existing footprint (unfished)	745,000	217,207
Total area closed	757,000	220,706

Freezing the existing bottom trawl footprint resulted in approximately 745,000 km^2 of untrawled or lightly trawled habitat within PFMC jurisdiction closed to bottom trawling. Most of this area comprises habitat prohibitively deep for trawl fisheries to fish with current technology. Additionally, 61 areas of sensitive habitat were identified for potential bottom trawl closures. In many cases, portions of the above-mentioned areas were located outside of the trawl footprint, and would be closed by freezing the footprint. Sensitive habitat areas proposed for closure within the trawl footprint (i.e. trawled areas that would be closed) totaled approximately 12,000 km^2 of habitat. The total area where bottom trawling would be permitted (the "open" area) totaled approximately 70,000 km^2.

The spatial management component of Revised Alternative C.12 provides substantial protection of sensitive habitat features while allowing for continued bottom trawling opportunities. A large proportion of sensitive habitat types are protected by the areas selected. In other words, Revised Alternative C.12 is a practicable alternative to minimize the adverse impacts of bottom trawling on Essential Fish Habitat. The following maps (Figure 2 to Figure 7) display the spatial management component of Revised Alternative C.12 and illustrate the areas open or closed to bottom trawling. For a detailed illustration of individual areas and the criterion used to develop boundaries of the open or closed areas, see the figures at the end of this document (Figures 8 through 61).

Habitat-forming invertebrate data

NOAA bottom trawl surveys from 1977 to 2003 document 3,270 occurrences, totaling 16,765 kilograms, of habitat-forming invertebrates (corals, sponges, sea whips and sea pens) off the Pacific coast. Revised Alternative C.12 would close a significant portion of areas where those animals occurred. The area closed to bottom trawling under Revised Alternative C.12 contains 1,288 records of habitat-forming invertebrates (39% of all occurrences documented during NOAA trawl surveys). Further, the proposed closed areas contain a larger proportion of high density records, encompassing areas where 11,275 kg, or over 67% of the invertebrate biomass, was sampled. Deep sea coral records from other sources (Etnoyer and Morgan 2003) are well represented in the proposed closed areas with 356 of 400 coral records (89%) located within the proposed closed areas.

Unfortunately, this metric of analysis to consider important seafloor habitat was not used in the EFH DEIS to evaluate most of the other mitigation alternatives. As such, Revised Alternative C.12 encompasses far more records of this habitat type than other alternatives that did not consider this criterion.

Table 2: Records[5] of habitat-forming invertebrates (corals, sponges, sea whips and sea pens) in proposed areas. Areas where no or low numbers of records exist are likely due to lower sampling effort and do not indicate the absence of these animals in that area.

	Total records in revised closed areas	1624

Untrawlable areas

The closed areas in Revised Alternative C.12 encompass 4,935 of 8,943 polygons, or 1,057 km^2 (over 57%) of 1,847 km^2, of "untrawlable" area (trawl hangs, pinnacles) as defined by Zimmerman (2003).

Estimated displaced tows, catch, and ex-vessel revenue

The estimates of displaced revenue of the original Alternative C.12 proposal were provided by the WDF&G, who estimated displaced revenue by summing catch from 2003 trawl logbook set points contained within the closed area. The estimates of the revised Alternative C.12 were made by determining the proportional overlap of a closed area with 2000-2003 trawl effort data that was provided in 10 x 10 minute blocks. The proportional method assumes a uniform distribution of fishing effort across a block. However, the revised closed area boundaries were made with the spatial distribution of trawl tracks. The estimates of displaced revenue from the revised Alternative C.12 reported below are likely grossly overestimated (Table 3). The methodology used to determine displaced revenue relied on the assumption that trawl effort and catches were distributed uniformly within the block area for which economic information was provided. Analysis of trawl logbook set and haul back points indicated that this is not the case. Trawl activity is patchy, and is located in discrete areas. This was confirmed by the overlay maps of the set points with the proposed closed areas. Since the boundaries of closed areas were refined to avoid patches of heavy trawl effort, the actual displaced revenue is minimized much more than simply reducing the area would indicate. Nonetheless, even assuming uniform fishing effort across a block, our modified closed areas reduced the previously estimated displaced revenue by over 30% from displaced revenue of $5.4 million in original Alternative C.12 to $3.4 million in Revised Alternative C.12 (Table 3).

As a result of analyses of the spatial distribution of trawl track information from logbooks, input from trawl fishermen, and comments from the SSC, areas of Alternative C.12 were revised to provide for expanded trawl grounds while protection of habitat areas. This revised Alternative C.12 reduces revenue displacement across the EFH area while maintaining integrity of protection/mitigation. The revised Alternative C.12 results in displacement of less than 15% and far less loss in any actual revenue.

Table 3: Revised Alternative C.12 revenue displacement comparison to original Alternative C.12

	Grand Total	17,653	3,114.4 mt	$3,408,709

Overall, the spatial management components of Revised Alternative C.12 represents an estimated displacement of $3,408,709 in annual trawl revenue, protects areas containing 1,624 records of habitat-forming invertebrates (corals, sponges, sea whips, and sea pens). Of the approximately 82,000 km^2 bottom trawl footprint identified using the best available logbook data, 12,000 km^2 (under 15%) is closed to bottom trawling in this alternative leaving a total open area to bottom trawling of 70,000 km^2**.**

Other management measures

Trawl effort reduction

Dinmore et al. (2003) found that without commensurate reductions in fishing effort, closing off a heavily trawled area may result in significant displacement of trawled effort into remaining open areas, including previously untrawled areas. For this reason, the NRC (2002) report on the effects of bottom trawling notes that effort reduction is the "cornerstone of habitat protection". While there may be several ways to reduce bottom trawl effort, the crucial factor is that the total area swept by bottom trawl gear is reduced. Alternative C.12 specifically attempts to avoid closing heavily trawled areas in order to minimize displacement of trawl effort in to new areas. Also, recent measures enacted by the PFMC have reduced trawl effort to rebuild overfished species. Recent buyouts have also reduced the total annual trawl effort on the U.S. west coast. However, as stated in the NRC (2002) recommendations, trawl effort may still need to be reduced to ensure the adequacy of any measures to fully mitigate the adverse impacts of trawl gear. Revised Alternative C.12, therefore, recommends Council-developed bottom trawl effort reductions.

Gear restrictions

In 2000, the Pacific Fishery Management Council adopted regulations designating where different size bottom trawl gear may be fished. Only bottom trawls with footrope diameter 8 inches or smaller (including rollers, bobbins, or other material along the length of the footrope) may be used shoreward of the Rockfish Conservation Areas (RCA). Footrope restrictions are linked to fish trip limits as a means of management by the PFMC. The Bellman and Heppel study (Appendix A-19) provides evidence that an 8 inch roller maximum roller size gear restriction can be an effectively reduce trawl effort over rocky substrate. This study suggests that adverse impacts in some specific areas have been reduced as an indirect effect of roller size restrictions. It is crucial that this gear restriction remain permanent to ensure continued protection to Essential Fish Habitat, and be expanded to encourage further mitigation of adverse impacts.

A loophole exists in that while fishing for species without trip limits, the footrope restrictions do not apply. Also, the existing footrope restrictions area not permanent, and be reinstated annually by the PFMC. Seaward of the RCA, there are no restrictions on trawl gear. A four seam Aberdeen trawl is commonly used for the deepwater fleet with rollers or rockhoppers up to 14 inches in diameter (Recht, 2003). These vessels target dover sole, sablefish, and thornyheads.

The Revised Comprehensive Alternative includes an 8 inch roller size restriction for all bottom trawl gear deployed in the U.S. West Coast EEZ. Limitations on the roller size of bottom trawl gear provide an effective management measure to reduce bottom trawl effort on rocky substrates with substantial structural complexity. Bellman and Heppell (in press) found that the 8 inch roller size restriction implemented by the Pacific Fishery Management Council in 2000 effectively reduced bottom trawl effort at five sites with hard, rocky substrate on the U.S. West Coast by 86%. This gear restriction, however, was only implemented in specific depth ranges and therefore does not protect rocky substrate types in areas where it was not implemented. Therefore, expanding this existing gear restriction throughout the entire U.S. west coast EEZ is an effective way to prevent trawl damage to complex rocky substrates in areas that remain open in this alternative.

The Comprehensive Alternative includes the following footrope restrictions:

- Bottom trawling within the open bottom trawl area may only use footropes 8 inches or smaller in diameter;

- The footrope restriction must be applied for all bottom trawling, regardless if the target species has trip limits; and
- Footrope restrictions are made permanent instead of re-authorized on an annual basis.

While gear modifications must be an integral component of a comprehensive strategy to mitigate the adverse effects of trawling on Essential Fish Habitat, they are not a substitute for bottom trawl closures. The International Council for the Exploration of the Seas (ICES) released a statement that "the only proven method of preventing damage to deep-water biogenic reefs from fishing activities is through spatial closures to towed gear that potentially impact the bottom" (cited in Christiansen and Lutter 2003).

Comprehensive research and benthic mapping

Basic biology and life history information is lacking for many deep sea coral and sponge species. Understanding growth rates, reproduction, dispersal, and ages of deep sea corals and sponges and other habitat-forming invertebrates will provide estimates of recovery time for different habitat types. EFH identification research should explore the community ecology of coral and sponge habitats, including the production functions between the biogenic habitat features and commercial fish species, and prey species for commercial fish species, among other functions. Basic biology and life history information is lacking for many deep sea coral and sponge species. Understanding growth rates, reproduction, dispersal, and ages of deep sea corals and sponges will provide estimates of recovery time for different habitat types.

The distribution of sensitive habitat types off the Pacific Coast can be determined through a combination of seafloor mapping projects and developing Habitat Suitability Indices for biogenic substrates. Leverette (2003) developed a methodology for predicting likely areas of deep sea coral concentrations off Atlantic Canada by identifying key ecological determinants of the known distribution of these habitat types. Using sidescan sonar and multibeam scanning techniques, these habitat suitability models can be ground-truthed to determine their precision and accuracy. While the habitat suitability modeling approach is being used for fish species in the current EFH EIS, the Comprehensive Alternative explicitly includes this type of modeling and groundtruthing for living habitat features that are vulnerable to trawling.

Research and benthic mapping should be also designed to provide opportunity for reevaluating the open and closed areas to bottom trawling to protect EFH. Criteria for opening areas would include that they have been mapped or thoroughly observed in situ, do not contain sensitive habitats, and it can be demonstrated that bottom trawling may occur in the area without adversely impacting habitat. In addition, new areas of sensitive habitat may be discovered within the open-bottom trawl areas and become candidates for new closed areas.

The components of Revised Alternative C.12 described in this section emphasize the need for adequate funding dedicated specifically to EFH research, mapping, and observer coverage. While this research will require a substantial allocation of agency resources, the rationale for this expenditure is that more spatially explicit information will allow more cost effective management in the future. This is because higher spatial resolution can be used to develop fine scale management measures that allow fishermen to adequately obtain their catch without damaging the habitat, its ecological functions, or the underlying productivity of the fish they are harvesting.

Monitoring the habitat impacts of the bottom trawl fleet

NMFS and the PFMC must include in any mitigation alternative a framework to measure and monitor habitat impacts. A direct approach for measuring habitat impacts of fishing is to examine bycatch, or incidental catch, of habitat-forming invertebrates. Bycatch can be monitored by onboard observers. While it may be difficult to estimate the total reduction in habitat quality caused by each per unit reduction in these habitat indicators, this approach allows a comparison of habitat damage over different areas and using different gear types.

The Revised Comprehensive Alternative includes the following monitoring and enforcement components:

1. Increase onboard observer coverage on bottom trawl vessels to a level determined to be necessary by NOAA to estimate annual bycatch of habitat-forming invertebrates and quantify habitat interactions with fishing gear;
2. Require vessel Monitoring Systems (VMS) on all vessels using bottom trawl gear to catch groundfish in the U.S. West Coast EEZ with positions recorded at a time stamp of every 5 minutes (time);
3. Improve electronic logbooks to provide better fishing effort information to NOAA and state authorities;
4. Annual publication of a NMFS *West Coast Groundfish Habitat Status Report* to make habitat impact and bycatch data available to the Council, the public and the fleet at as high a spatial and temporal resolution as possible; and
5. Establish baseline data and a process for setting and implementing bycatch limits on structure-forming invertebrates and/or other habitat performance standards.

Monitoring habitat impacts of individual vessels allows fishery managers to evaluate the effectiveness of management measures, reveal vessels or areas of concern, and provide future management options that utilize performance standards and incentive-based regulations. Fishermen control many factors that determine the degree to which their activities impact the seafloor. The placement (physical location) of their nets and the specific type of gear they use are largely at the discretion of individual vessel captains. The various factors that play into this decision are the likelihood of catching valuable target species and the likelihood that they will damage the gear they are using. By using state-of-the-art sounders and fish-finders, fishermen are able to identify schools of particular species of fish and obtain information about bottom type before setting their gear. While some seafloor types cause major damage to trawl nets, such as large, sharp boulders, there is little evidence that vulnerable habitat types such as living substrates damage trawl gear. Therefore, there exists no immediate incentive to avoid such habitats in the pursuit of fish, particularly if there are higher abundances of fish in these areas.

A direct approach for measuring habitat impacts of fishing is to examine bycatch, or incidental catch, of habitat features. Since each habitat feature may vary in its catchability, indicators that are caught by fishing gear should be used. Bycatch can be monitored by onboard observers. In Alaska, for example, observers routinely report bycatch of corals and sponges. While it may be difficult to estimate the total reduction in habitat quality caused by each per unit reduction in these habitat indicators, this approach allows a comparison of habitat damage over different areas and using different gear types.

Bycatch data availability

There is no question that observer bycatch data should be used to the fullest extent in groundfish management. Habitat-related observer bycatch data are important tools for protecting sensitive habitats and the long-term productivity and sustainability of the groundfish fisheries. Such data should be made available on a regular basis to the Council, the fleet and the public in as spatially and temporally explicit a format as possible. We recommend this information be released annually by NMFS in a *West Coast Groundfish Habitat Status Report.*

Monitoring habitat impacts with VMS

The Comprehensive Alternative includes a vessel monitoring system (VMS) requirement with positions recorded at a time stamp of every 5 minutes for all vessels fishing for groundfish using bottom trawl gear. Vessel monitoring systems (VMS) track the location and speed of vessels in real time, allowing managers to assess more accurately where trawling actually occurs. This data can be used to enforce bottom trawl closed areas and can be combined with other data to provide detailed spatial information on individual vessel catch, bycatch, and habitat impacts.

Conclusion

Revised Alternative C.12 considers the interrelatedness and spatial arrangement of complex sensitive habitat criteria in relation to areas prosecuted by bottom trawl fisheries to develop an approach to manage the effects of bottom trawling on habitat. Revised Alternative C.12 is a comprehensive approach to protect Essential Fish Habitat, as required by law, while maintaining vibrant commercial fisheries for the Pacific Coast.

Descriptions of specific closed areas
Detailed maps of the respective areas for Revised Alternative C.12 reflect the modifications to boundaries for each area.

1. Olympic_1
Original Alternative C.12 estimated displaced revenue= $1,286,058
Revised Alternative C.12 estimated displaced revenue= $431,115 (likely overestimated, trawl tracks fall outside of area, see Figure below)

According to 2003 bottom trawl logbook data, several heavily fished areas were located within the proposed closed area of *Olympic_1* (Figure A) in Original Alternative C.12. Boundaries to *Olympic_1* were adjusted in Revised Alternative C.12 to avoid heavily trawled areas in the northeast and southern end of the original proposed closed area (Figure 8). The closed area in Revised Alternative C.12 also expands eastward to encompass deeper, lightly fished areas.

Revised Alternative C.12 contains 330 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003).

As indicated by databases supplied by NOAA, every trawl survey haul performed within the proposed area has recorded habitat-forming invertebrates. A total of 54 records of habitat-forming invertebrates have been recorded in the area since 1979. These include *Calcigorgia sp.* and *Swiftia sp.* gorgonian corals, black corals, sea pens, sea whips, and Hexactinellid sponges.

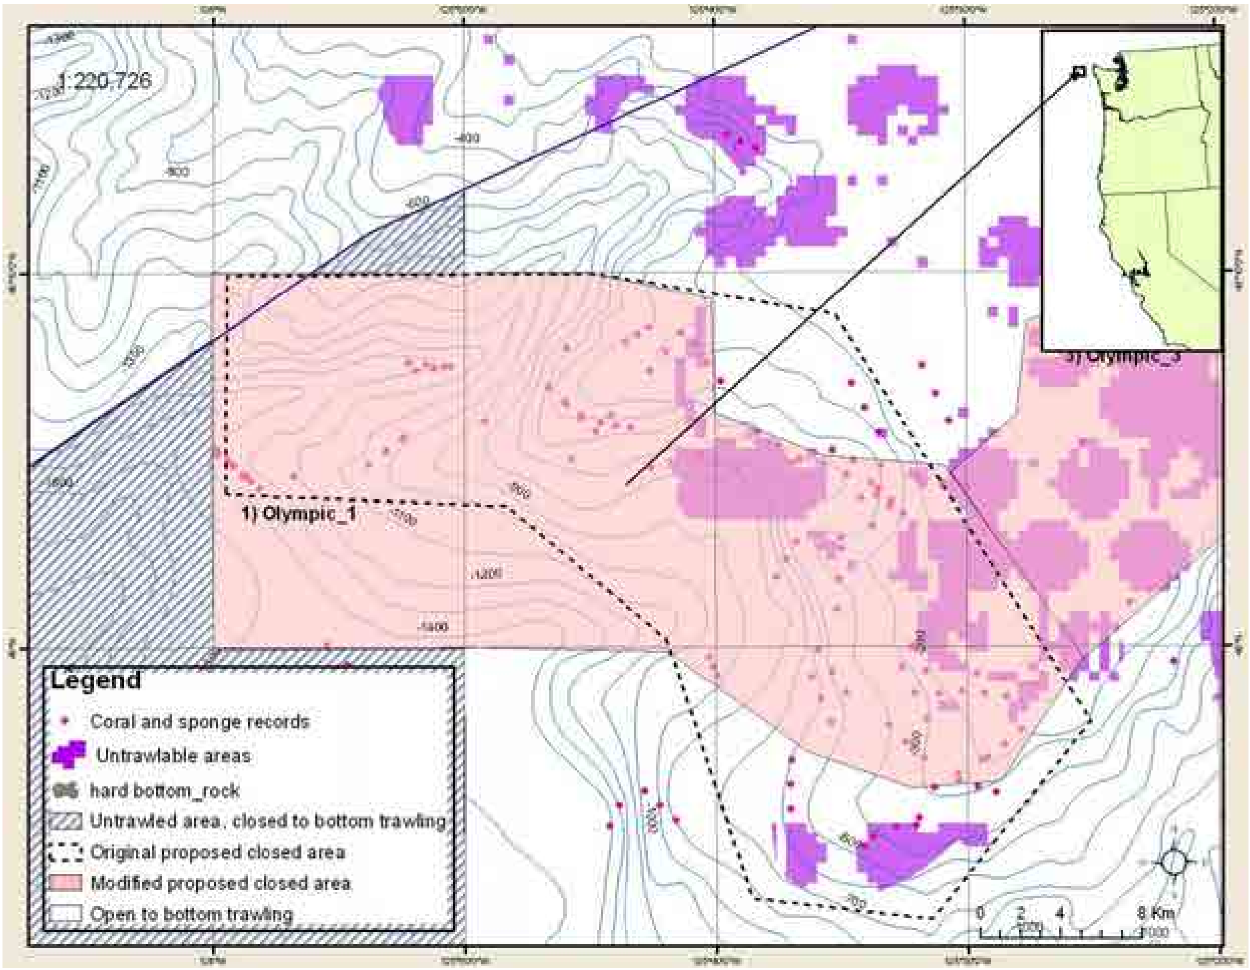

Figure 8: Olympic_ 1

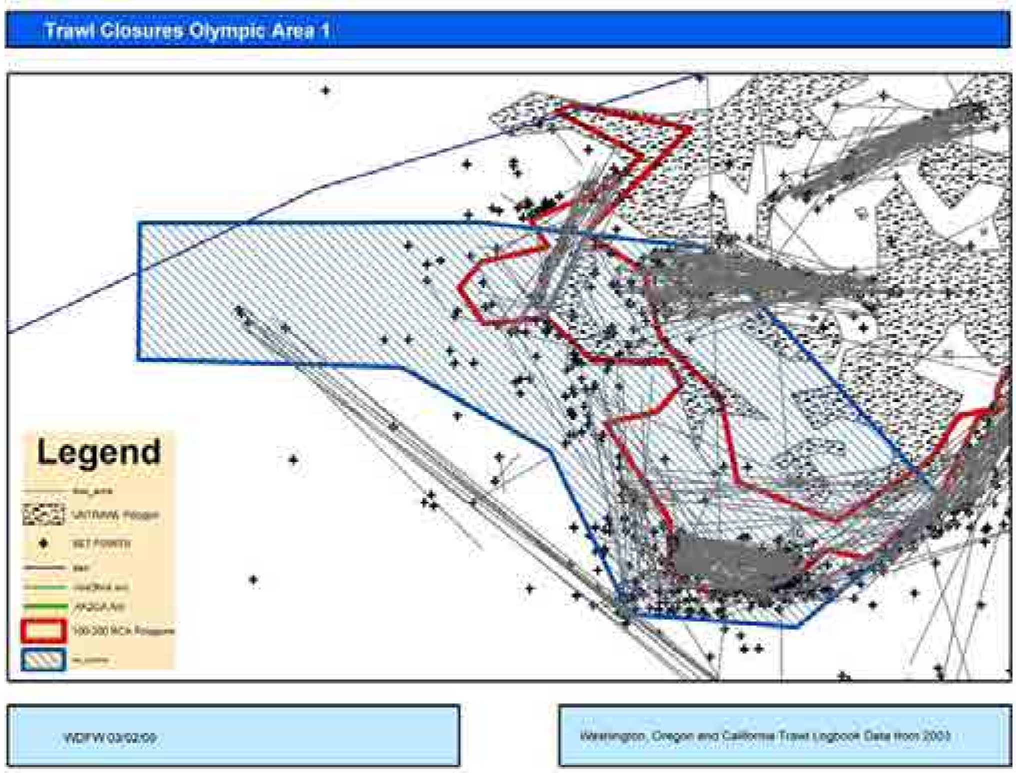

Figure A: 2003 bottom trawl logbook set points (courtesy WDF&W).

2. Olympic_2
Original Alternative C.12 estimated displaced revenue= $326,284
Revised Alternative C.12 estimated displaced revenue= $280,685 (likely overestimated, trawl tracks fall outside of area, see Figure below)

Trawl logbook data from 2003 indicated some fishing in the northern and southern portion of the Original Alternative C.12 closed area (Figure B). The boundary for the proposed closed area in Revised Alternative C.12 was adjusted to avoid those fishing areas (Figure 9).

The proposed closed area contains the only known location in the Northwest Pacific of *Lophelia pertusa,* a reef-forming deep-sea coral. Observation of the reef in 2004 indicated a large proportion of the reef was broken, and both trawl tracks and derelict fishing gear were observed nearby (Hyland et al. 2004). Research in the Atlantic shows that reefs of *Lophelia* are extremely susceptible to damage by bottom trawl gear (Fossa et al. 1999).

A total of 18 records of habitat-forming invertebrates have been recorded in the Revised Alternative C.12 closed area by NOAA trawl surveys. These include *Alcyonacea* soft corals, other gorgonian corals, scleractinian corals, and Hexactinellid sponges. A larger number of records and greater sample weights occurred in the 1980's than more recent surveys, which may indicate evidence of habitat destruction.

The proposed closed area contains 523 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003).

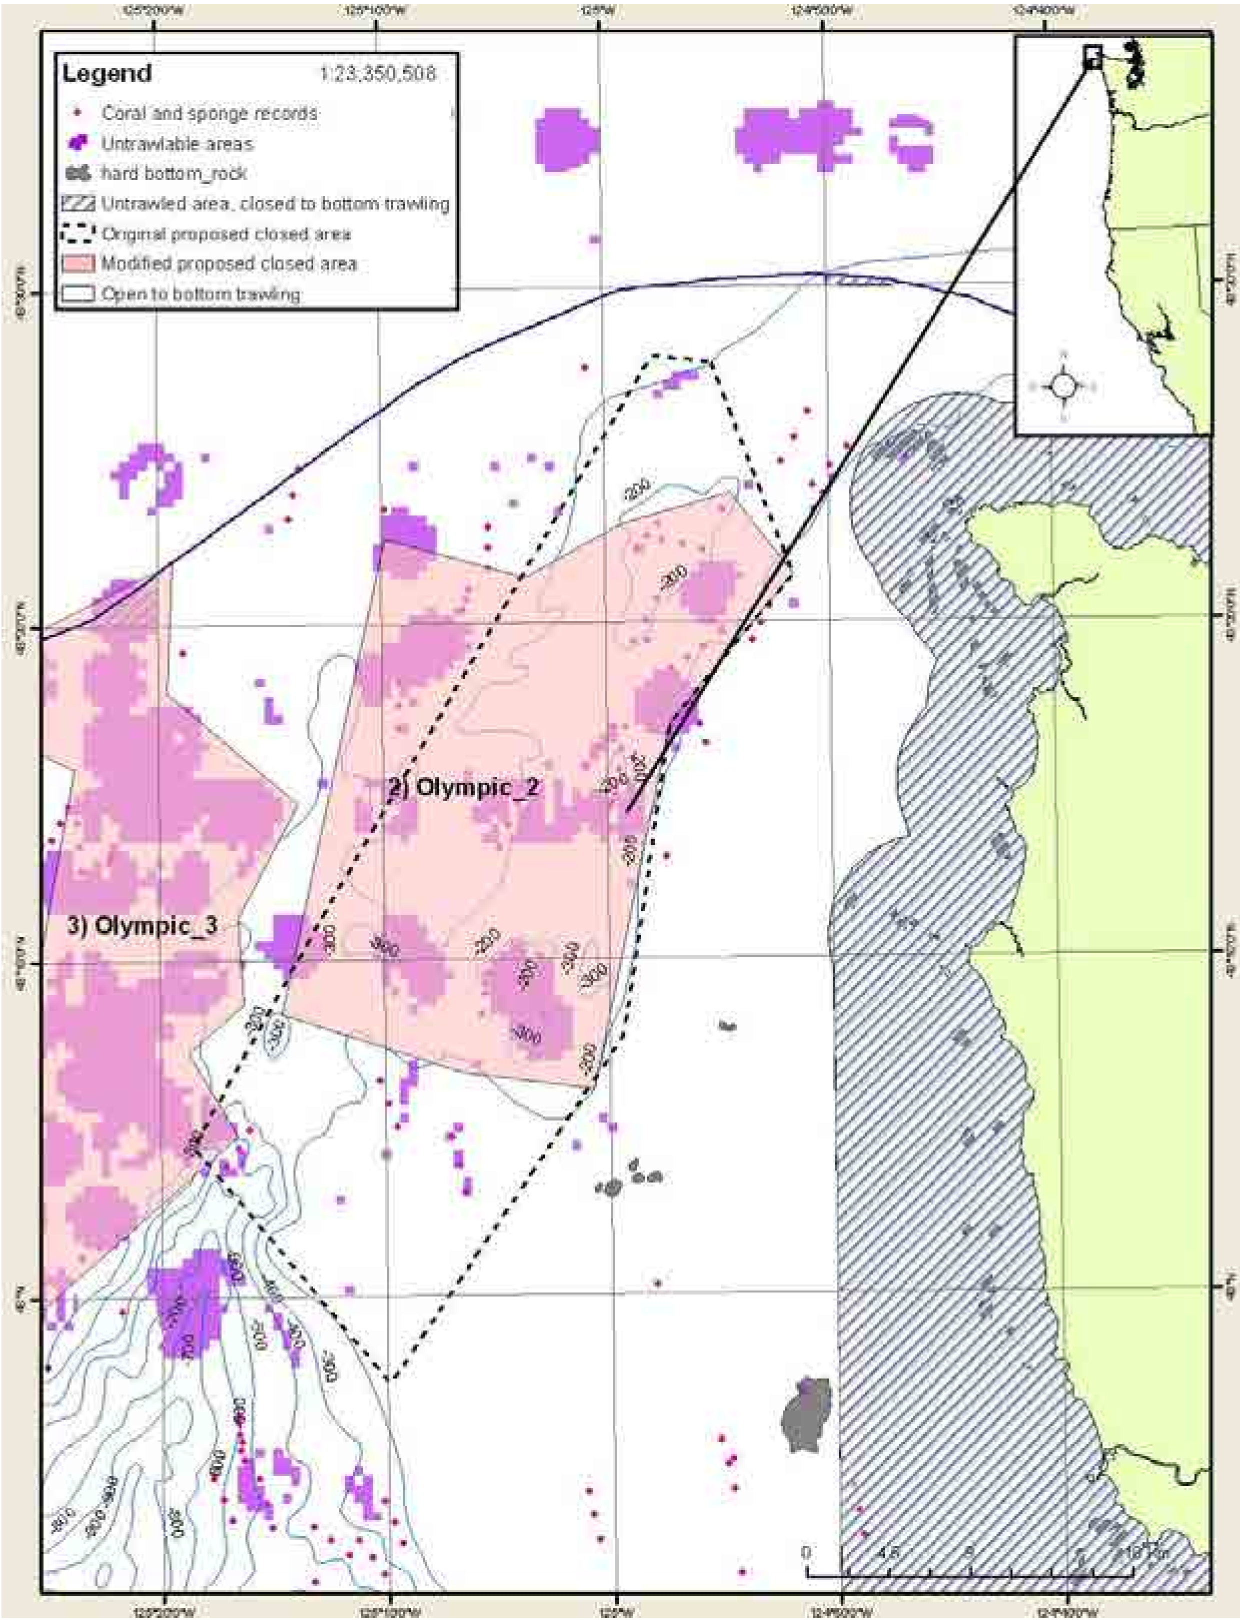

Figure 9: Olympic_2

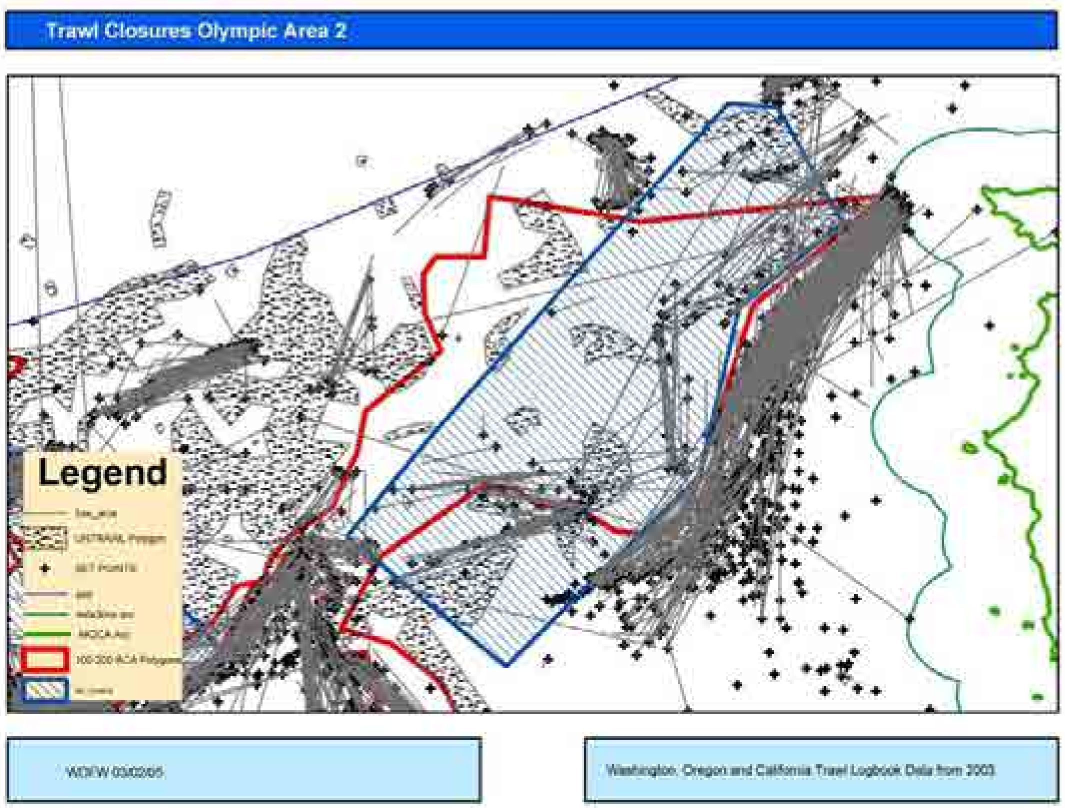

Figure B: 2003 bottom trawl logbook set points (courtesy WDF&W).

3. Olympic_3_untrawlable

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $395,676 (likely overestimated, trawl tracks fall outside of area, see Figure C below)

This portion of the Olympic Marine Sanctuary is located between proposed areas *Olympic_1* and *Olympic_2* (Figure 10). This area had not been previously identified as a closed area.

Localized multibeam mapping indicates the area contains pinnacles and high relief, rocky habitat (Steve Intelmann, GIS analyst, Olympic Marine Sanctuary, pers. comm.). Zimmerman (2003) indicates that much of this area is untrawlable, as very few NOAA trawl surveys have successfully been deployed in this area. Trawl logbook data from 2003 shows that the area appears to be avoided by the bottom trawl fleet (Figure C). This is corroborated by the Zimmerman (2003) "untrawlable areas" database, which shows the area to contain 1,098 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up. Although the area is not well surveyed, a total of nine records of habitat-forming invertebrates have been recorded in the area by NOAA trawl surveys. These include scleractinian corals, sea pens, and Hexactinellid sponges. A larger number of records and greater sample weights occurred in the 1980's than more recent surveys, which may indicate evidence of habitat destruction.

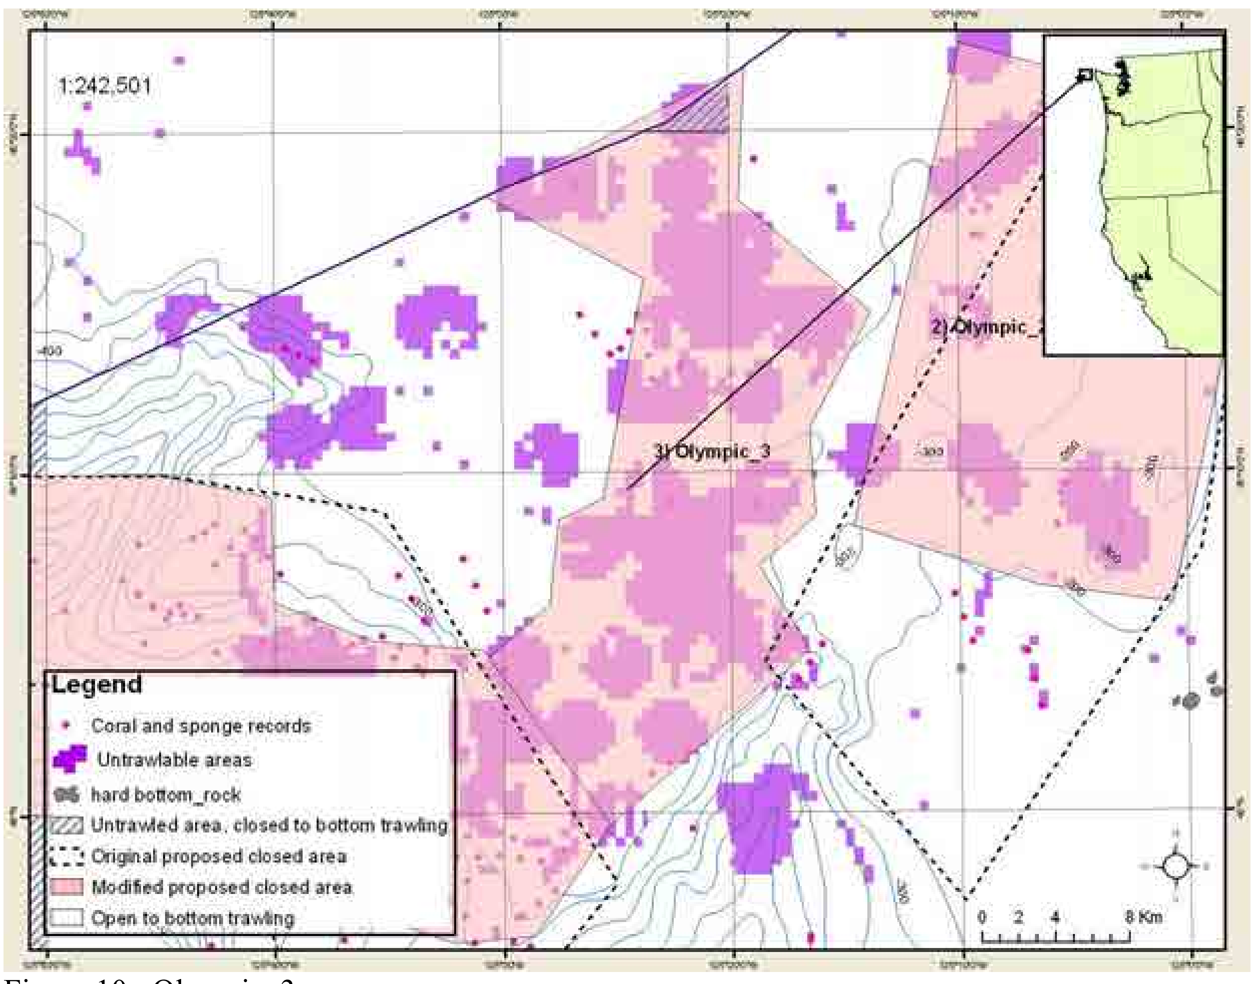

Figure 10: Olympic_3

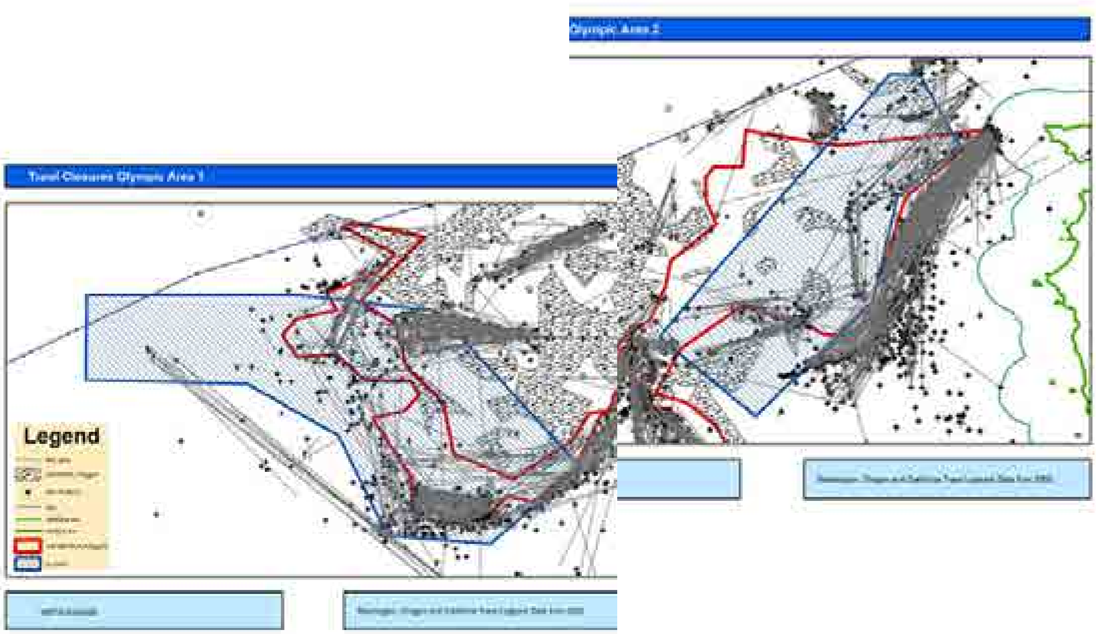

Figure C: 2003 bottom trawl logbook set points (courtesy WDF&W).

4. Biogenic_1

Original Alternative C.12 estimated displaced revenue= $172,849
Revised Alternative C.12 estimated displaced revenue= $36,486 (likely overestimated, trawl tracks fall outside of area, see Figure below)

Bottom trawl logbook data from 2003 indicates that bottom trawling mainly occurred in the eastern portion of the previously proposed closed area (Figure D). The boundary for the proposed closed area in Revised Alternative C.12 excludes this fished area (Figure 11). It is likely that the displaced revenue previously attributed to the closed area is mitigated by excluding that eastern portion. The new boundary also expands northward and deeper to include lightly fished and unfished areas, and include more records of habitat-forming invertebrates.

Every NOAA trawl survey haul performed in the proposed area has recorded the presence of habitat-forming invertebrates. NOAA slope surveys from 1992 onwards have documented 141 records of habitat-forming invertebrates in the proposed area including black corals, scleractinian corals, Hexactinellid sponges, bamboo corals, and sea whips. Records were more numerous and sample weights of sponges were larger in earlier surveys than more recent ones, which may indicate that habitat has been impacted.

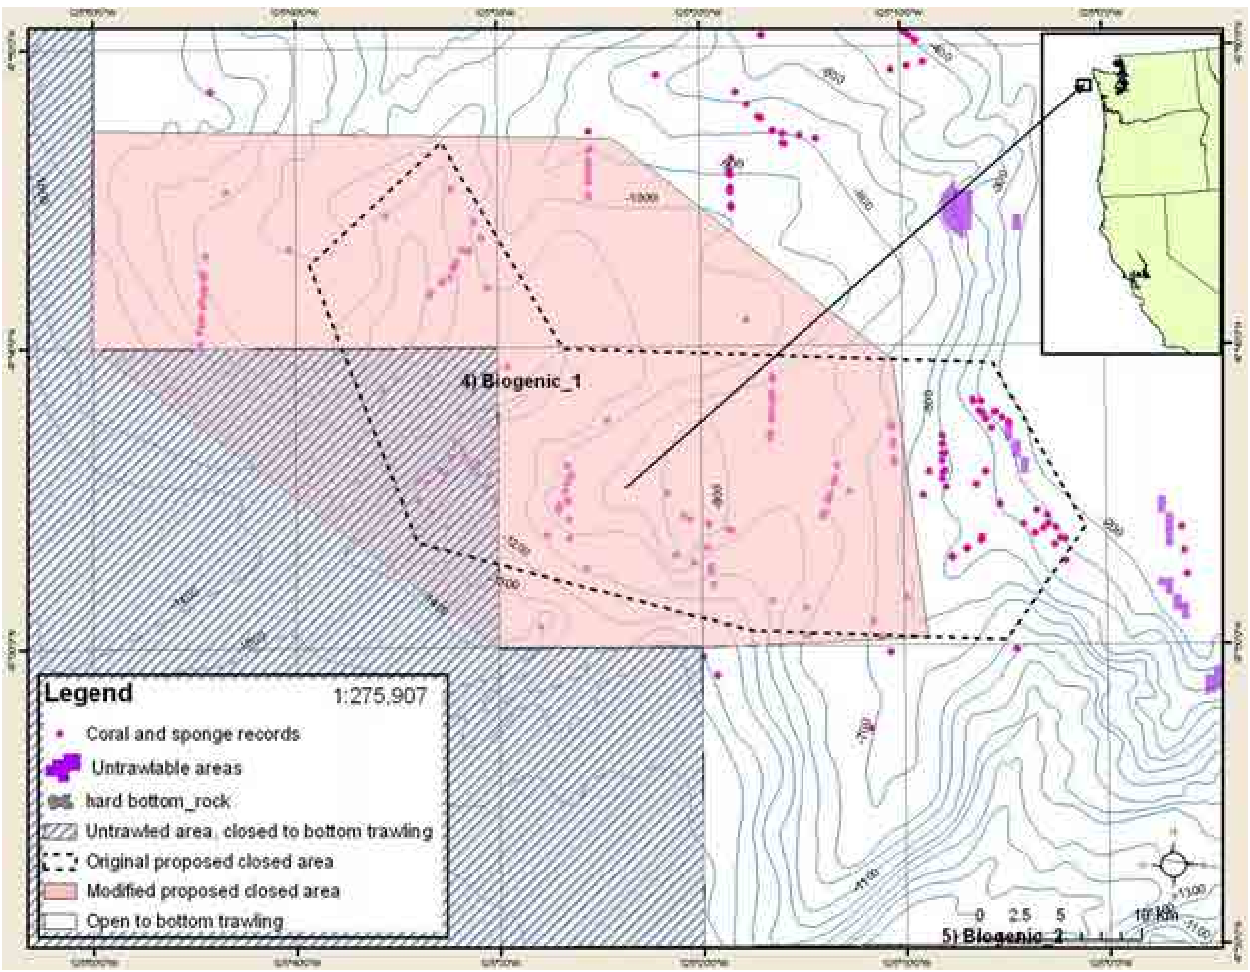

Figure 11: Biogenic_1

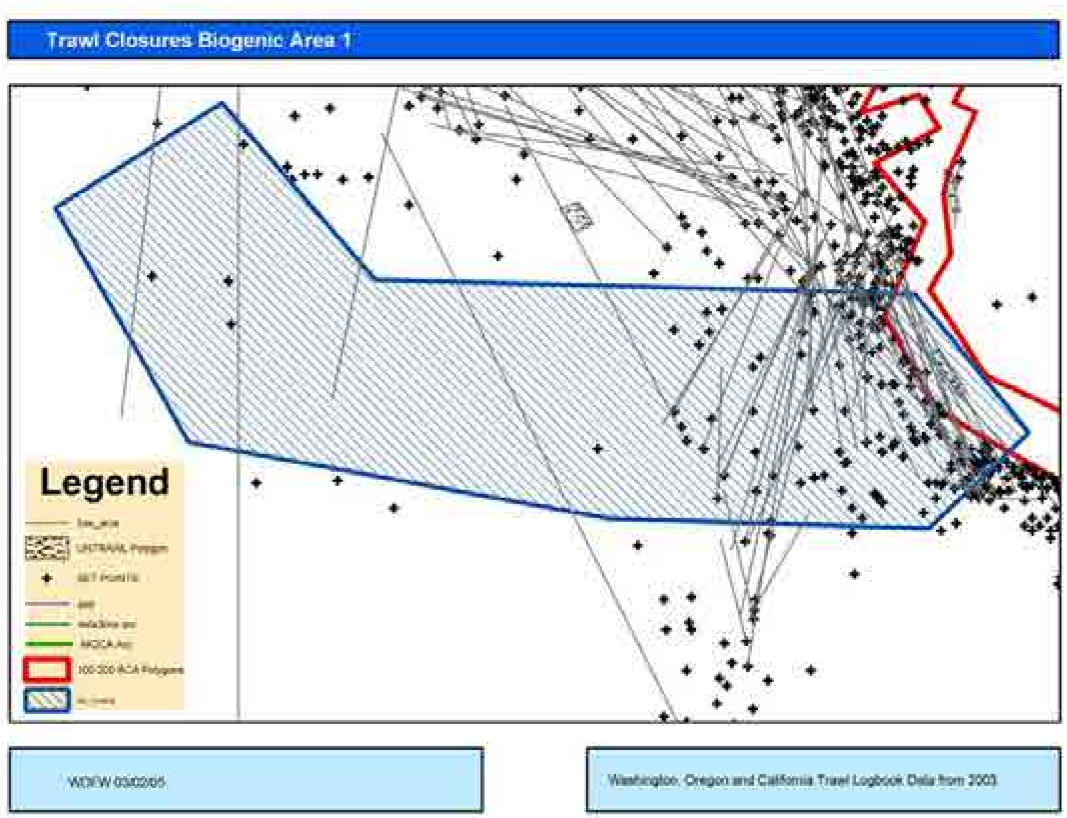

Figure D: 2003 bottom trawl logbook set points (courtesy WDF&W)

5. Biogenic_2
Original Alternative C.12 estimated displaced revenue= $31,982
Revised Alternative C.12 estimated displaced revenue= $15,483 (likely overestimated, trawl tracks fall outside of area, see Figure below)

Bottom trawl logbook data from 2003 indicates that bottom trawling occurred across a small eastern portion of the previously proposed closed area (Figure E). The Revised Alternative C.12 boundary for the proposed closed area excludes this fished area (Figure 12). The new boundary also extends north and south into unfished and lightly fished areas, as well as deeper to provide continuity with the area closed by freezing the trawl footprint.

Every NOAA trawl survey haul performed in the proposed area has documented the presence of habitat-forming invertebrates. NOAA trawl surveys have documented 64 records of habitat-forming invertebrates in the proposed closed area, including black corals, gorgonians, Hexactinellid sponges, and sea pens.

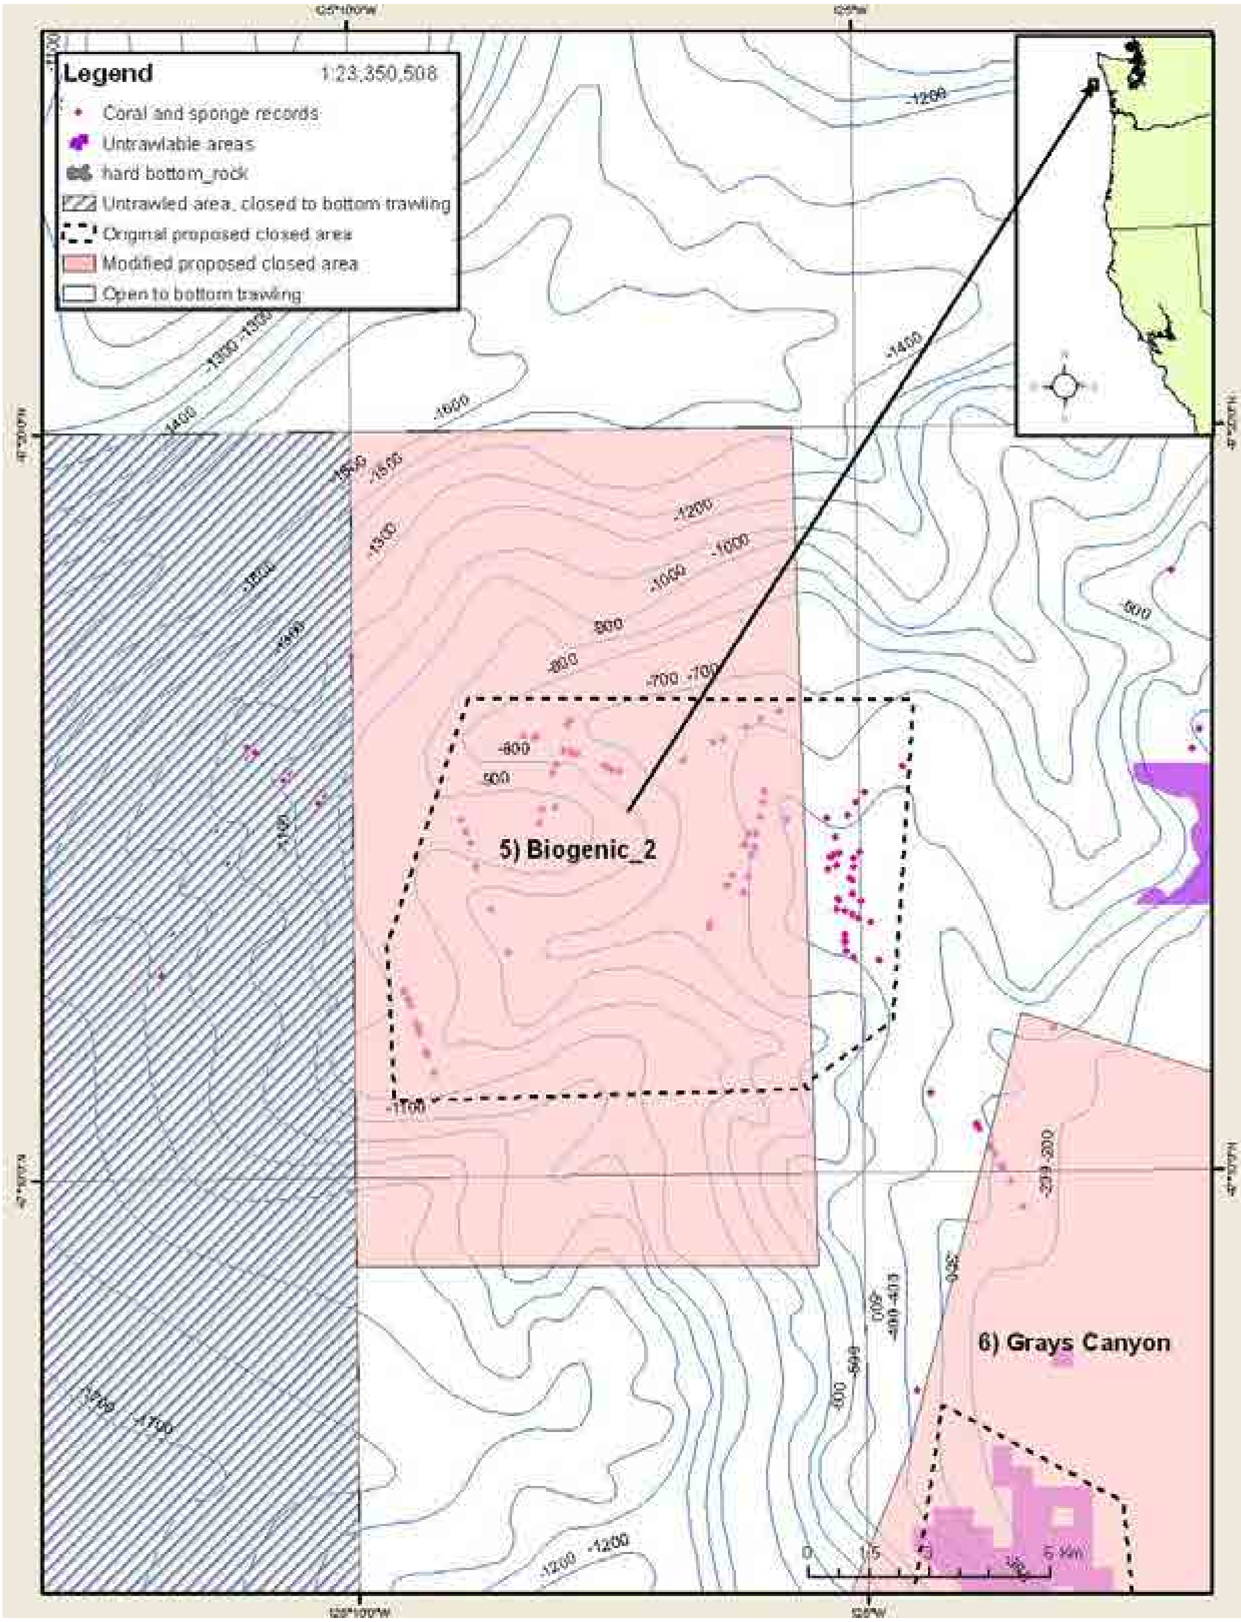

Figure 12: Biogenic_2

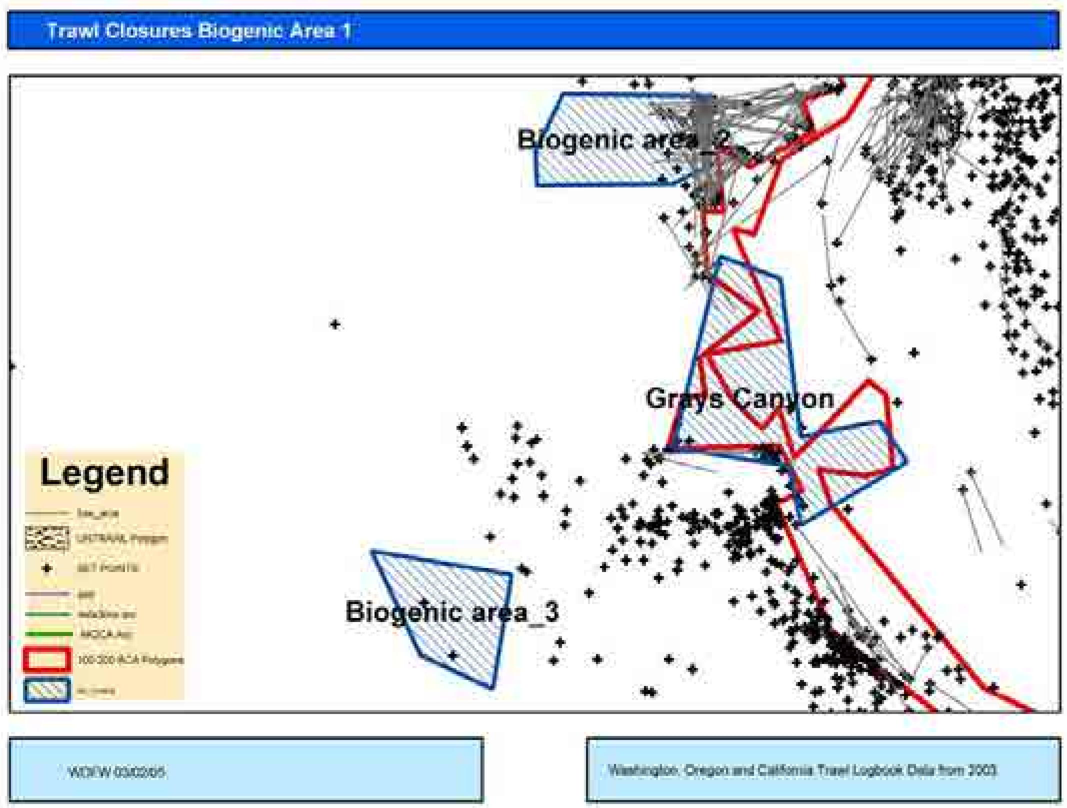

Figure E: 2003 bottom trawl logbook set points (courtesy WDF&W)

6. Grays Canyon

Original Alternative C.12 estimated displaced revenue= $5,917
Revised Alternative C.12 estimated displaced revenue= $34,512 (likely overestimated, trawl tracks fall outside of area, see Figure below)

This canyon was selected based on its high abundance of hard substrate and “untrawlable areas.” This site is known to have high upwelling and to be one of the most productive offshore sites off the Washington coast. It is also the site of major ecotourism and birdwatching operations.

Bottom trawl logbook data from 2003 indicates little bottom trawling occurred in the region of the proposed closed area (Figure E). The boundary for the Revised Alternative C.12 proposed closed area follows bathymetric contours and encompasses more of the canyon area (Figure 13).

Most NOAA trawl survey hauls in the proposed closed area documented habitat-forming invertebrates. There have been 48 records of black corals, gorgonian corals, scleractinian corals, and Hexactinellid sponges. In some cases, individual survey hauls recorded large densities of sponges, up to 907 kg per haul in 1985 and 505 kg per haul in 1983. There have been fewer records and lower sample weights of sponges in the more recent surveys, which may be an indication of adverse impacts of fishing on this habitat.

The proposed area contains 344 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the “untrawlable” polygons determined by Zimmerman (2003).

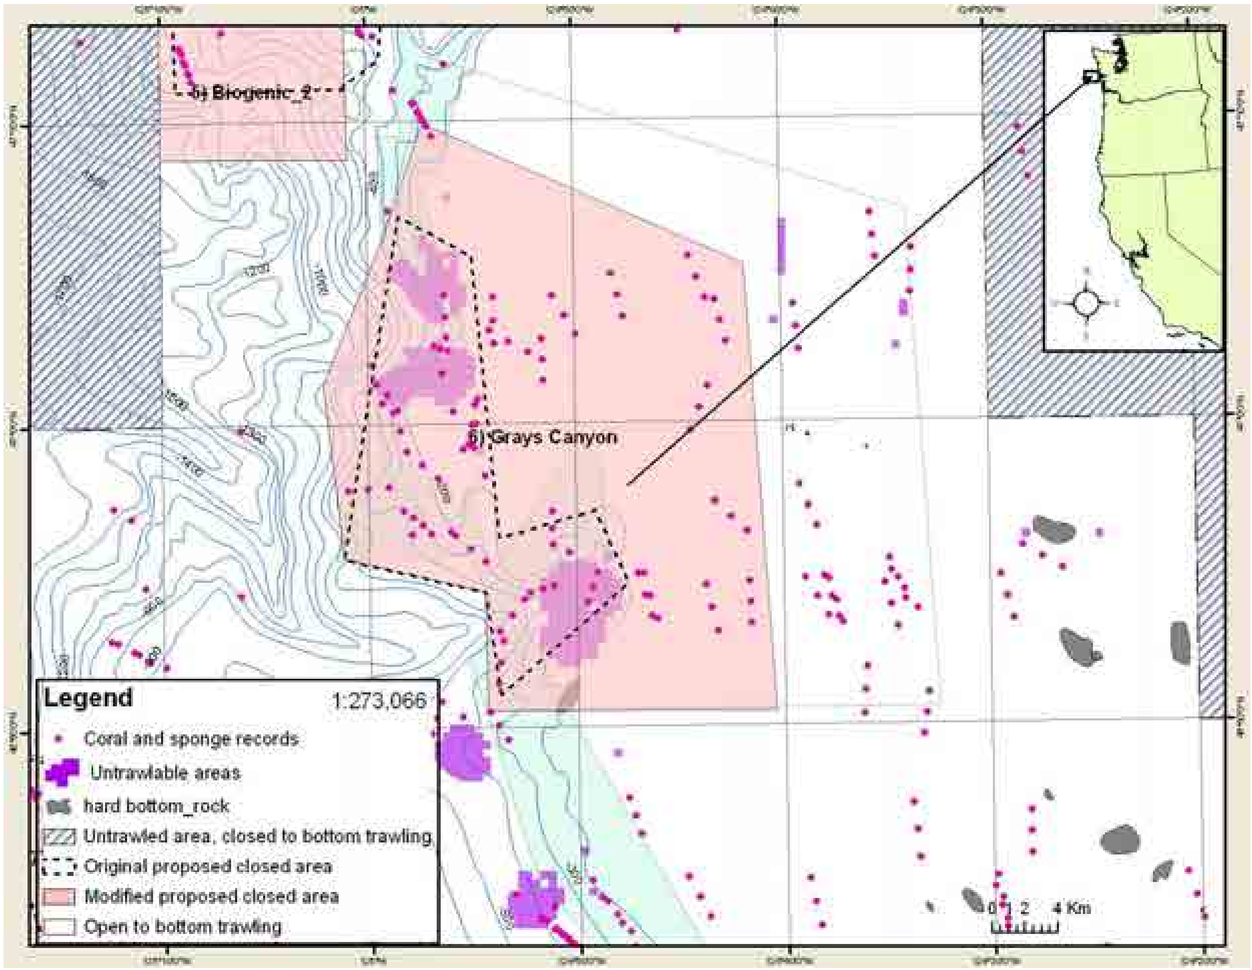

Figure 13: Grays Canyon

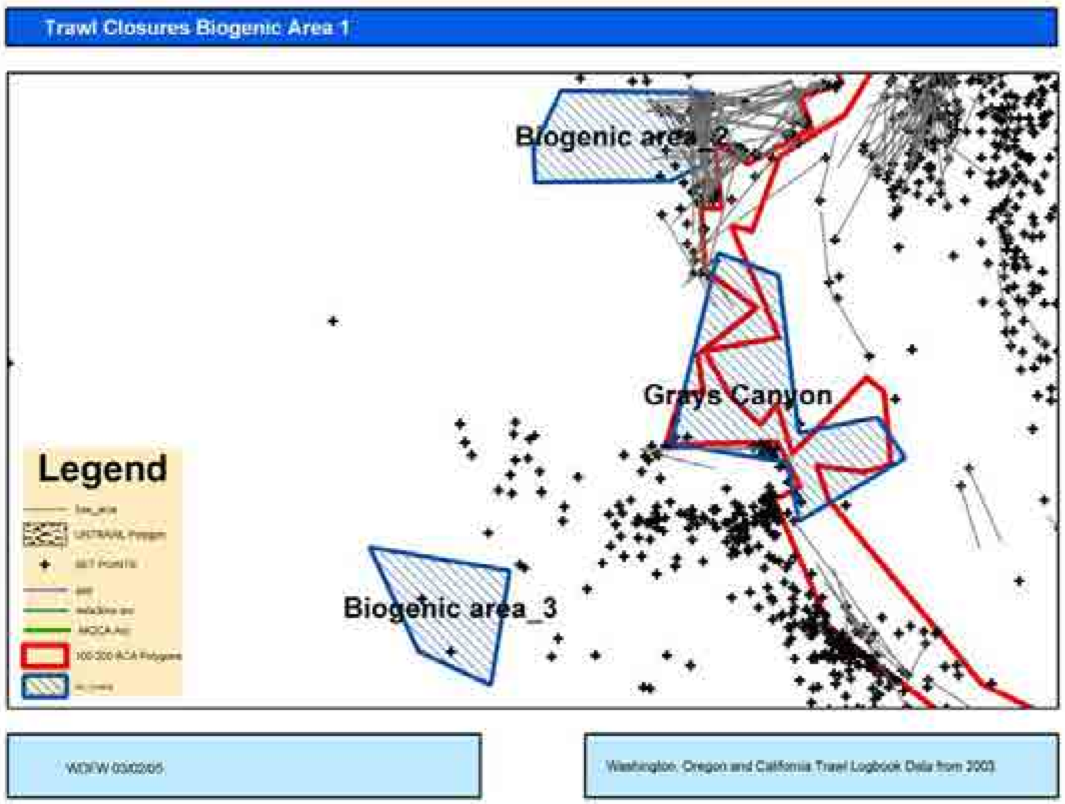

Figure E: 2003 bottom trawl logbook set points (courtesy WDF&W)

7. Biogenic_3

Original Alternative C.12 estimated displaced revenue= $2,351
Revised Alternative C.12 estimated displaced revenue= $4,554

According to trawl logbook data, little bottom trawling occurred in 2003 in the proposed closed area (Figure E). The boundary of the proposed area was expanded to provide continuity with areas closed by freezing the trawl footprint (Figure 14). The proposed closure spans an area of the slope from 900 to 1600 meters depth.

Every NOAA trawl survey haul performed within the proposed area has documented habitat-forming invertebrates. NOAA trawl surveys have documented 46 records of habitat-forming invertebrates within the proposed area, including black corals, gorgonian corals, sea whips, and sponges.

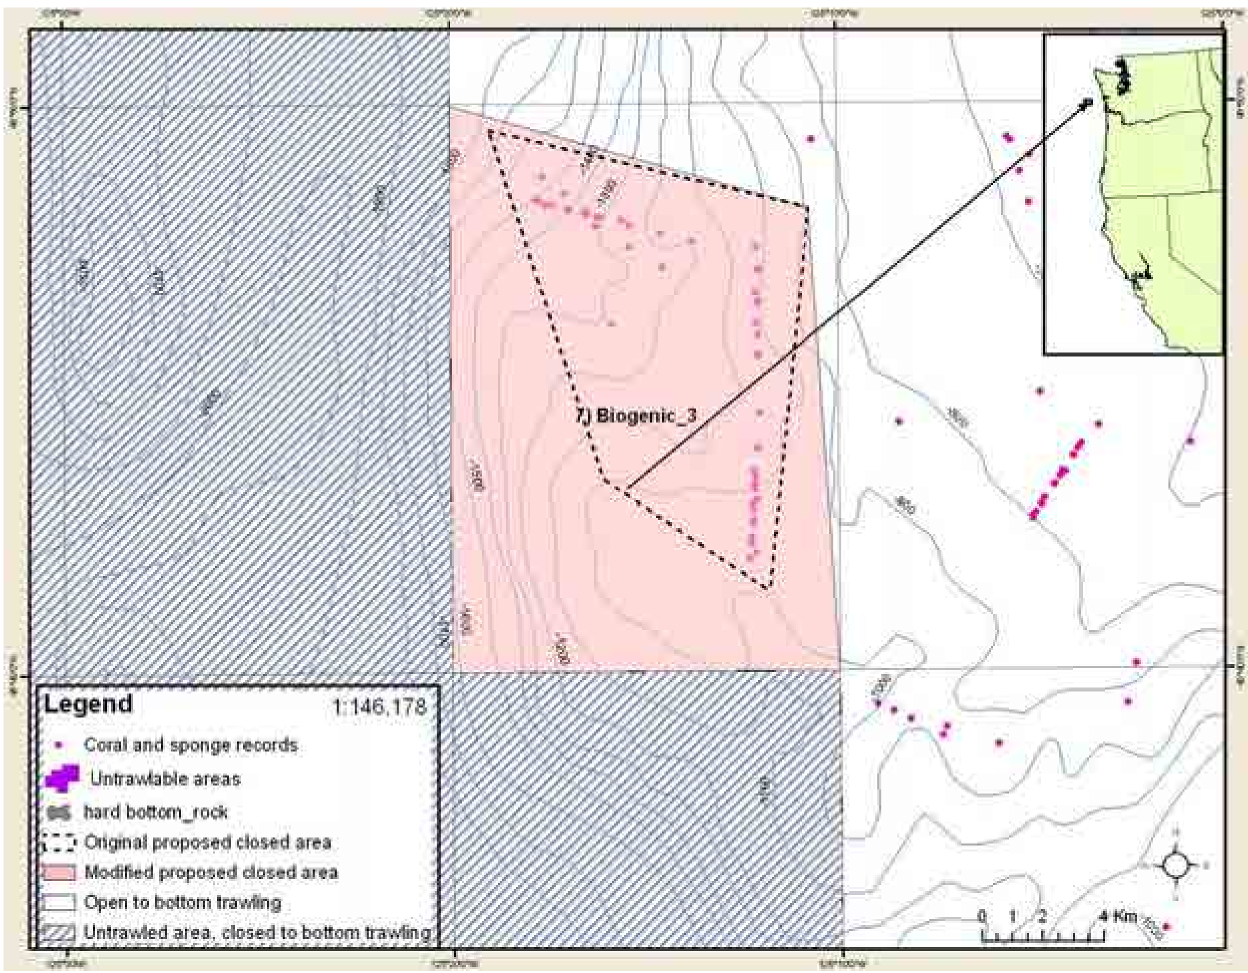

Figure 14: Biogenic_3

8. & 9. Astoria Canyon Region

Original Alternative C.12 estimated displaced revenue= $509,857
Revised Alternative C.12 estimated displaced revenue= $108,154 (likely overestimated, trawl tracks fall outside of area, see Figure below)

The largest submarine canyon in the Pacific Northwest is Astoria Canyon, off the mouth of the Columbia River. This canyon contains a range of habitat types from sand and mud bottom to hard rock canyon walls. There are several records of biogenic habitats in this canyon from the NMFS dataset (Clarke 2004). This canyon has been studied using ROPOS submersibles.

According to analysis of trawl logbook data by the WDF&W, a significant amount of bottom trawl catches were made 2003 in the previously proposed closed area encompassing Astoria Canyon (Figure F). We attempted to mitigate displaced catches by splitting the previously closed area of Astoria Canyon into two areas while avoiding fishing areas identified by WDF&W's logbook analyses (Figure 15).

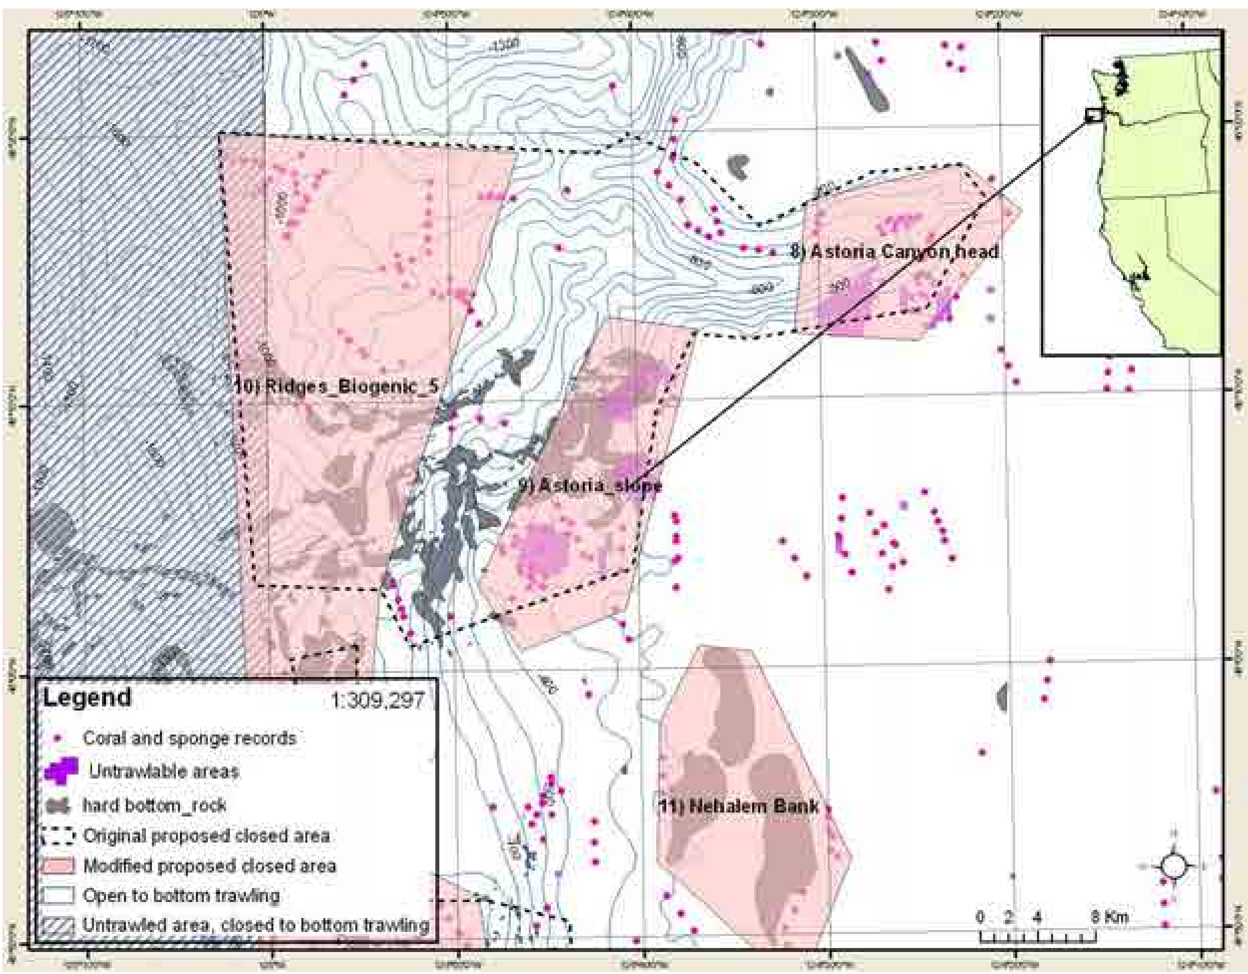

Figure 15: Astoria Canyon_head and Astoria_slope

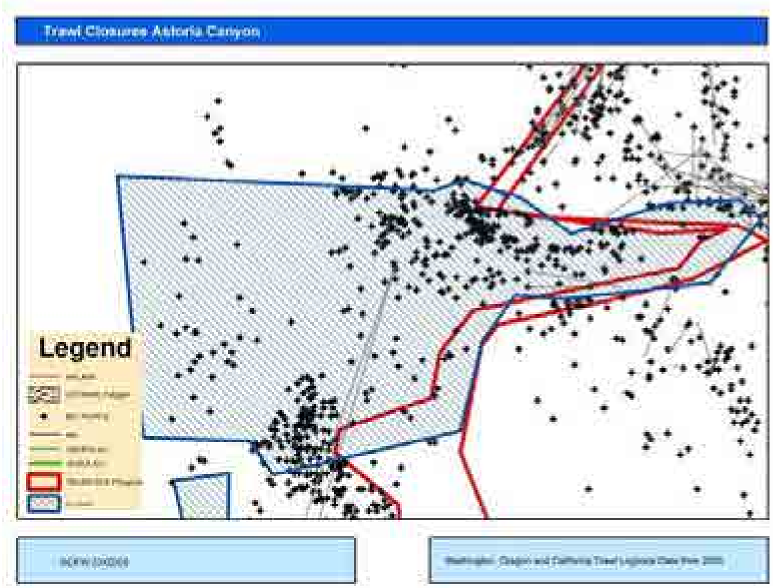

Figure F: 2003 bottom trawl logbook set points (courtesy WDF&W)

8. Astoria Canyon head

This area encompasses the head of the deepwater Astoria Canyon. Areas of untrawlable habitat (17.5 km^2) and habitat-forming invertebrates are located within the Revised Alternative C.12 proposed closed area (Figure 15). The proposed area contains 108 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). Habitat-forming invertebrates were documented in 10 of 33 NOAA trawl survey hauls in the proposed closed area of the Astoria Canyon head. The largest sample weights of sponges and scleractinian corals occurred in the 1980's. The area spans canyon habitat from 200 to 500 meters depth.

9. Astoria Canyon slope

Areas of untrawlable habitat (31.8 km^2) and habitat-forming invertebrates are located within the Revised Alternative C.12 proposed closed area (Figure 15). Habitat-forming invertebrates were documented in 14 of 21 NOAA trawl survey hauls in the proposed closed area, and include records of sea pens, sea whips, and Hexactinellid sponges. The proposed area contains 170 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). The area spans habitats from 200 to 800 meters depth.

10. Ridges_biogenic_5

Original Alternative C.12 estimated displaced revenue= $189,585
Revised Alternative C.12 estimated displaced revenue= $136,537 (likely overestimated, trawl tracks fall outside of area, see Figure below)

Trawl logbook data indicates bottom trawl activity in the eastern portion of the previously proposed closed area (Figure G). The boundary in Revised Alternative C.12 excludes this area of fishing and expands over lightly fished area to be continuous with the area closed by the trawl footprint and the Astoria canyon closure above (Figure 16).

The proposed closed area contains habitat-forming invertebrates. NOAA trawl survey hauls have documented 118 records of habitat-forming invertebrates in the proposed closed area, and up to 249 kg of sponges per survey haul. Black corals, sea pens, sea whips, and sponges have been documented here.

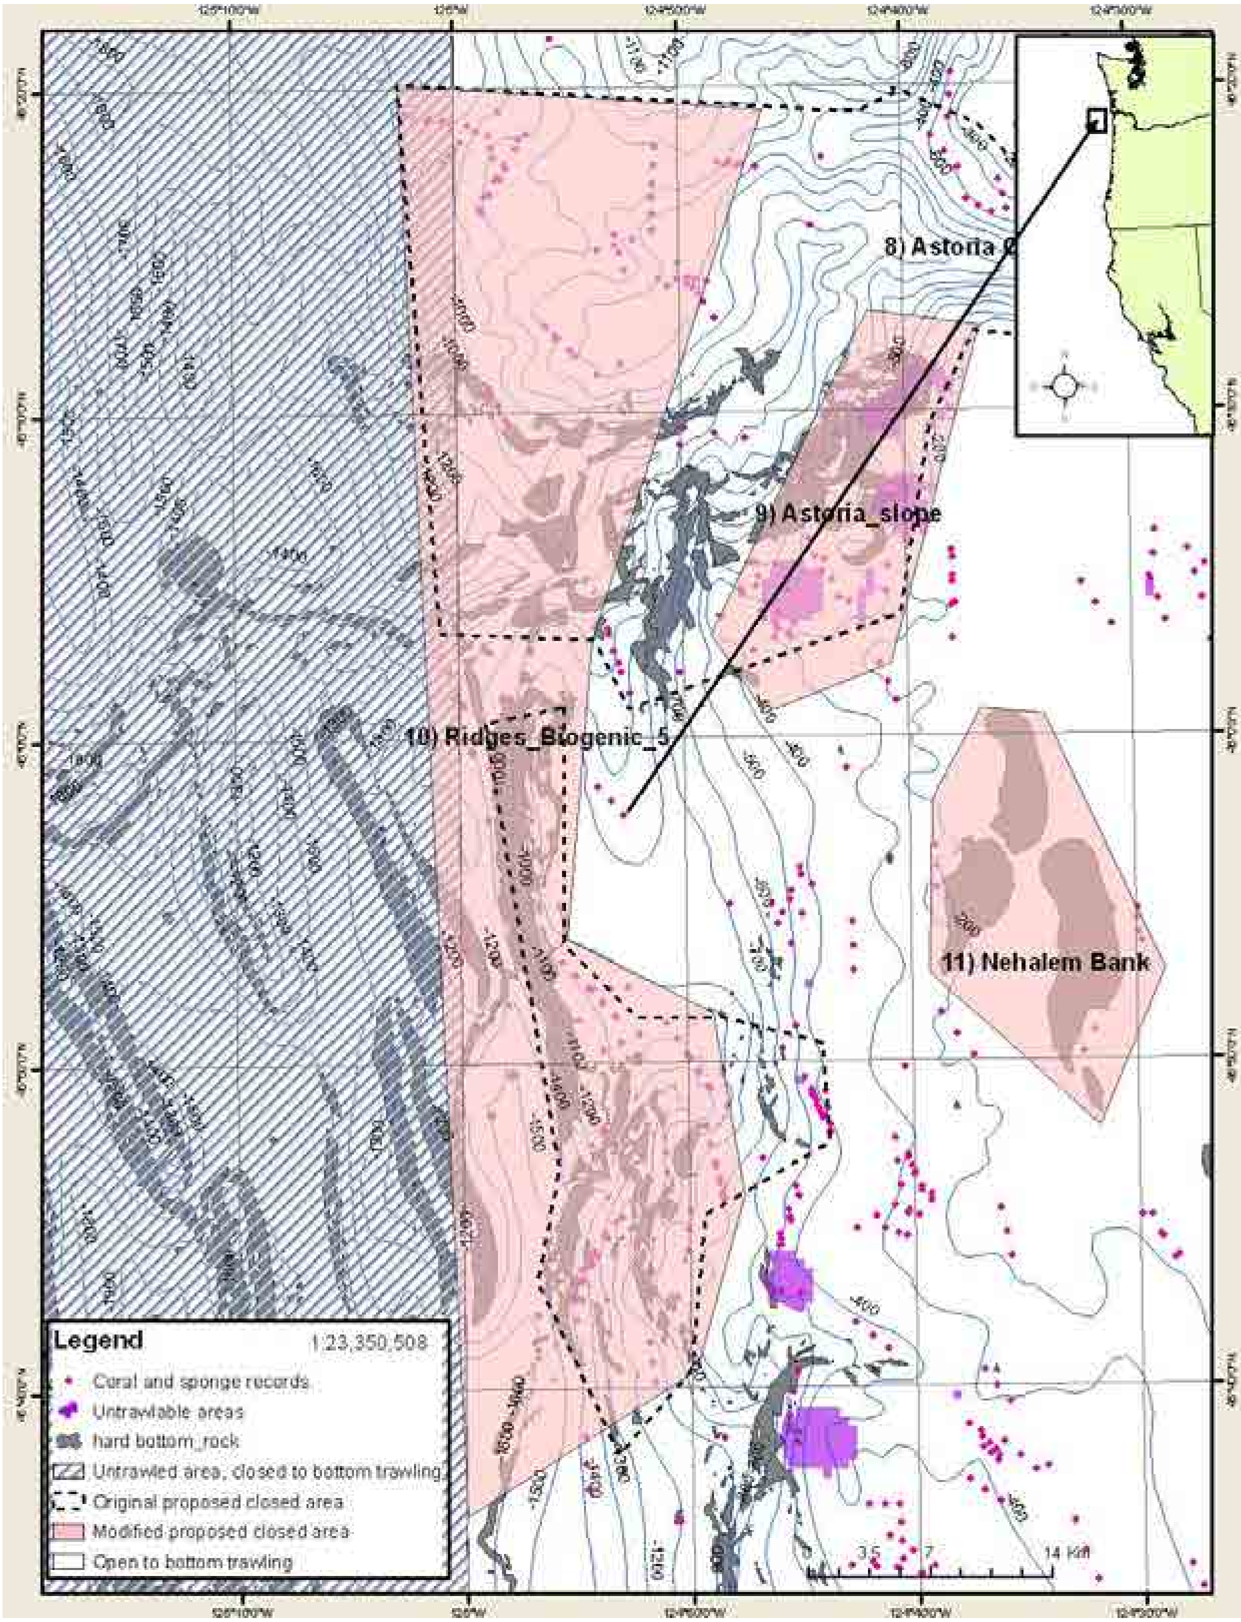

Figure 16: Ridges_biogenic_5

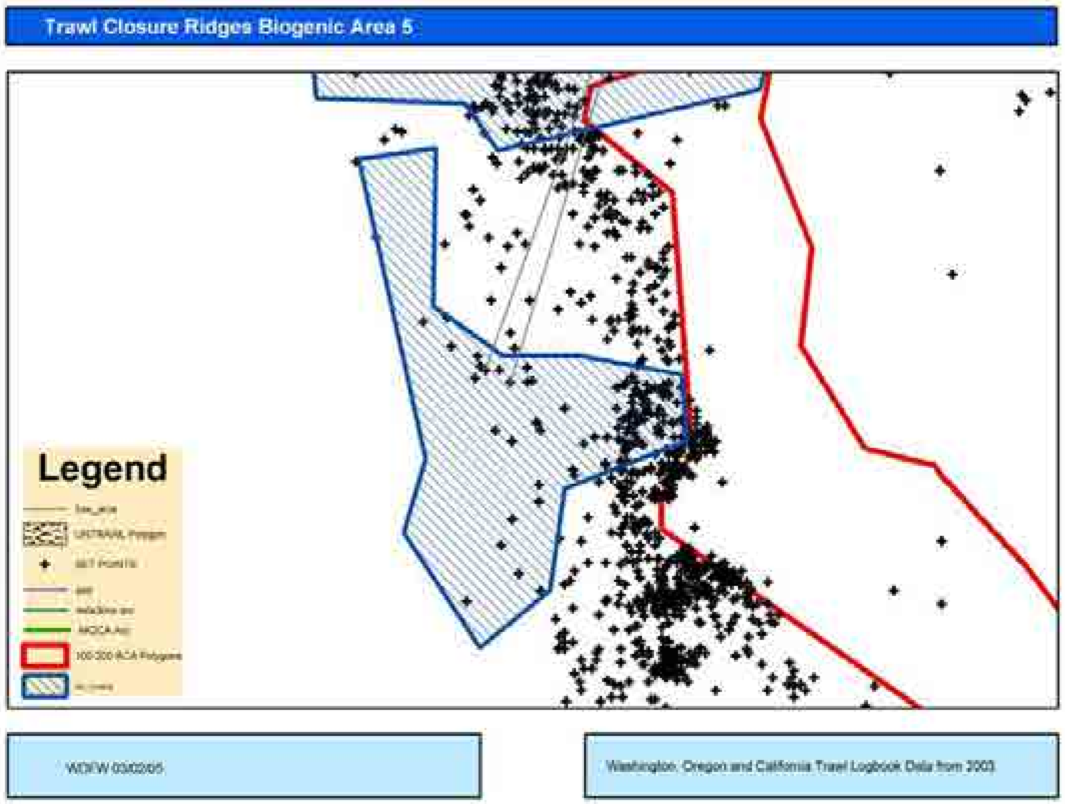

Figure G: 2003 bottom trawl logbook set points (courtesy WDF&W)

11. Nehalem Bank
Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $8,824 (likely overestimated, trawl tracks fall outside of area, see Figure below)

These rocky banks are 23 offshore of the Oregon coast (Figure 17). Marine nautical charts designate the features as rocky shale. The area has not been well sampled by NOAA trawl surveys, but 4 records of habitat-forming invertebrates (sponges and sea pens) have been recorded in the area. In the past, these banks were trawled upon by commercial fishing boats. Since trawl footrope restrictions were enacted in 2000, much less trawl effort has focused on the banks (Figure H) (Bellman and Hepel 2004). However, logbook information indicates that the occasional trawl was set on the bank even while footrope restrictions were in place (Figure H). Closing these banks to trawling would allow for recovery of previously impacted habitat, and prevent the occasional trawl set from compromising habitat recovery. Little current bottom trawl effort would be displaced by this proposed closure.

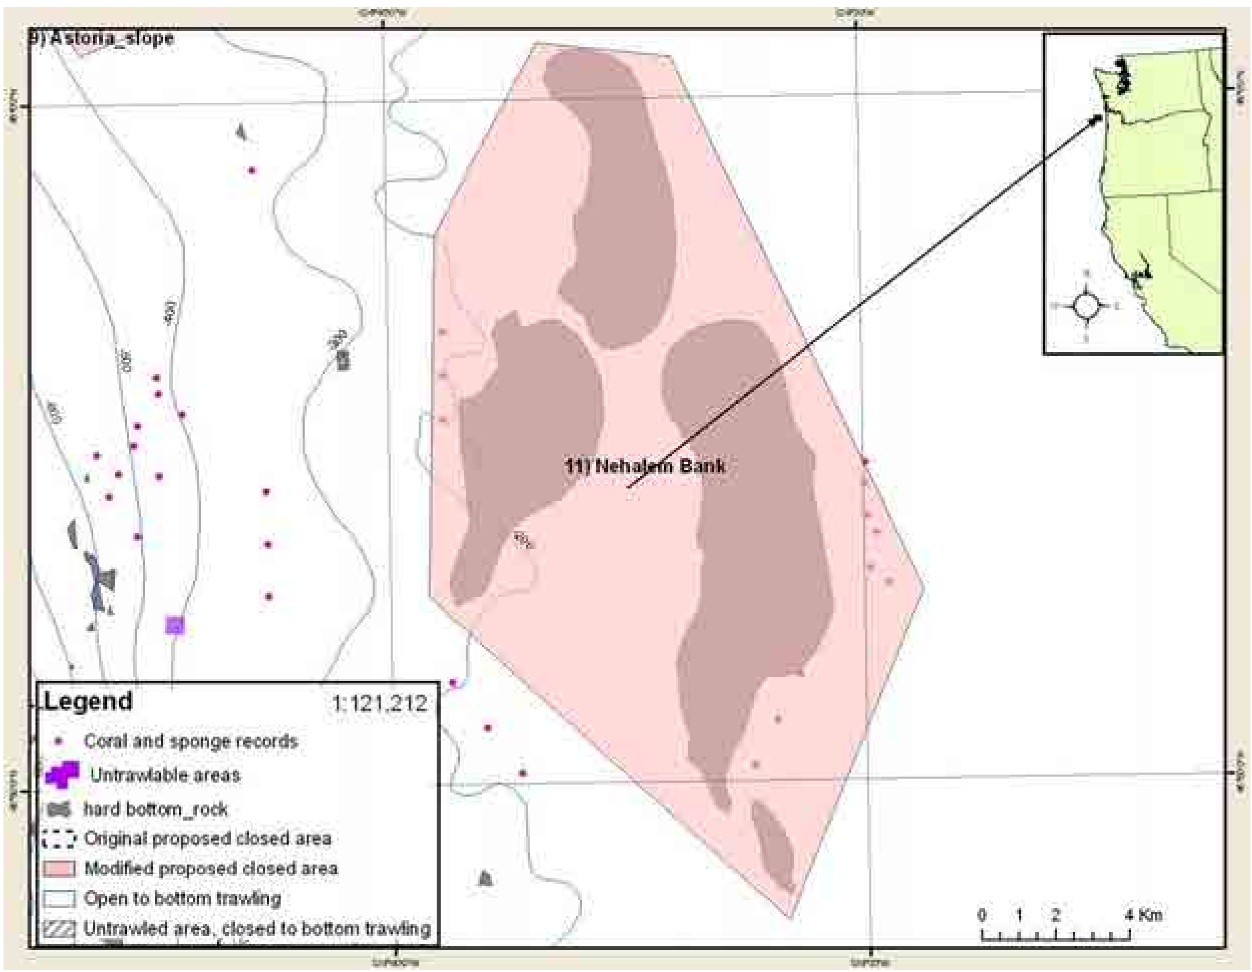

Figure 17: Nehalem Bank

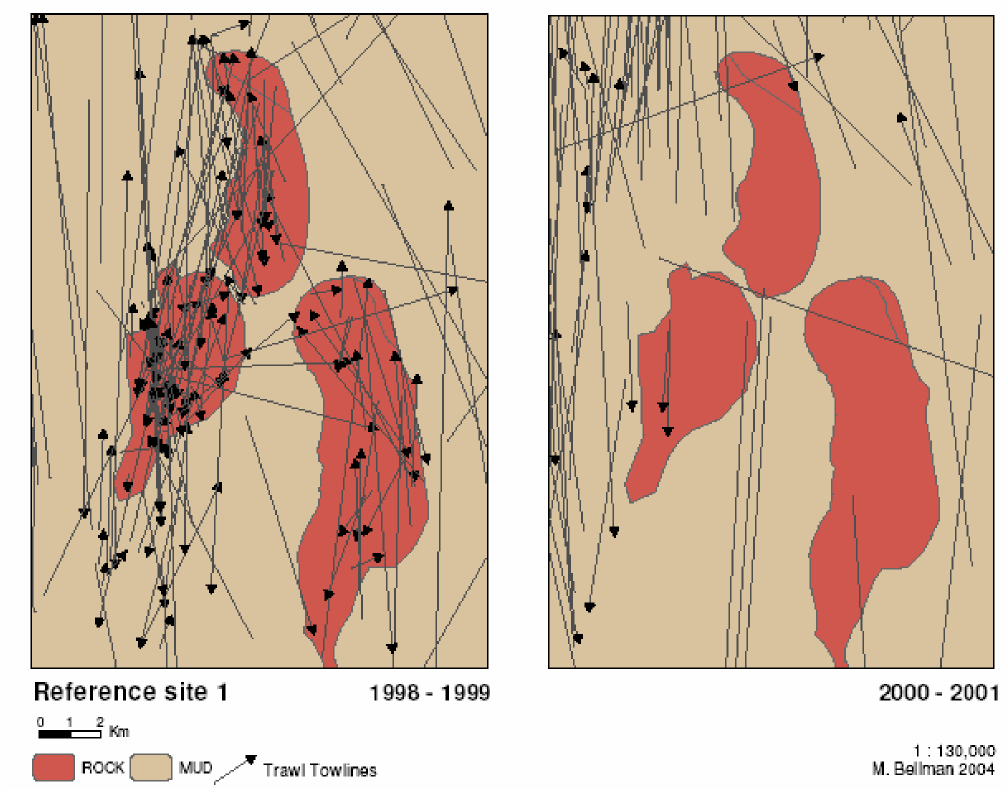

Figure H: Nehalem Bank reference site showing trawl logbook set and haul points prior to and following footrope restrictions (Bellman and Heppel 2004).

12. Biogenic_new_1

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $69,960

This area contains spans habitat from 400 to 600 meters depth and contains records of habitat-forming invertebrates (Figure 18). NOAA trawl surveys have documented 77 records of habitat-forming invertebrates in the proposed closed area, including sponges, sea whips, sea pens, and gorgonian corals. Every trawl survey haul performed in the area has documented habitat-forming invertebrates. Trawling that has occurred in the area has impacted habitat. Data from the West Coast Observer Program in the area noted a mean of 105 pounds of corals and sponges per haul in commercial bottom trawl hauls where corals or sponges were observed as bycatch.

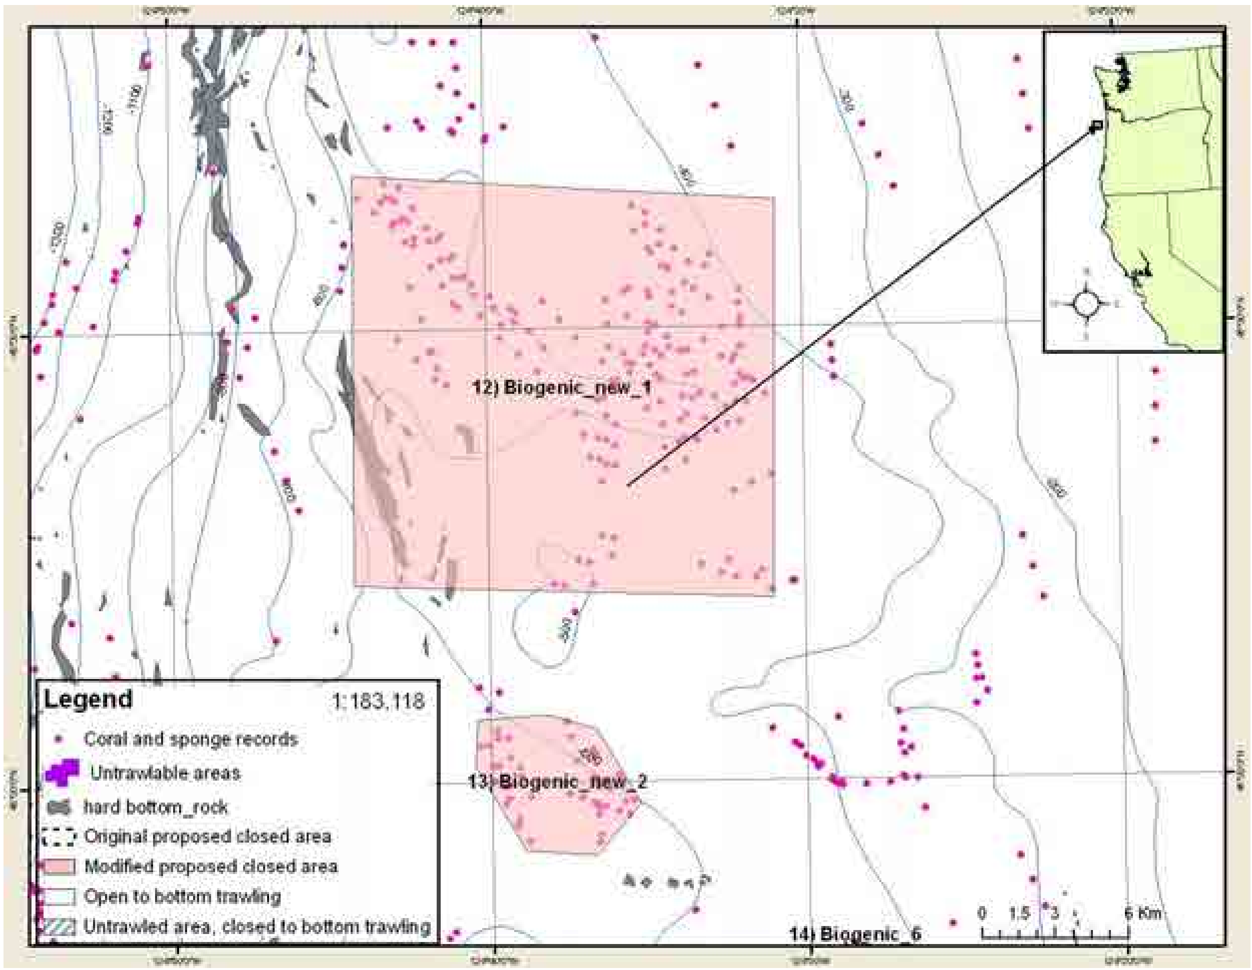

Figure 18: Biogenic_new_1 and Biogenic_new_2

13. Biogenic_new_2

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $5,969

This area is located at 500 meters depth and contains records of habitat-forming invertebrates (Figure 18). Every NOAA trawl survey haul in the proposed area has recorded habitat-forming invertebrates. NOAA trawl surveys have documented 26 records of habitat-forming invertebrates in the proposed area, and up to 118 kg (260 lbs) of sponges per survey haul.

14. Biogenic area_6

Original Alternative C.12 estimated displaced revenue= $3,585
Revised Alternative C.12 estimated displaced revenue= $29,402 (likely overestimated, trawl tracks fall outside of area, see Figure below)

Analysis of trawl logbook data from 2003 indicated that little bottom trawling activity occurred in the vicinity of the proposed area (Figure I). As such, the boundaries of the proposed area were expanded in Revised Alternative C.12 to include more records of habitat-forming invertebrates (Figure 19).

This area contains habitat conducive to the growth of Hexactinellid sponges. NOAA trawl surveys have documented 25 records of habitat-forming invertebrates in the proposed area, and particularly dense records of sponges. Survey hauls have documented up to 312 kg (686 lbs) of sponges per haul in 1988, 281 kg (618 lbs) per haul in 1984, and 226 kg (497 lbs) per haul in 1977. Survey hauls in 2001, however, recorded a maximum of 22 kg (48 lbs) of sponges per haul, which may indicate habitat degradation in recent years that needs to be mitigated. Data from the West Coast Observer program in the proposed area noted a mean of 103 pounds of corals and sponges per haul in commercial bottom trawl hauls where corals or sponges were observed as bycatch (NWFSC, unpublished data).

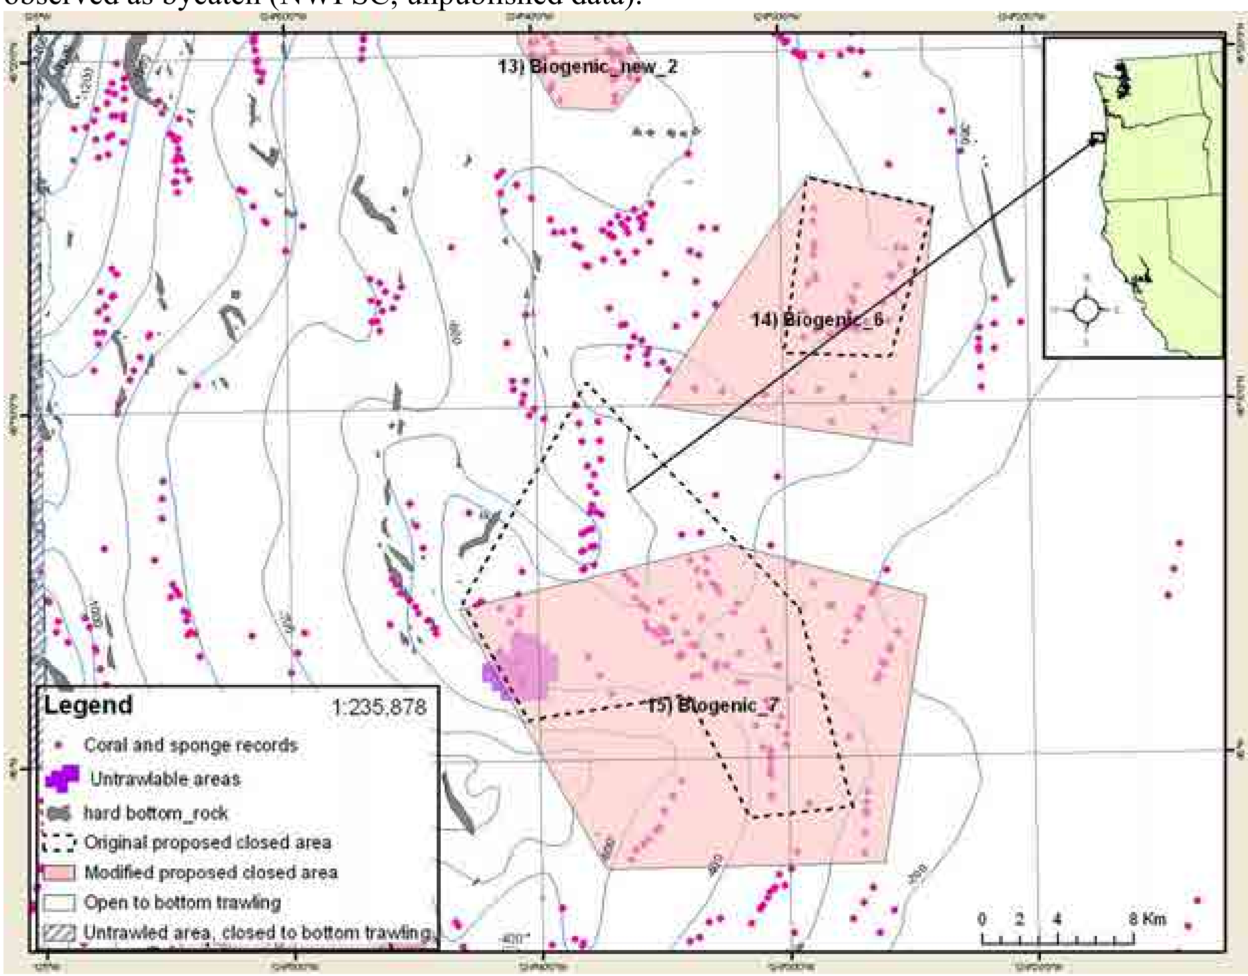

Figure 19: Biogenic area_6 and Biogenic area_7

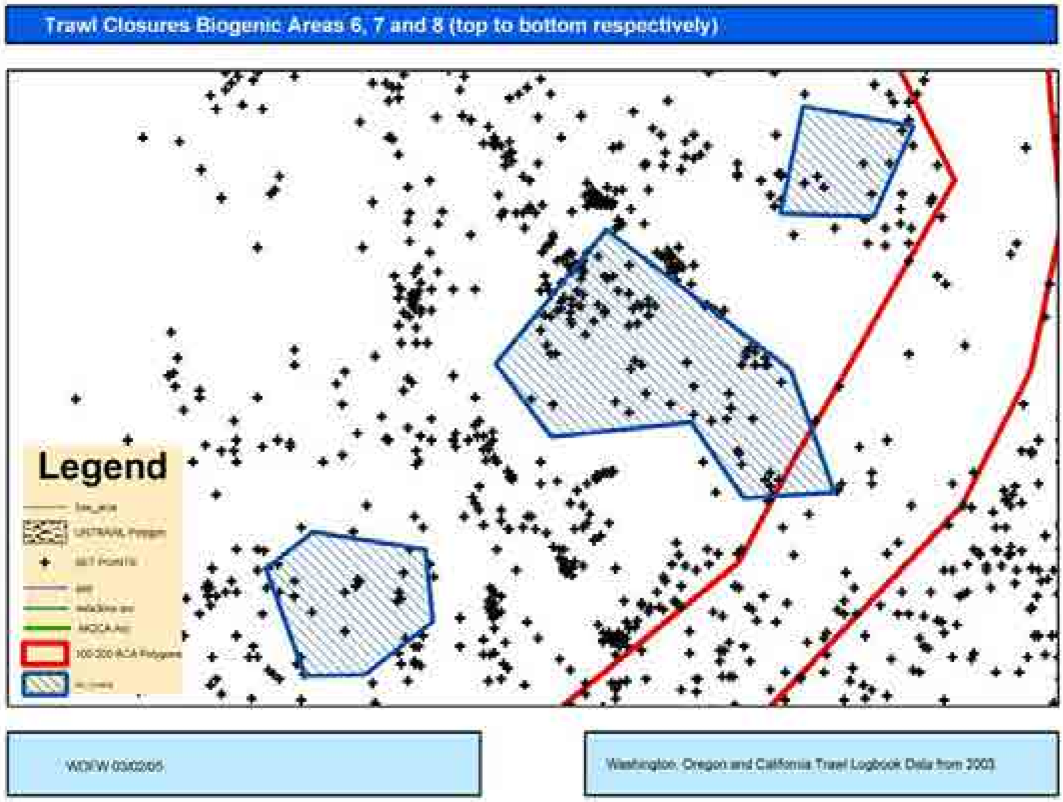

Figure I: 2003 bottom trawl logbook set points (courtesy WDF&W)

15. Biogenic area_7

Original Alternative C.12 estimated displaced revenue= $76,470
Revised Alternative C.12 estimated displaced revenue= $91,908 (likely overestimated, trawl tracks fall outside of area, see Figure I above)

Analysis of trawl logbook data from 2003 indicates some bottom trawl effort occurred in the northern portion of the proposed area and little activity south and east of the area (Figure I). The boundaries of Revised Alternative C.12 exclude the fishing area in the northern portion, and expand south and east to include more records of habitat-forming invertebrates in the less trawled area (Figure 19).

NOAA trawl surveys have documented 73 records of habitat-forming invertebrates in the proposed area, including dense records of sponges. Survey hauls documented up to 1,274 kg (2,803 lbs) of sponges per haul in 1988 and 334 kg (735 lbs) of sponges per haul in 1996. Survey hauls in 2001 recorded a maximum of 61 kg (134 lbs) of sponges per haul, which may indicate habitat degradation in recent years. Data from the West Coast Observer Program in the proposed area noted a mean of 304 pounds per haul in commercial bottom trawl hauls where corals or sponges were observed as bycatch (NWFSC, unpublished data).

The proposed area contains 40 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003).

16. Biogenic area_8

Original Alternative C.12 estimated displaced revenue= $36,172
Revised Alternative C.12 estimated displaced revenue= $41,852 (likely overestimated, trawl tracks fall outside of area, see Figure I above)

The boundaries of the proposed closed area in Revised Alternative C.12 expand northward to include more records of habitat forming invertebrates (Figure 20). Trawl logbook information indicated little activity in the area (Figure I). Every NOAA trawl survey haul in the proposed area has documented habitat-forming invertebrates, including gorgonian corals, sea pens, and Hexactinellid sponges. A total of 51 records of habitat-forming invertebrates have been documented in the proposed area, with up to 160 kg (352 lbs) of sponges per haul.

The proposed area contains 40 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003).

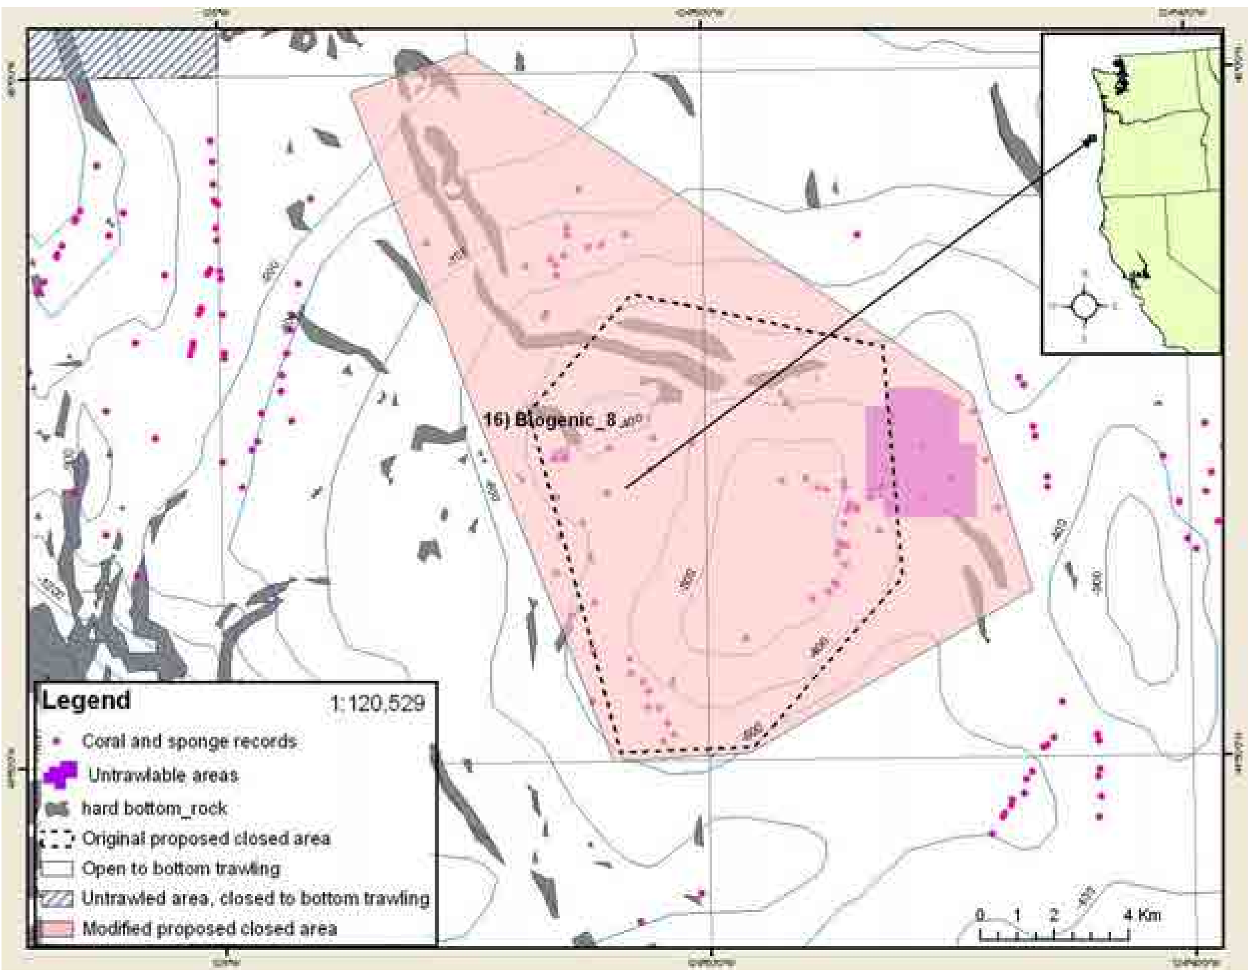

Figure 20: Biogenic area_8

17. Siletz Reef

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $132

Siletz Reef is a rocky reef located within the 3 nm Oregon state waters boundary (Figure 21). While it is unlikely that this reef is targeted by bottom trawl fishermen, the 2000-2003 bottom trawl logbook data indicated that the northern portion of the reef fell within the bottom trawl footprint. Part of the reef is known locally as "Tacklebuster Reef" as massive rock structures easily snag fishing gear. Depths range from 10-45 meters with vertical relief at the northern end punctuated by dramatic, massive structures up to 20m high and tens of meters across.

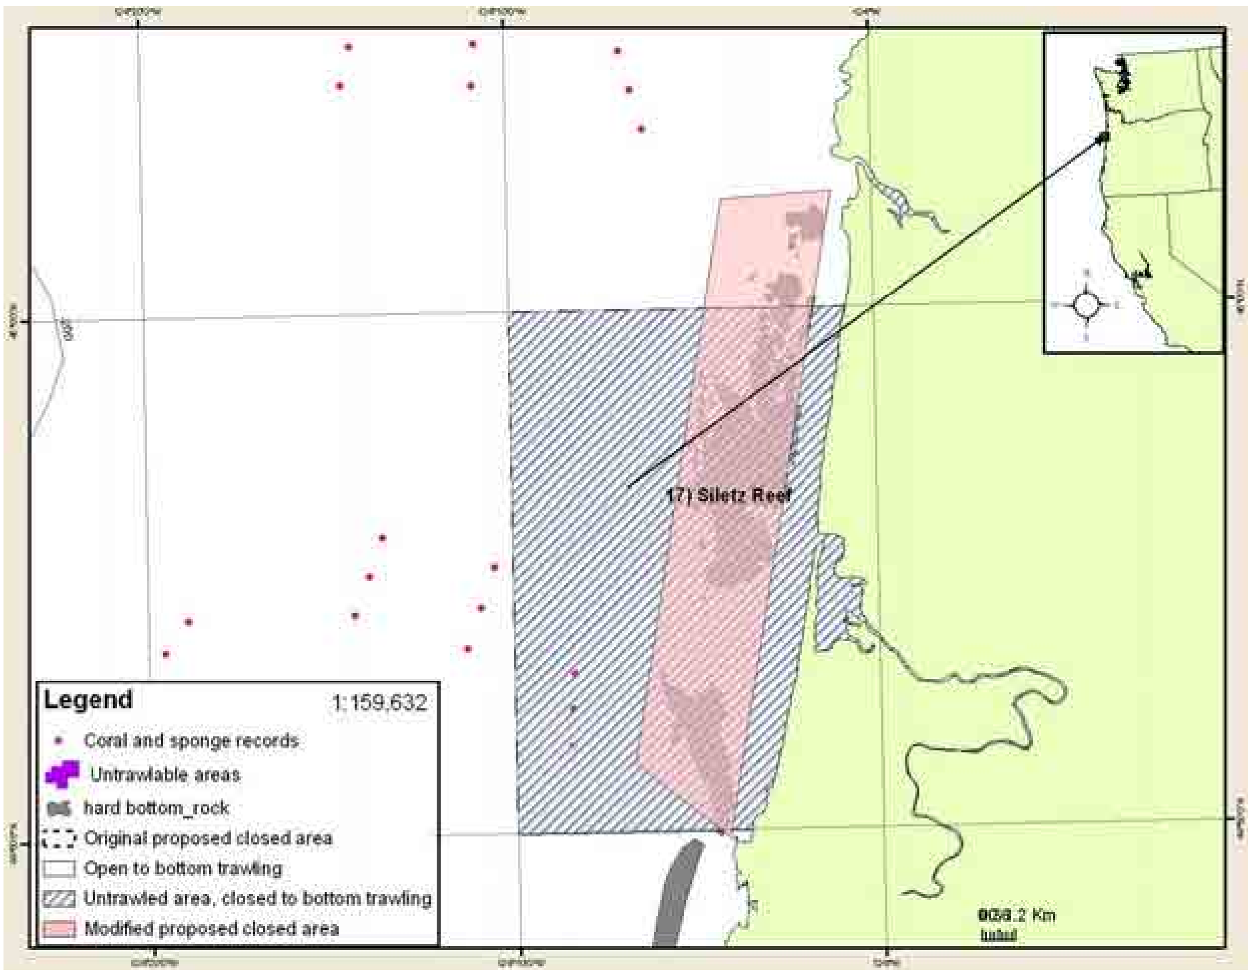

Figure 21: Siletz Reef

18. Daisy Bank

Original Alternative C.12 estimated displaced revenue= $0
Revised Alternative C.12 estimated displaced revenue= $11,768 (likely overestimated, trawl tracks fall outside of area, see Figure J below)

Daisy Bank, a 100 km^2 area north of Heceta Bank, has been less heavily fished and is also comprised largely of hard bottom habitat (Figure 22). Hixon (1991) documented large sponge beds on this bank. Since it is less heavily fished than Heceta Bank, a larger portion of Daisy Bank can be protected from bottom trawling with fewer negative impacts.

NOAA trawl surveys have documented 7 records of habitat forming invertebrates on the bank, including sponges, black coral, and scleractinian coral. However, the bank is not easily sampled with trawl gear. The proposed area contains 15 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). The bank has been explored with submersible and video; Hixon et al. (1990) observed sponges to be prevalent on Daisy Bank, with some over a meter tall. Daisy bank is currently located within the fishery closures associated with the Rockfish Conservation Area, yet some trawl setpoints in 2003 did approach the bank (Figure J).

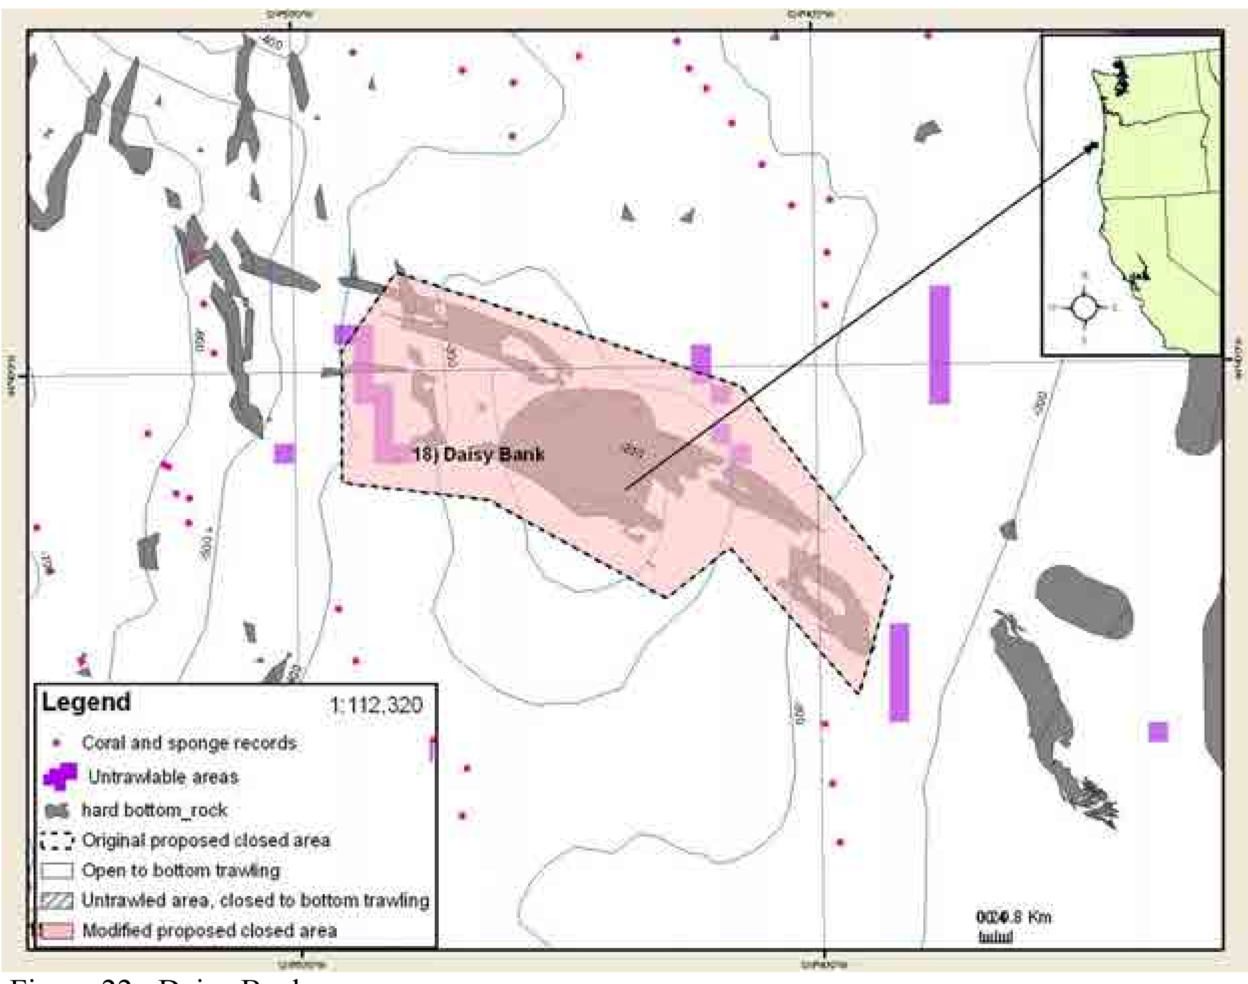

Figure 22: Daisy Bank

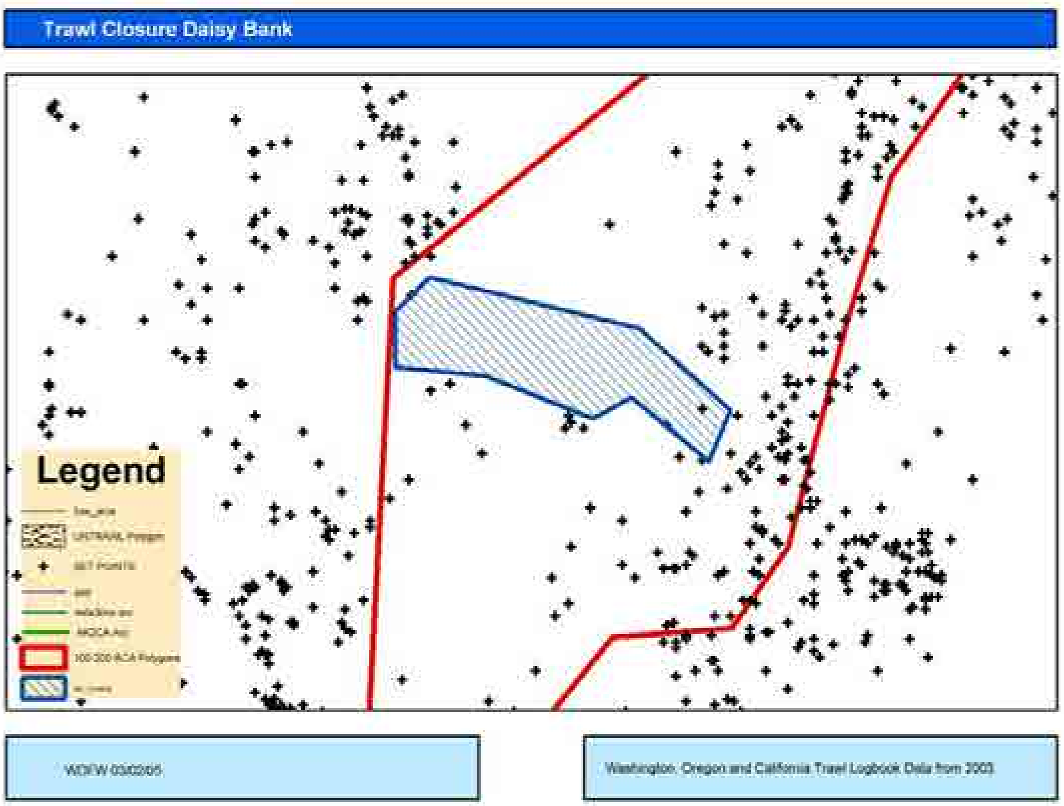

Figure J: 2003 bottom trawl set points from logbook data compiled by WDF&G

19. Biogenic_new 3

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $70,573

This area contains records of biogenic habitat (Figure 23). NOAA trawl surveys have documented 39 records of habitat-forming invertebrates in the proposed closed area, including black corals, gorgonian corals, sea whips, sea pens, and sponges. Sampling by the West Coast Observer program indicates that the area contains records where up to 211 pounds of corals or 55 pounds of sponges were recorded as bycatch per haul.

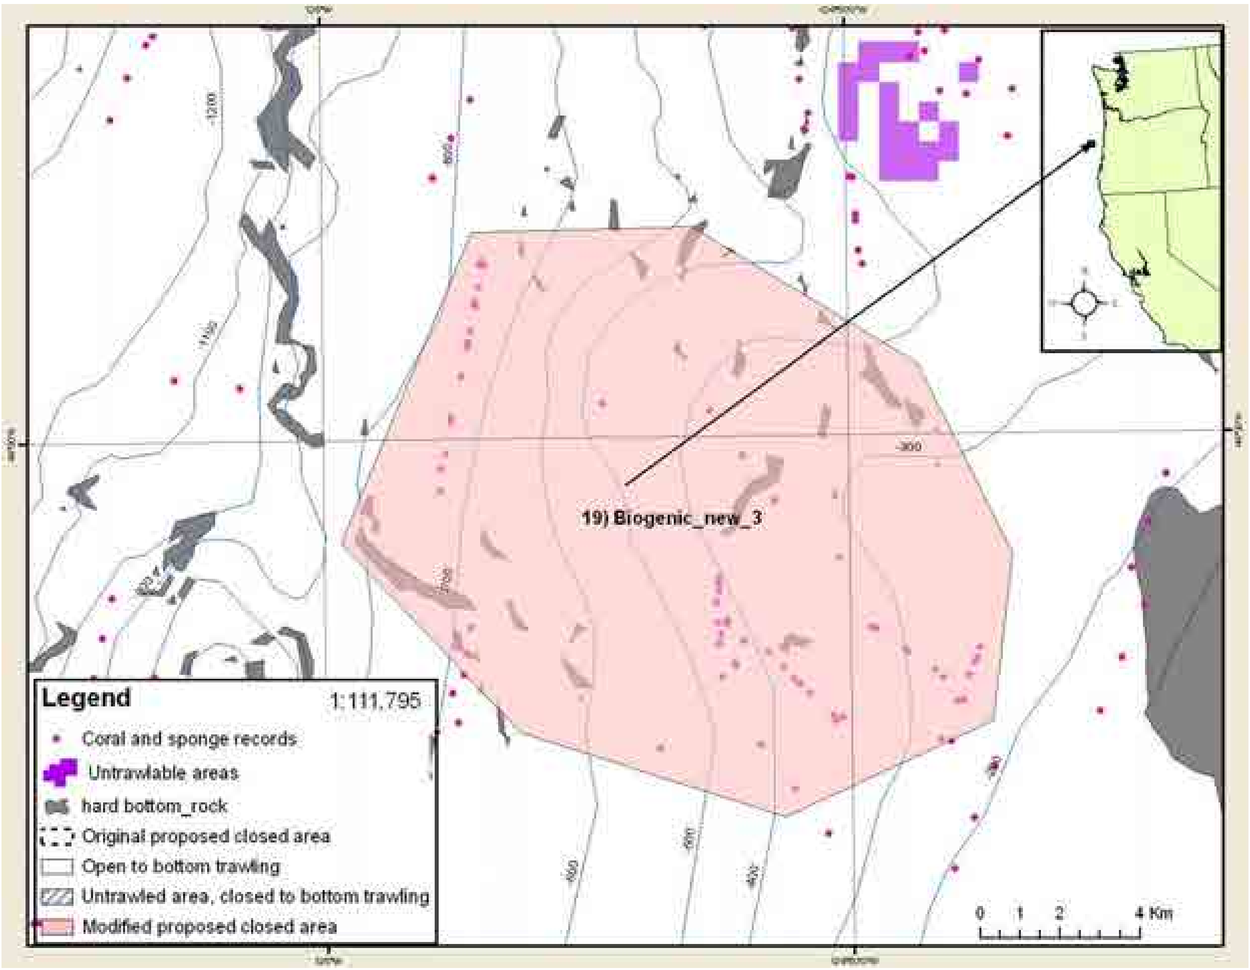

Figure 23: Biogenic_new_3

20. Stonewall Bank

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $7,252

Stonewall Bank is designated as a Rockfish Conservation Area to protect yelloweye and canary rockfish (Figure 24). Little bottom trawl activity occurs on the bank, and closing the bank to trawling would result in minimal displaced revenue.

The proposed area contains 116 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). As it is difficult to trawl here, the bank has not been well sampled by NOAA trawl surveys. However, 2 records of sponges were documented here.

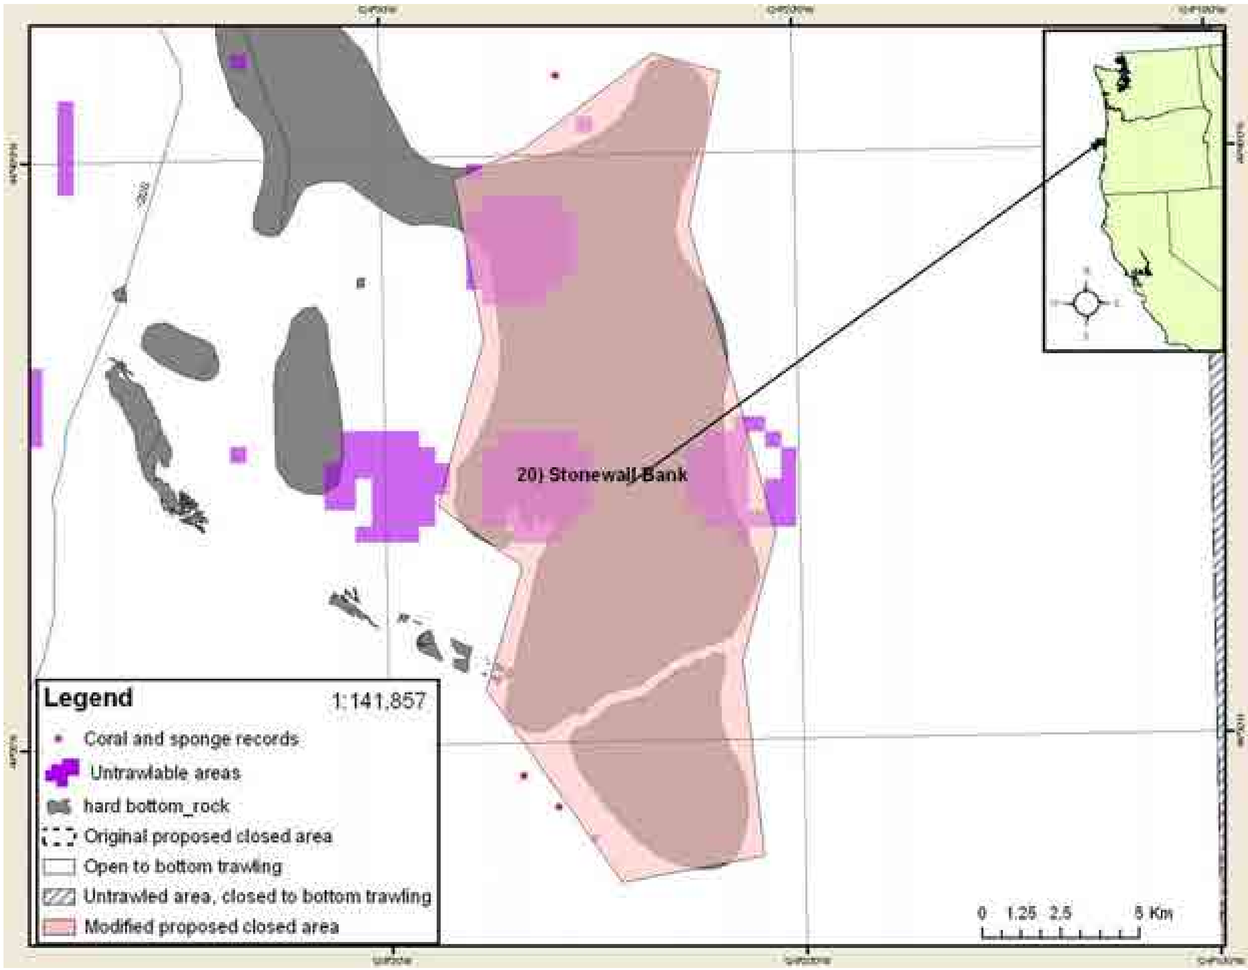

Figure 24: Stonewall Bank

21. Cape Perpetua Reef

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $125

Cape Perpetua Reef is a rocky reef off the Oregon coast (Figure 25). Oregon State's Nearshore Rocky Reef Project mentions the Cape Perpetua Reef as the most undisturbed and pristine reef off the Oregon coast Little trawl activity occurs near the bank and closing the bank to bottom trawling would result in minimal displaced revenue. As it is likely difficult to trawl here, the bank has not been sampled by NOAA trawl surveys.

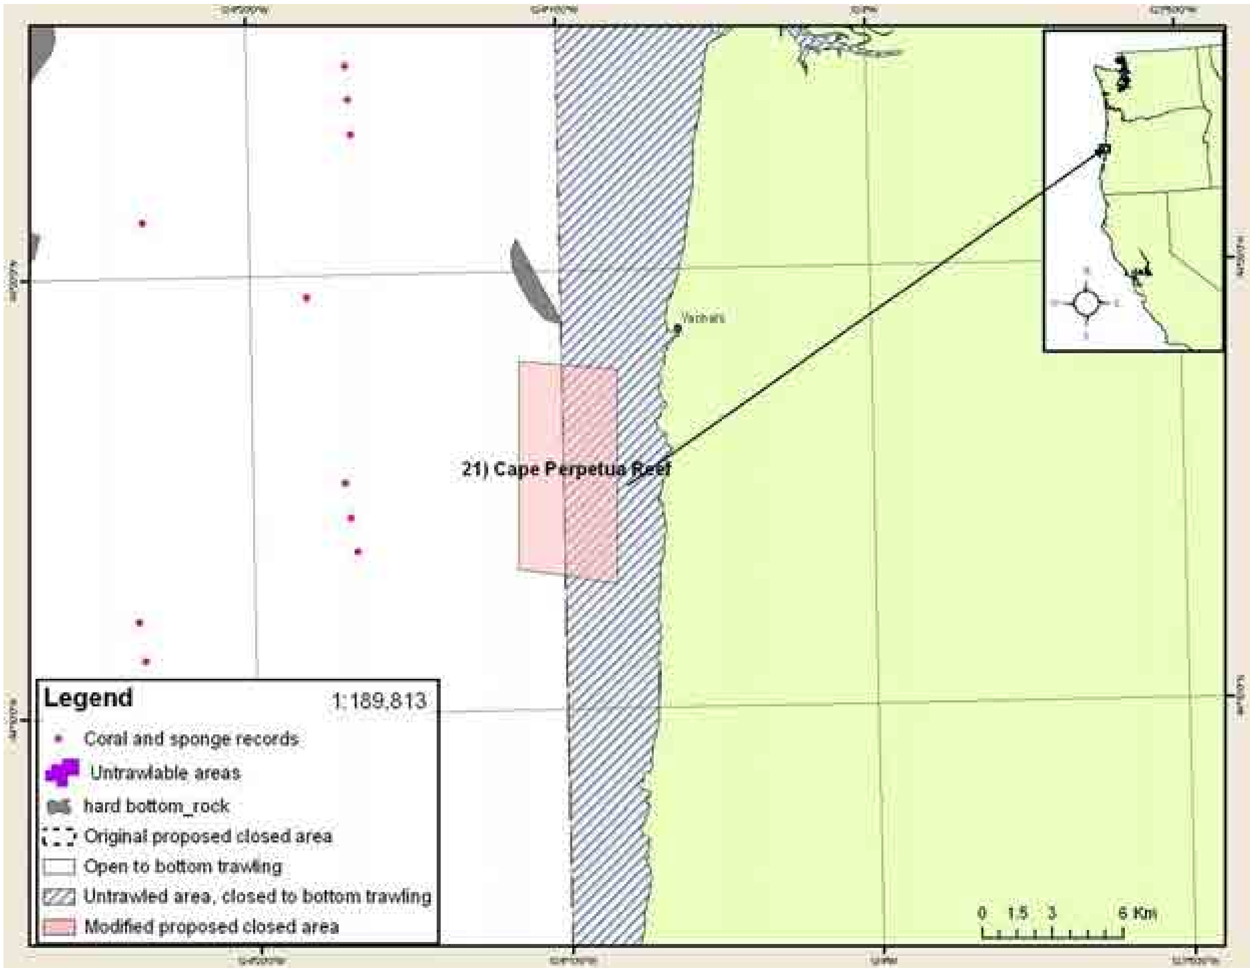

Figure 25: Cape Perpetua Reef

22. & 23. Heceta Bank area

Original Alternative C.12 estimated displaced revenue= $379,291
Revised Alternative C.12 estimated displaced revenue= $229,475 (likely overestimated, trawl tracks fall outside of area, see Figure K below)

Trawl logbook data indicated trawl activity within the previously proposed boundaries of the Heceta bank closed area. Trawl effort appeared concentrated on the slope off Heceta Bank and south (Figure K). The proposed area was split into the 2 areas below, which avoids much of the trawl effort and likely results in less displaced effort from the closure (Figure 26).

22. Heceta Bank

Revised Alternative C.12 estimated displaced revenue= $200,810 (likely overestimated, trawl tracks fall outside of area, see Figure K below)

Heceta Bank is the largest rocky reef off the U.S. Pacific Coast. It is composed largely of hard bottom substrate. The proposed area contains 591 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the “untrawlable” polygons determined by Zimmerman (2003). NOAA trawl surveys have documented 16 records of sponges on the bank, but the bank has not been well-sampled with trawl survey gear. Recent explorations have documented key areas of sponges and crinoids. Video from submersible dives have noted some dense areas of habitat forming invertebrates on the bank (Hixon et al. 1990, Waldo Wakefield unpublished data).

23. Heceta Escarpment

Revised Alternative C.12 estimated displaced revenue= $28,665

NOAA trawl surveys have documented 50 records of habitat-forming invertebrates in the proposed closed area, including black corals, gorgonian corals, sea whips, sea pens, and sponges.

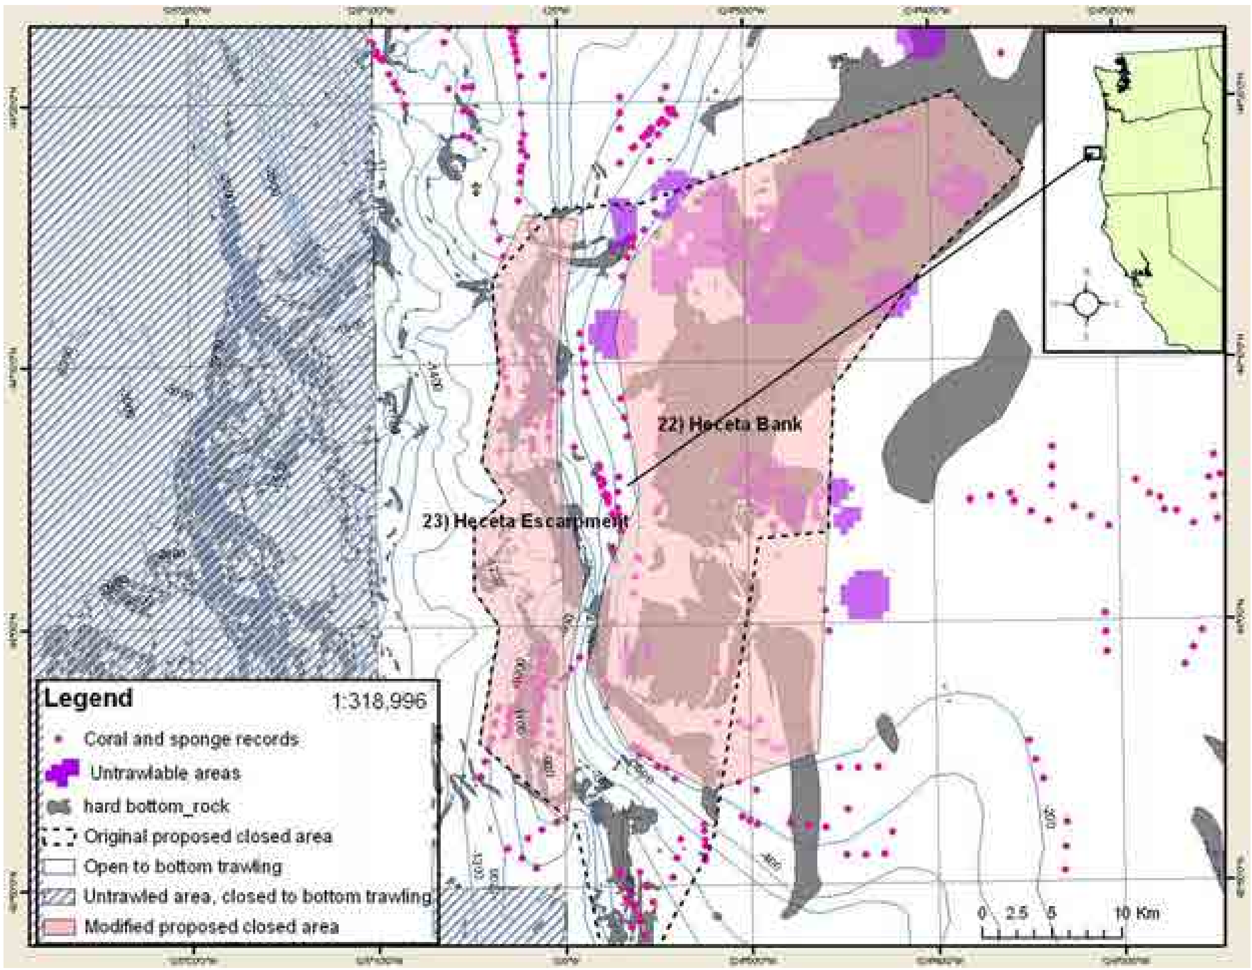

Figure 26: Heceta Bank and Heceta Escarpment

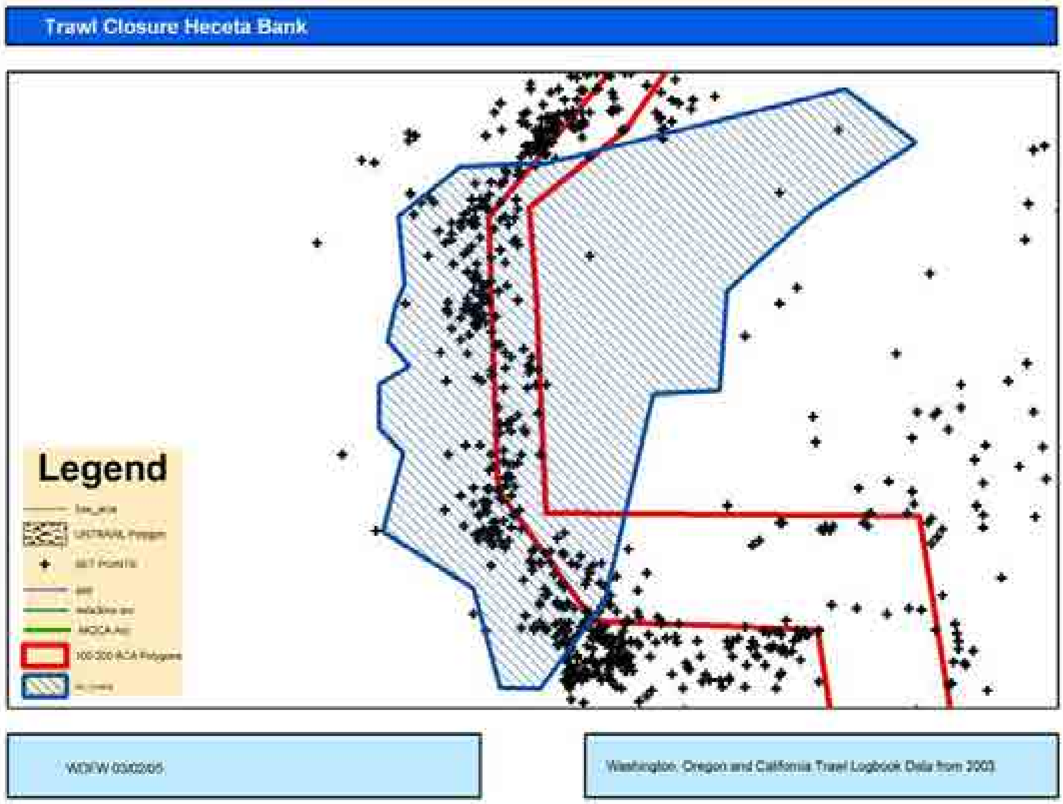

Figure K: 2003 bottom trawl logbook set points (courtesy WDF&W)

24. Ridges_biogenic_10
Original Alternative C.12 estimated displaced revenue= $7,114
Revised Alternative C.12 estimated displaced revenue= $94,628 (likely overestimated, trawl tracks fall outside of area, see Figure L below)

The two previously proposed closed areas were combined into one area and boundaries extended to encompass more records of habitat-forming invertebrates (Figure 27). Trawl logbook data from 2003 indicated little overlap of bottom trawl activity within the proposed area (Figure L). The proposed closed area encompasses habitat from 700 to 1500 meters depth. NOAA trawl surveys have documented 103 records of habitat-forming invertebrates within the proposed closed area. Hexactinellid sponges, black corals, sea whips, and bubblegum corals have been documented in the proposed area.

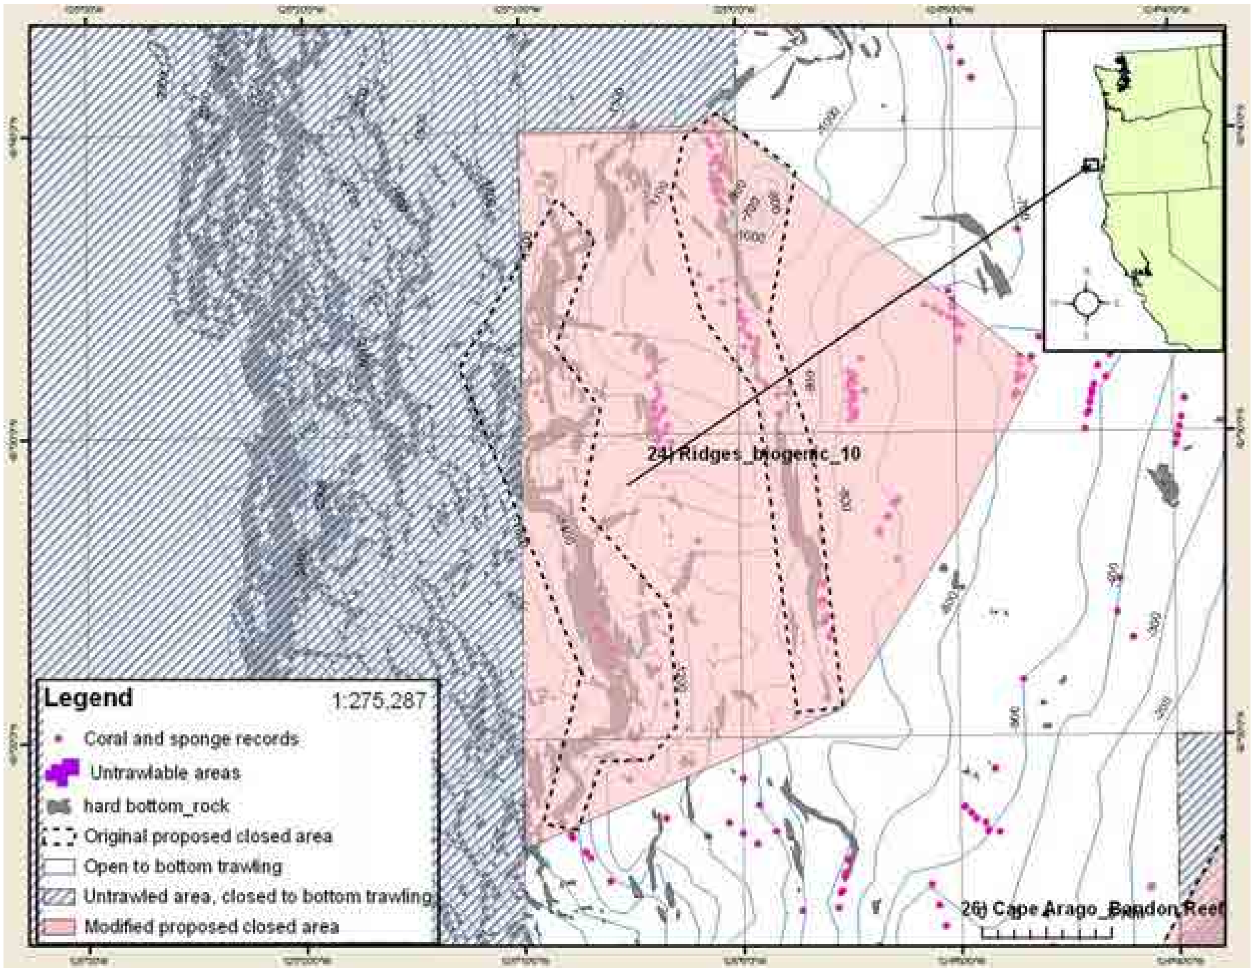

Figure 27: Ridges_biogenic_10

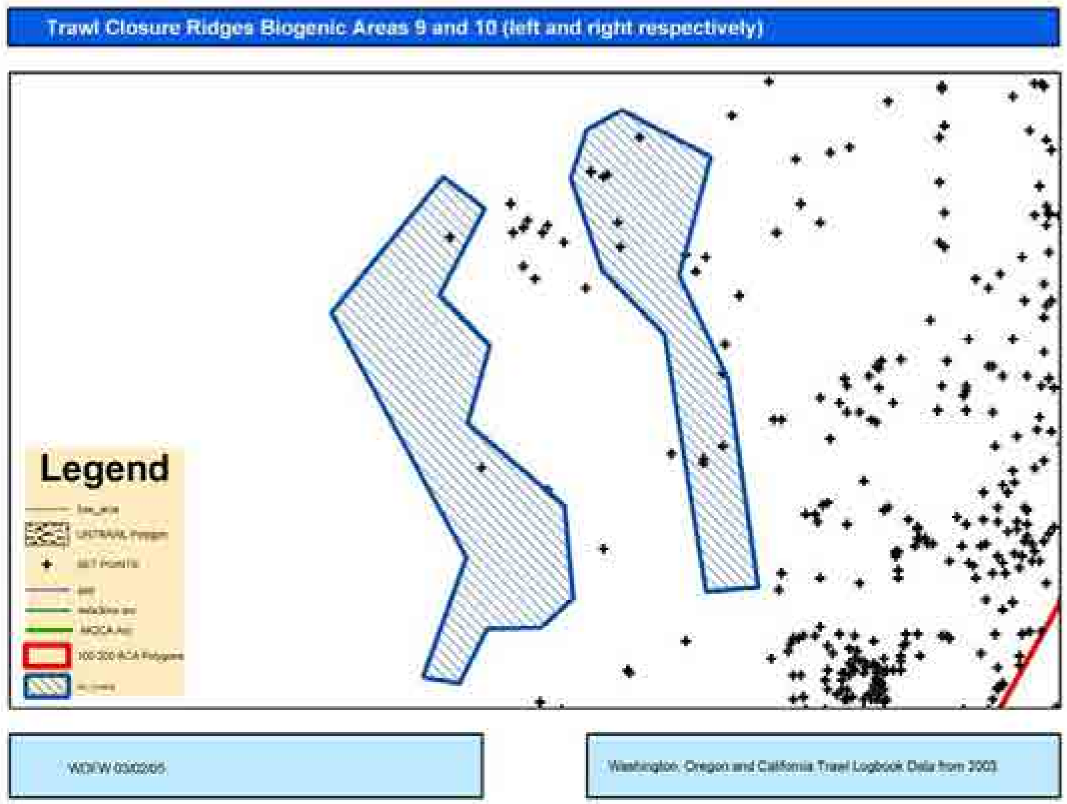

Figure L: 2003 bottom trawl logbook set points (courtesy WDF&W)

25. Siltcoos Reef

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $383

Siltcoos Reef is a rocky reef off the Oregon Coast (Figure 28). The proposed area contains 30 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). As it is difficult to trawl here, the area has not been well surveyed by NOAA trawl surveys. It is also likely that little bottom trawling occurs on the reef, and closing the area would result in minimal displaced effort.

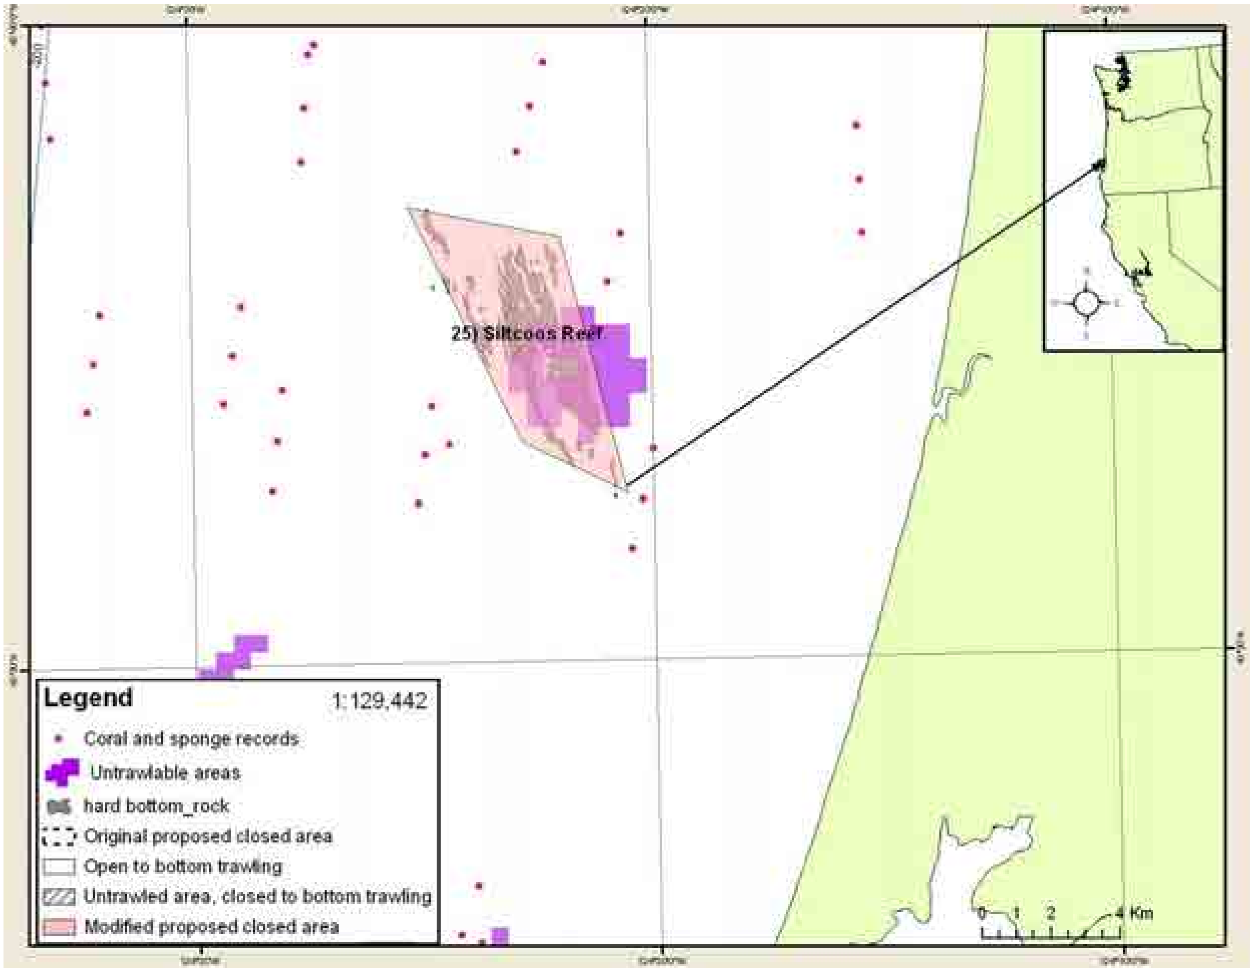

Figure 28: Siltcoos Reef

26. Cape Arago_Bandon Reef

Original Alternative C.12 estimated displaced revenue= $2,016
Revised Alternative C.12 estimated displaced revenue= $12,018

This area was previously identified as "hard-bottom feature_1". The proposed area contains a large proportion of rocky and hard bottom habitat and pinnacles (Figure 29). The proposed closed area in Revised Alternative C.12 contains 253 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). As it is difficult to trawl here, the area has not been well surveyed by NOAA trawl surveys, but 2 records of sponges were documented in 1980.

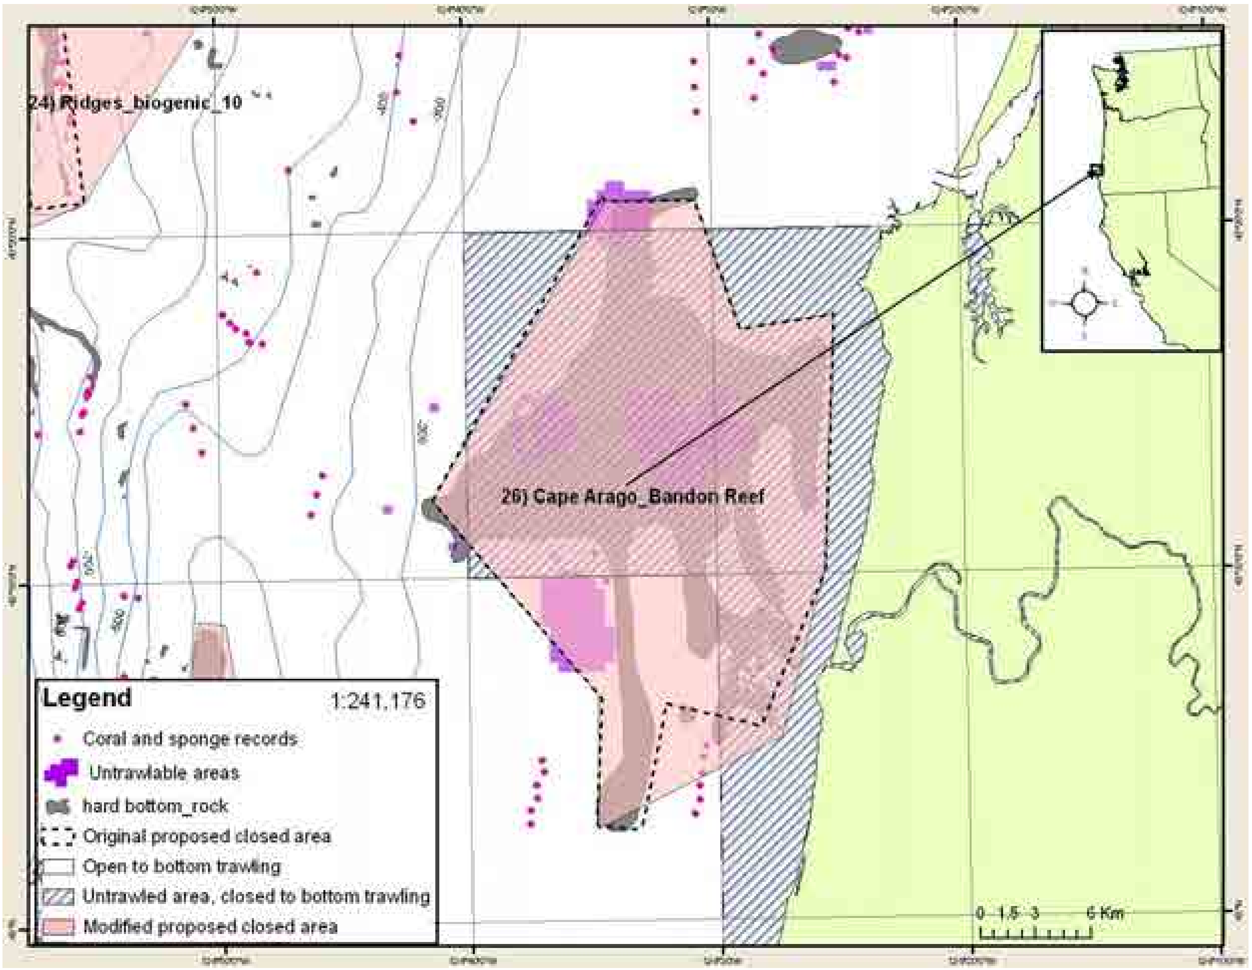

Figure 29: Cape Arago_Bandon Reef

27. Orford and McKenzies Reef

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $3,929

The area around Orford Reef contains extensive bull kelp beds and rockfish habitat. Orford Reef is also an important rookery for the endangered Steller sea lions and is the second largest rookery south of Alaska. This area is located within the 3nm limit of Oregon state waters. Trawl logbooks from 1997-2002 did not document any trawling activity on the reef (Bellman and Heppel 2004). It is likely that it is difficult to trawl on the reef complex. The proposed area contains 108 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). Few successful NOAA trawl survey hauls have occurred on the bank, but one record of sea pens was noted.

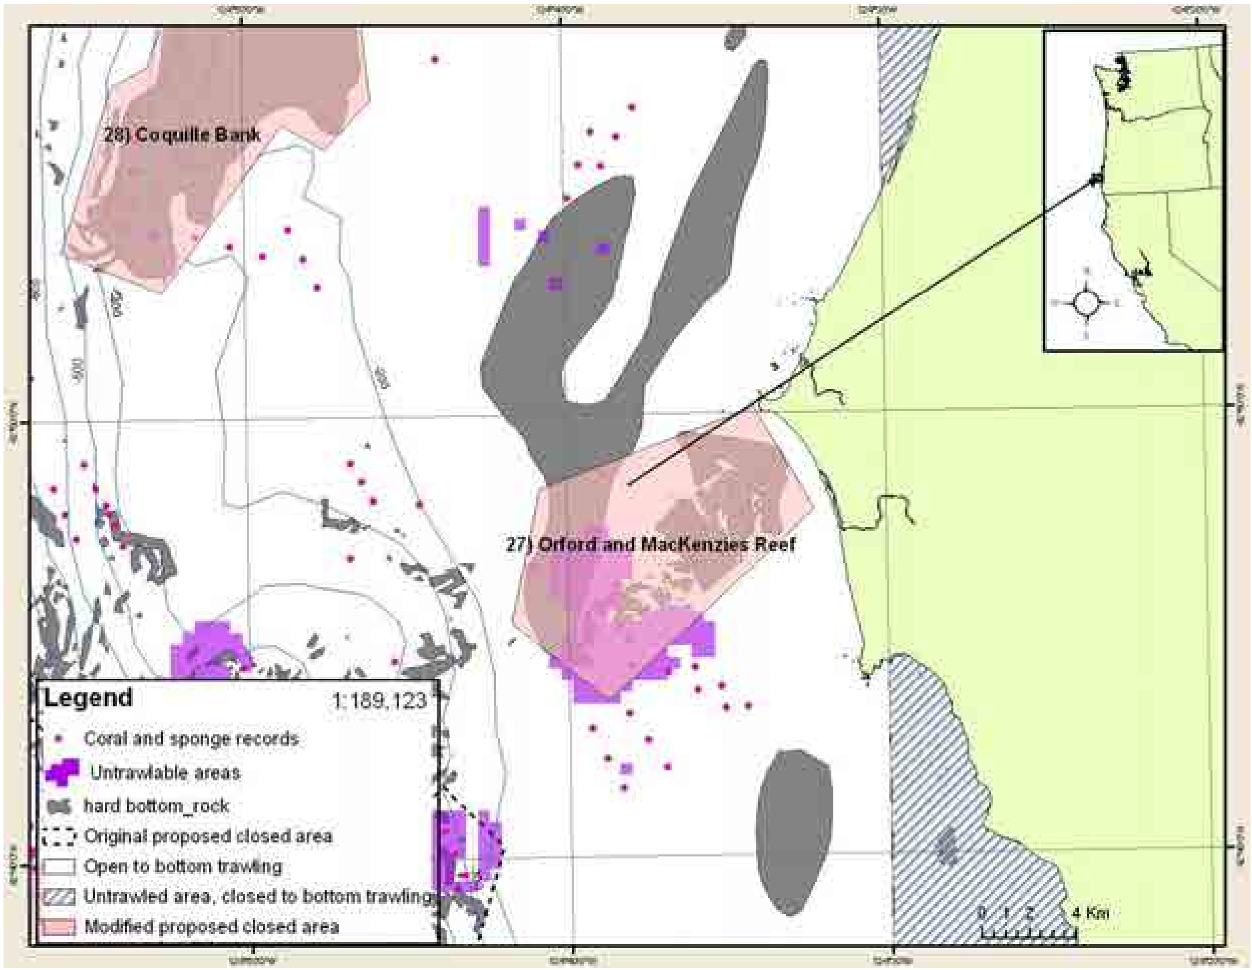

Figure 30: Orford and McKenzies Reef

28. Coquille Bank

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $75,004

The proposed area contains 3 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). Six records of sponges were documented on the bank by NOAA trawl surveys, and four of the six records occurred in the 1980's.

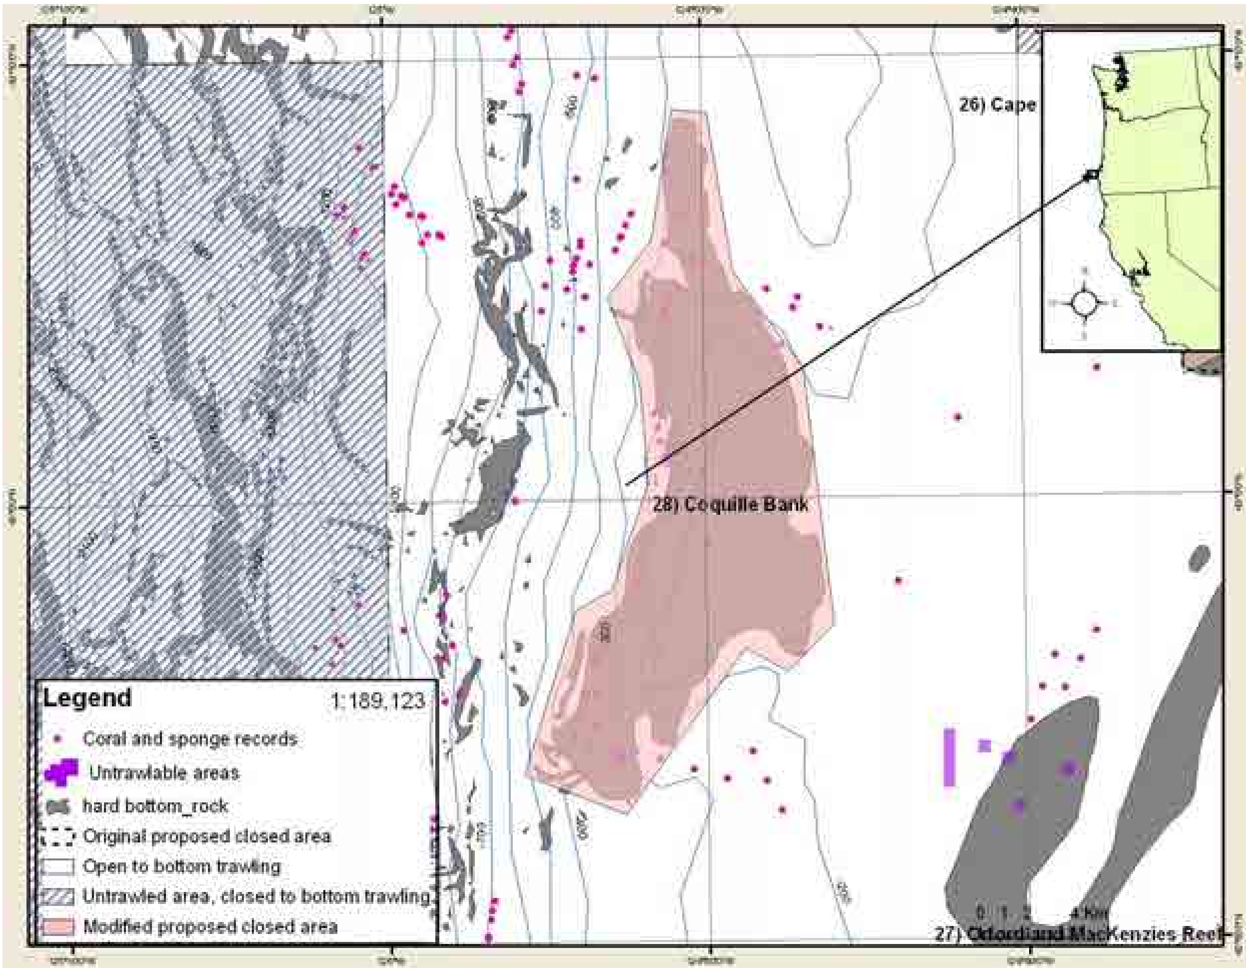

Figure 31: Coquille Bank

29. & 30. Rogue Canyon area

Original Alternative C.12 estimated displaced revenue= $491,706
Revised Alternative C.12 estimated displaced revenue= $145,172 (likely overestimated, trawl tracks fall outside of area, see Figure M below)

Trawl logbook data indicated trawl activity within the previously proposed boundaries of the Rogue Canyon closed area (Figure M). Bottom trawl fishermen indicated a preferred tow area within the proposed closed area, and suggested some areas for change. The proposed closed area was split into the two areas below for Revised Alternative C.12, which avoids much of the trawl effort and likely results in less displaced effort from the closure (Figure 32).

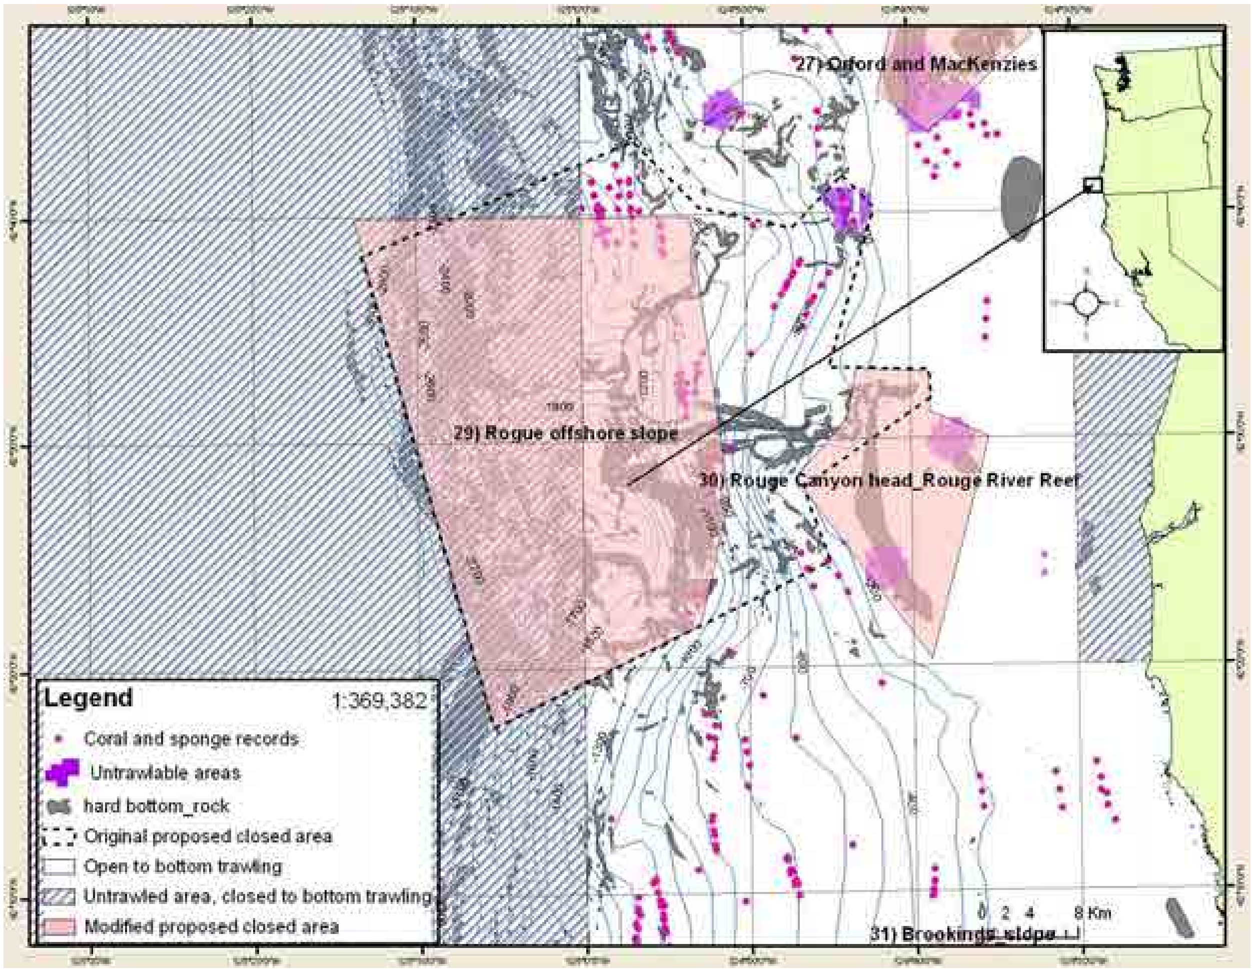

Figure 32: Rouge offshore slope and Rogue canyon head

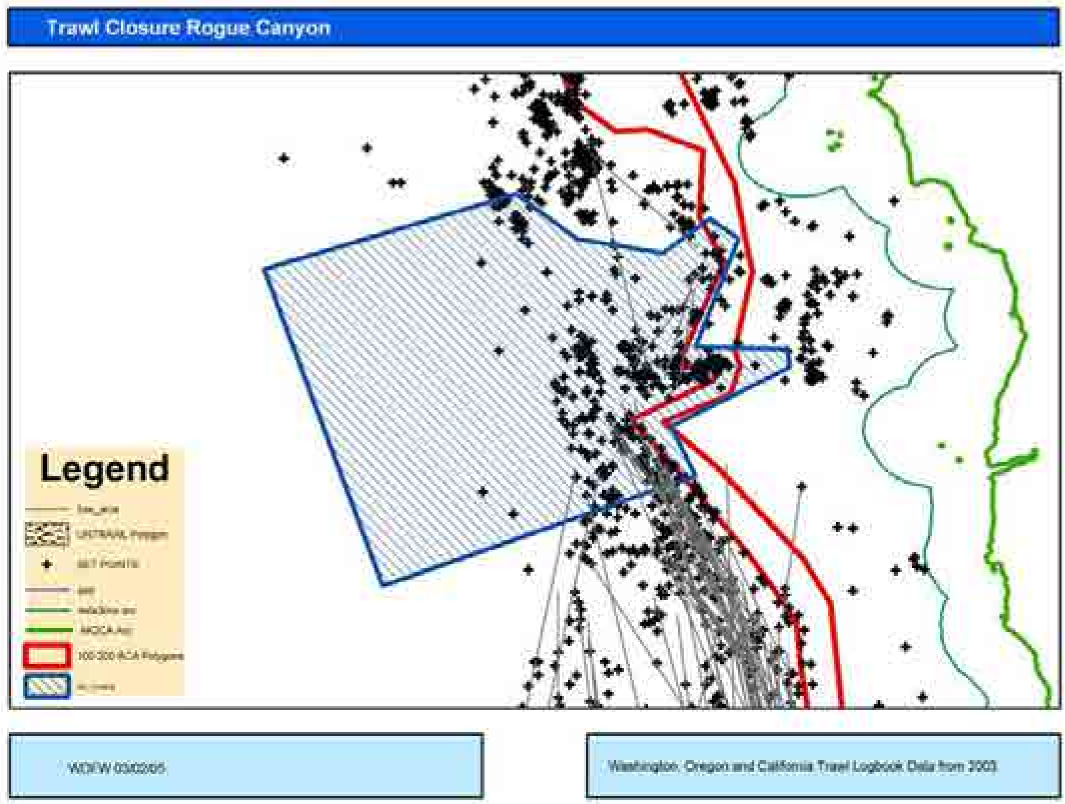

Figure M: 2003 bottom trawl logbook set points (courtesy WDF&W)

29. Rogue offshore slope
Revised Alternative C.12 estimated displaced revenue= $81,296

NOAA trawl surveys have documented 26 records of habitat-forming invertebrates within the proposed closed area. Hexactinellid sponges, black corals, sea whips, and gorgonian corals have been documented in the proposed area.

30. Rogue Canyon head_ Rogue River Reef
Revised Alternative C.12 estimated displaced revenue= $63,876

The proposed area contains 86 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). NOAA trawl surveys have not sampled the area well, as the area is likely difficult to trawl. However, two records of sponges have been noted by successful survey hauls (Figure 33).

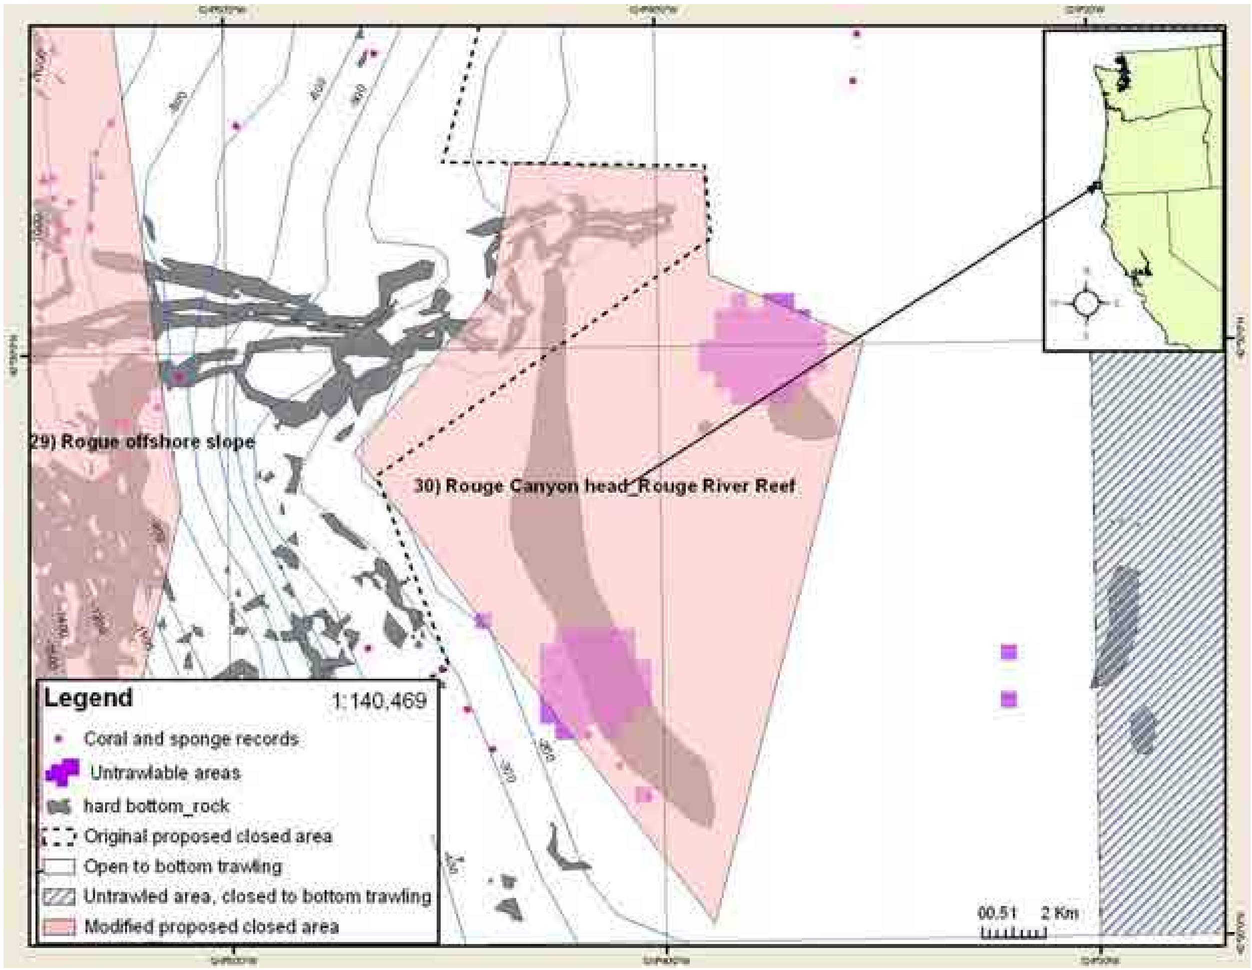

Figure 33: Rogue Canyon head_Rogue River Reef

31. Brookings_slope

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $48,884

This area encompasses slope habitat that is currently closed to bottom trawling in the rockfish conservation area (RCA), and as such, there is likely to be much less displace revenue than estimated. The proposed area contains 55 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). NOAA trawl surveys have not sampled the area well, but four records of sponges and sea pens have been documented in the proposed area (Figure 34).

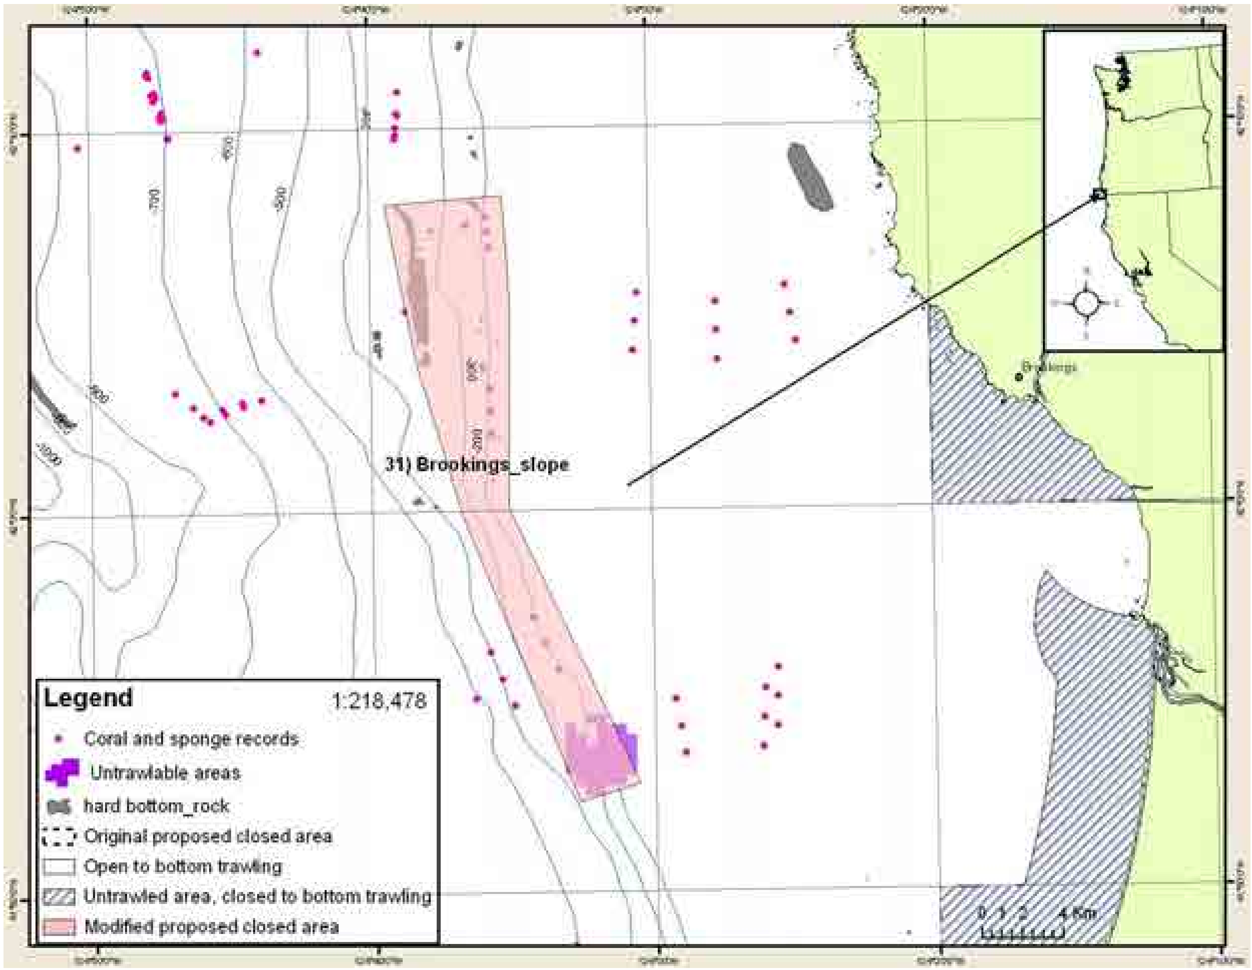

Figure 34: Brookings_slope

32. Crescent City deep_Biogenic_11

Original Alternative C.12 estimated displaced revenue= $2,734
Revised Alternative C.12 estimated displaced revenue= $9,635

This area is in deep water, and is located outside of the bottom trawl footprint (Figure 35). As such, there is likely to be much less displaced revenue than estimated here. This area was also proposed by the trawl industry as a candidate for closure. NOAA trawl surveys have documented 35 records of habitat-forming invertebrates within the proposed closed area. Hexactinellid sponges, black corals, sea whips, and gorgonian corals have been documented in the proposed area.

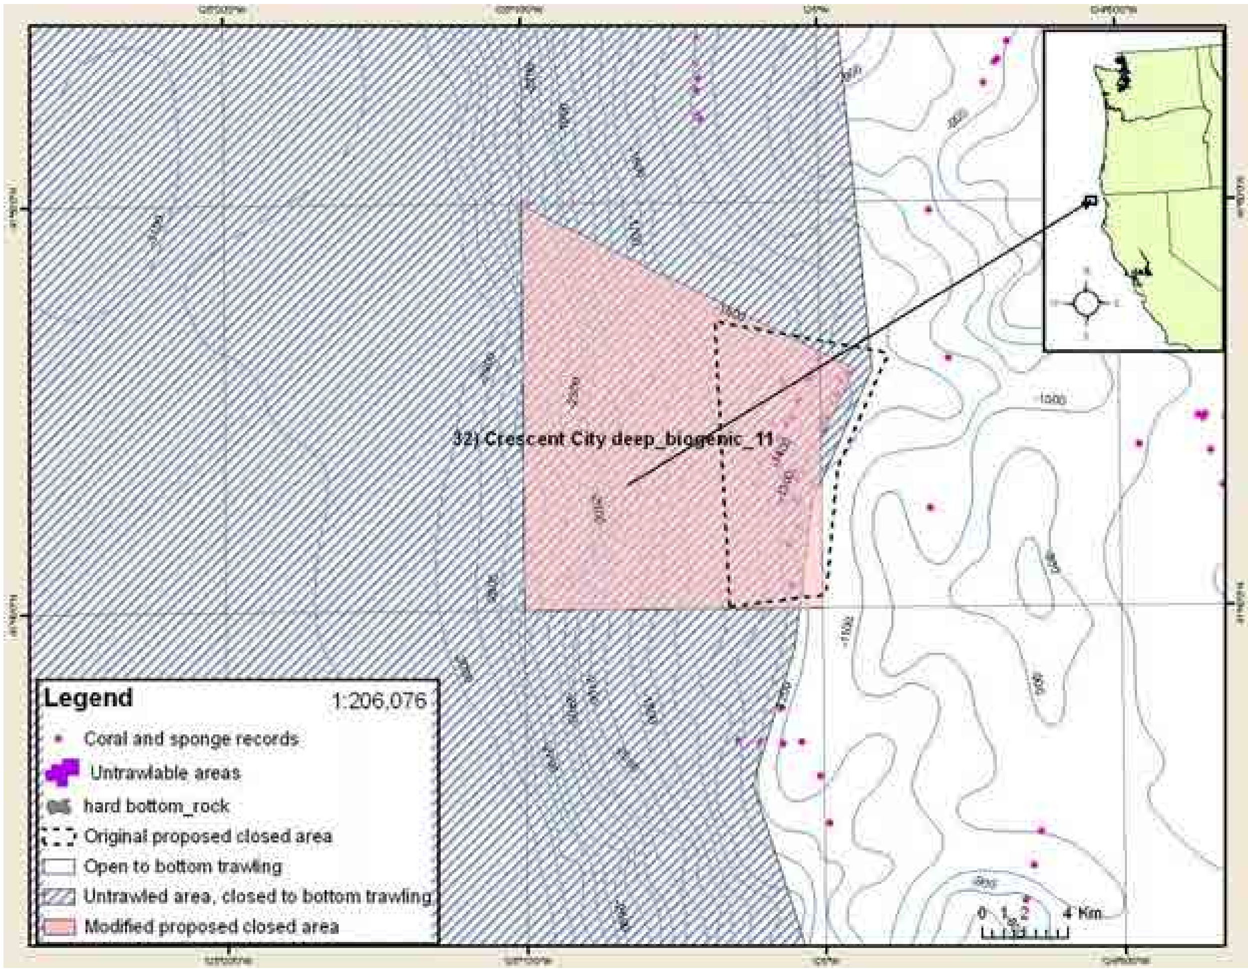

Figure 35: Crescent City deep_Biogenic_11

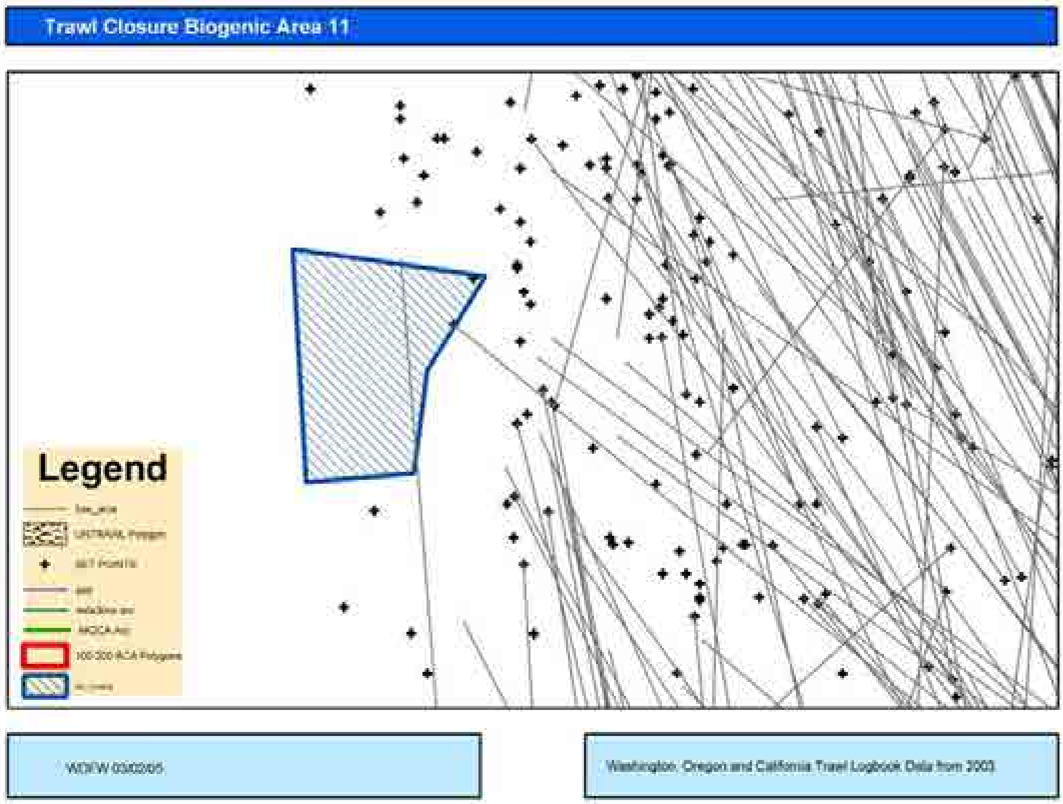

Figure N: 2003 bottom trawl logbook set points (courtesy WDF&W)

33. Crescent City slope

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $49,779

This area encompasses slope habitat located within the rockfish conservation area that is currently closed to bottom trawling. As such, there is likely to be much less displaced revenue than estimated here. The proposed area contains 72 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). While the area is not well sampled by NOAA trawl survey gear, 5 records of sponges and sea pens have been documented (Figure 36).

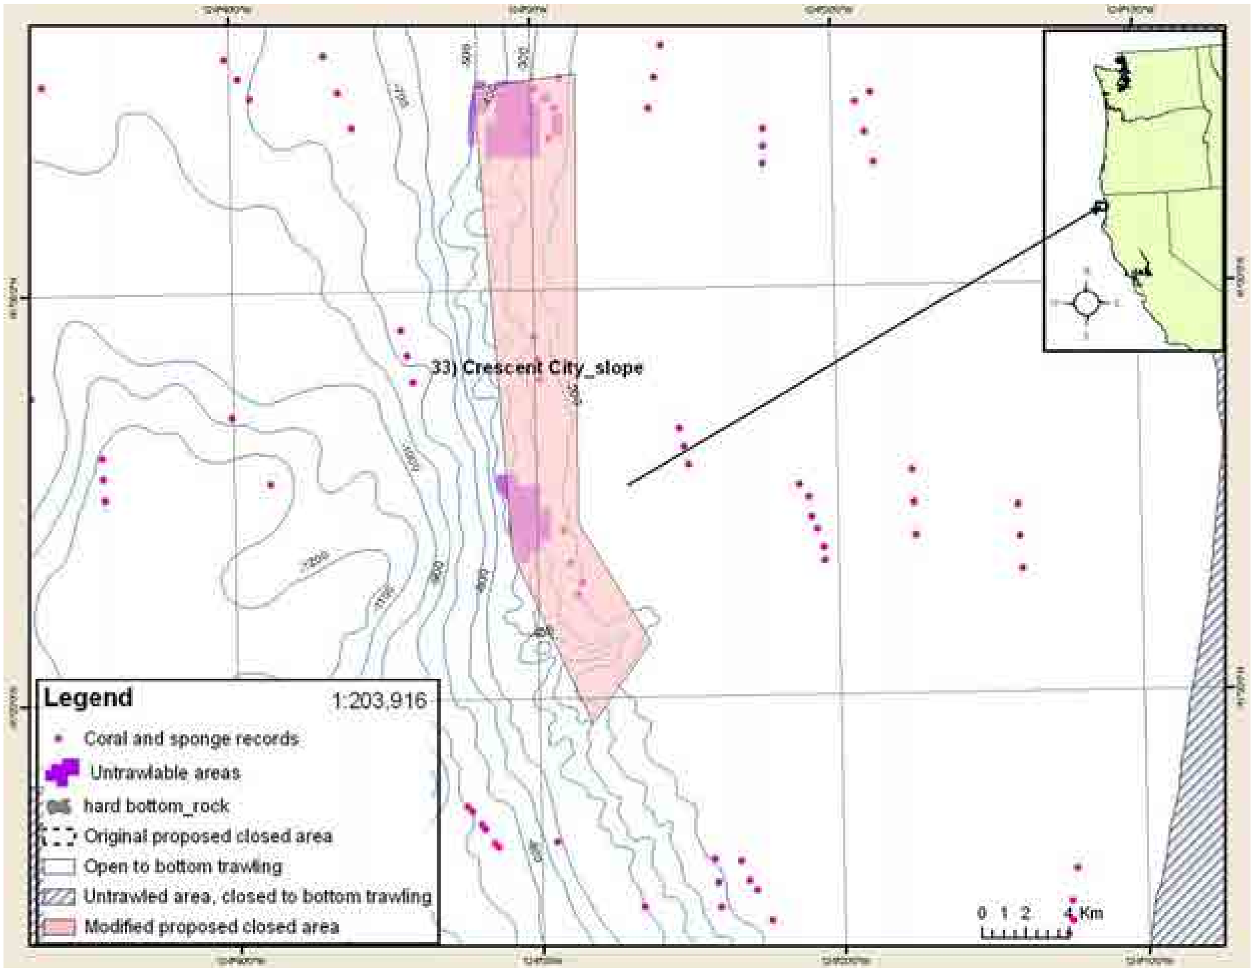

Figure 36: Crescent City slope

34. Eel River Canyon

Original Alternative C.12 estimated displaced revenue= $551,397
Revised Alternative C.12 estimated displaced revenue= $201,696 (likely overestimated, trawl tracks fall outside of area, see Figure O below)

Eel River canyon is a deepwater canyon located north of Mendoncino Ridge (Figure 37) The boundary of this area for Revised Alternative C.12 avoids some trawled areas along the canyon edge (Figure O). The boundary closely follows the closed area boundary suggested by representatives of the bottom trawl industry. Therefore, the closure should result in minimal displaced bottom trawl effort, probably much less than we estimate here. The proposed area contains 53 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the “untrawlable” polygons determined by Zimmerman (2003). NOAA trawl surveys have documented 7 records of gorgonian corals and sea pens.

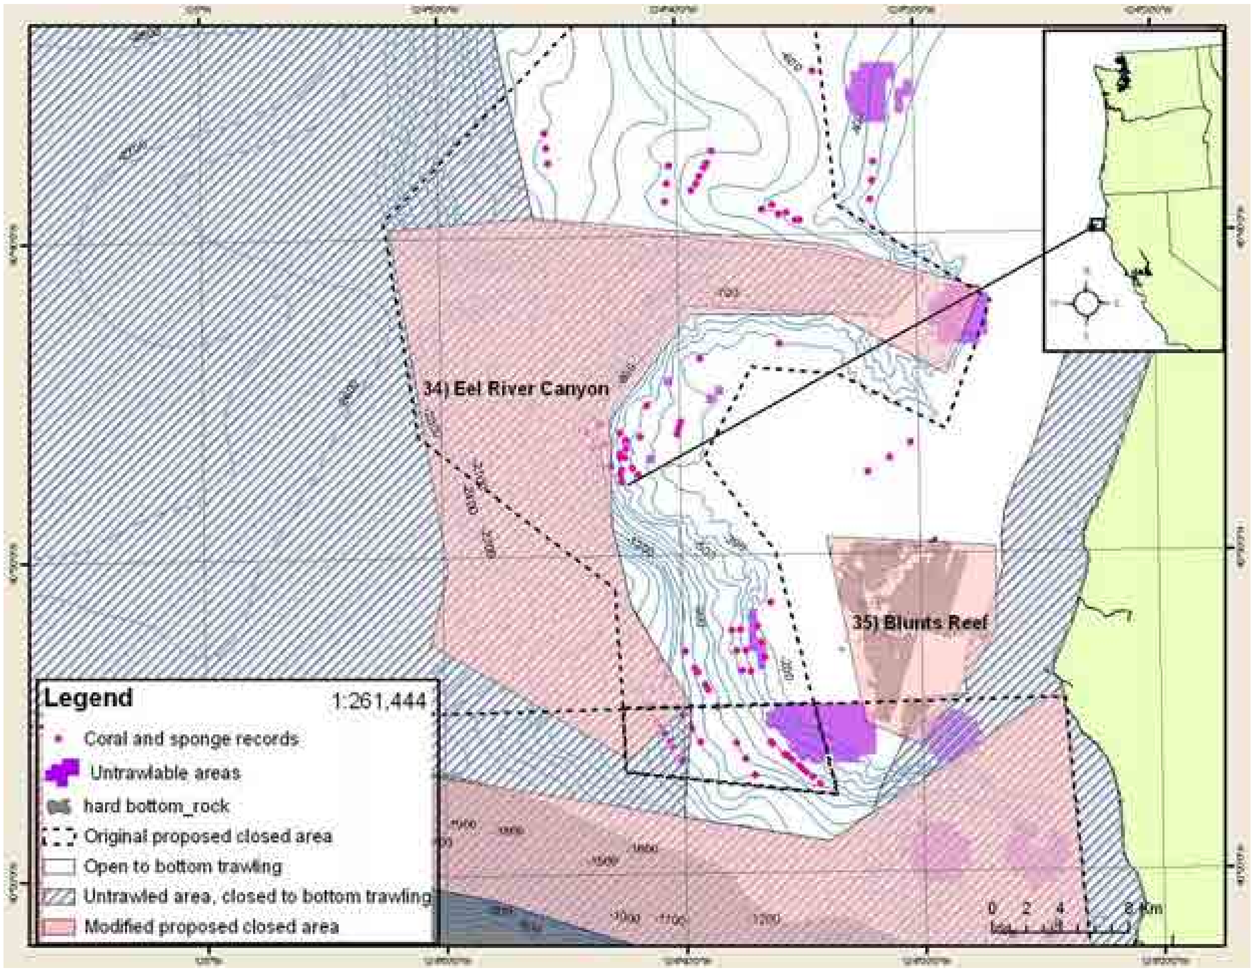

Figure 37: Eel River Canyon

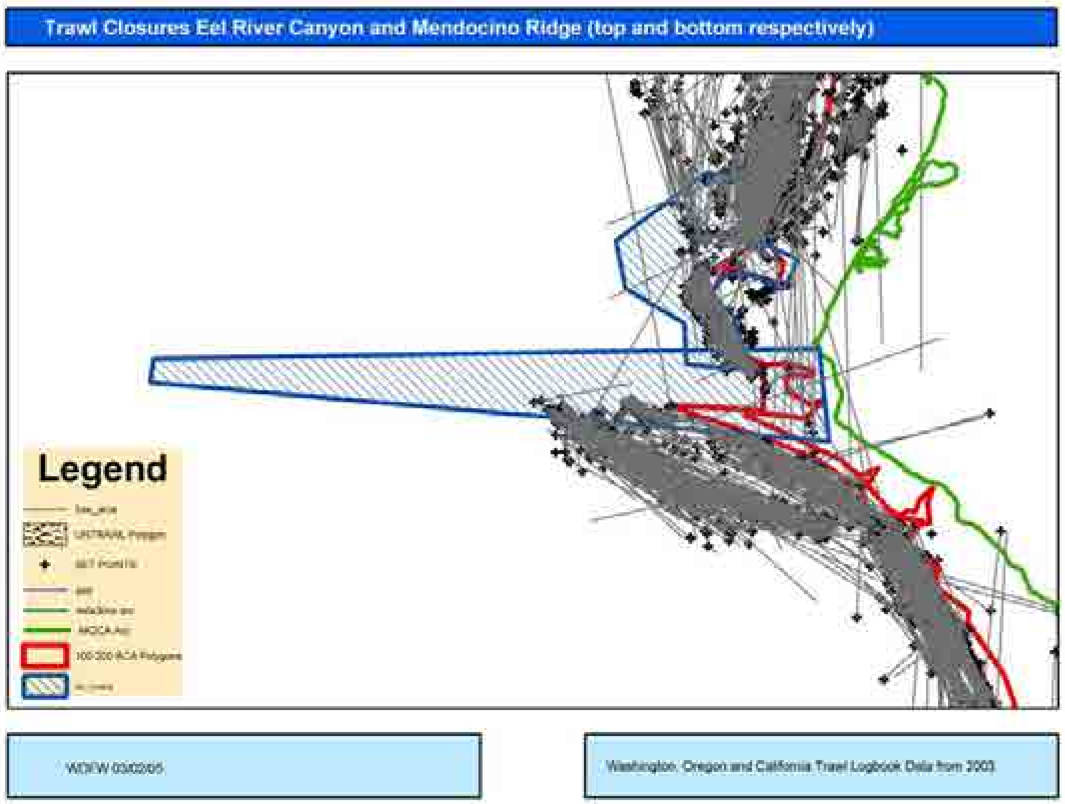

Figure O: 2003 bottom trawl logbook set points (courtesy WDF&W)

35. Blunts Reef

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $25,495 (likely overestimated, trawl tracks fall outside of area, see Figure O above)

This rocky reef off the shelf is located north of Mendocino Ridge (Figure 38). The proposed area contains 13 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). Logbook information (Figure O) indicates that little bottom trawling occurred in the area, and little effort should be displaced by this suggested closure.

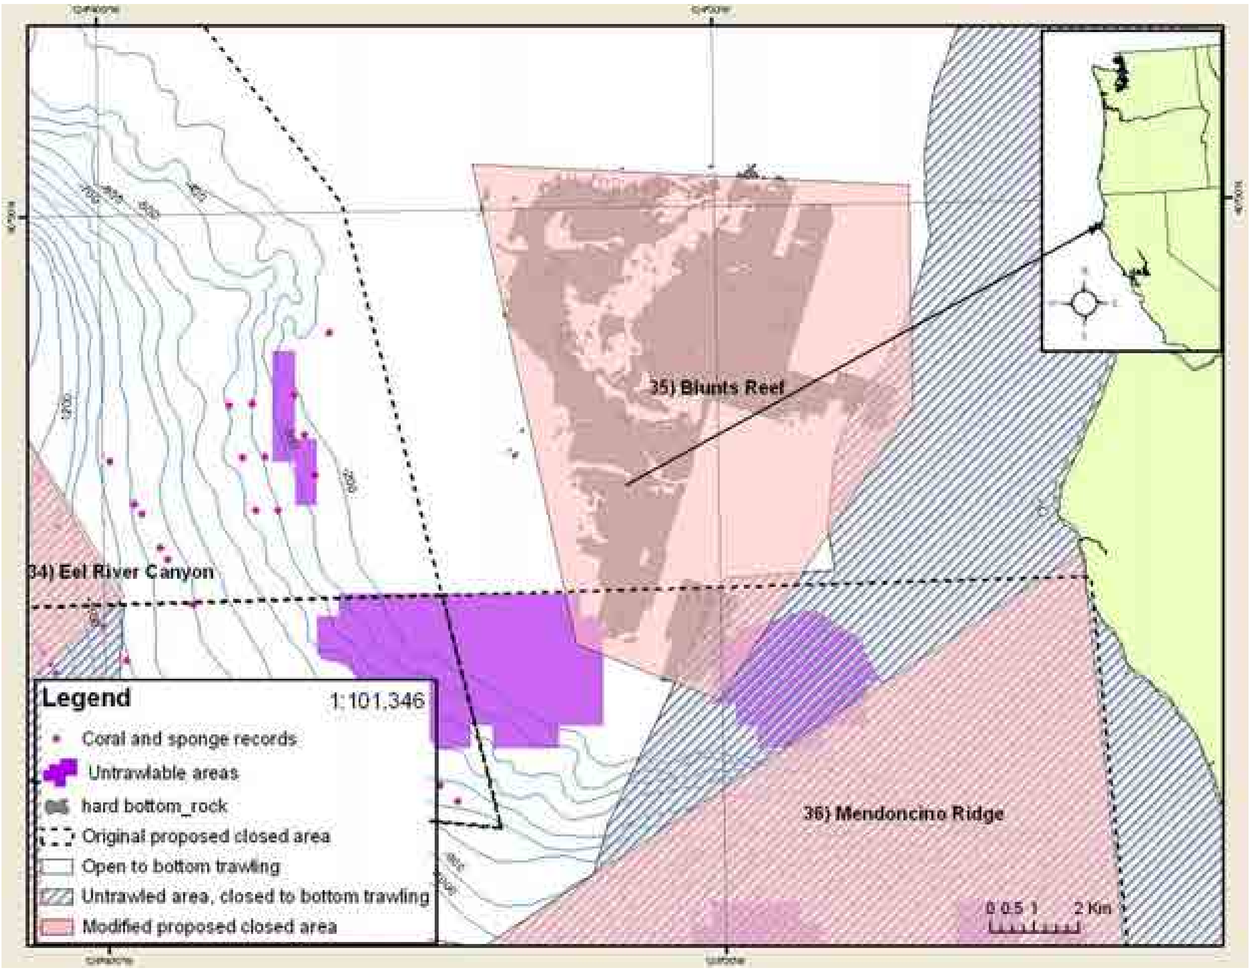

Figure 38: Blunts Reef

36. Mendocino Ridge

Original Alternative C.12 estimated displaced revenue= $201,902
Revised Alternative C.12 estimated displaced revenue= $108,769 (likely overestimated, trawl tracks fall outside of area, see Figure O above)

Mendocino Ridge, also known as the Gorda Escarpment, is a large underwater ridge running east to west separating two major marine ecological provinces (Figure 39). The boundary of the area as it was previously proposed contained some trawl activity (Figure 0). The boundary in Revised Alternative C.12 was modified to avoid some trawled areas along the north and south end of the ridge and this closely follows the closed area boundary suggested by representatives of the bottom trawl industry (Figure 39). As such, little bottom trawl effort should be displaced by this suggested closure and displacement is probably less than what is estimated here. The proposed area contains 279 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). The area has not been well sampled by NOAA trawl surveys, but 5 records of gorgonian corals, sea pens, and sponges have been documented.

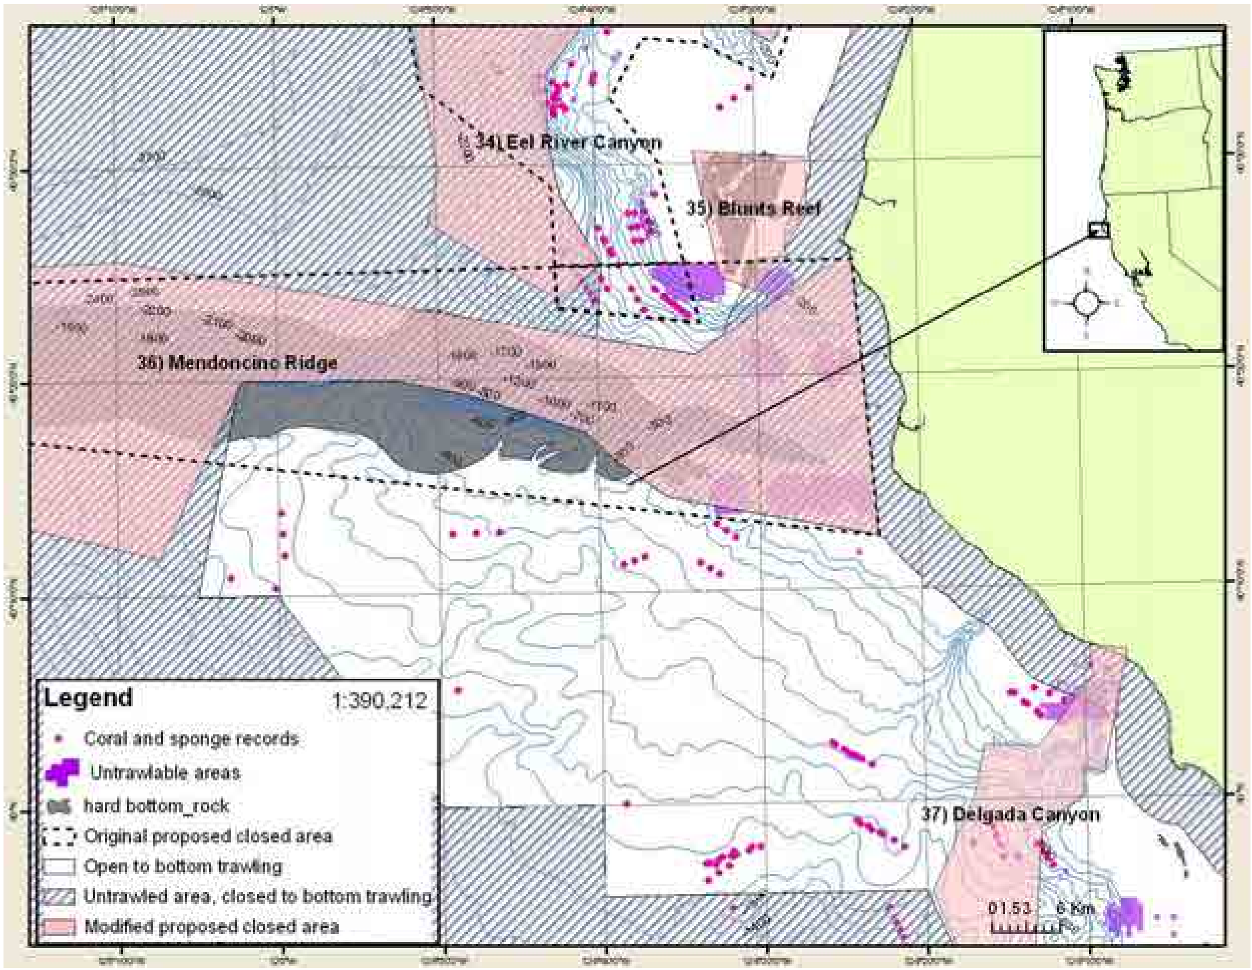

Figure 39: Mendocino Ridge

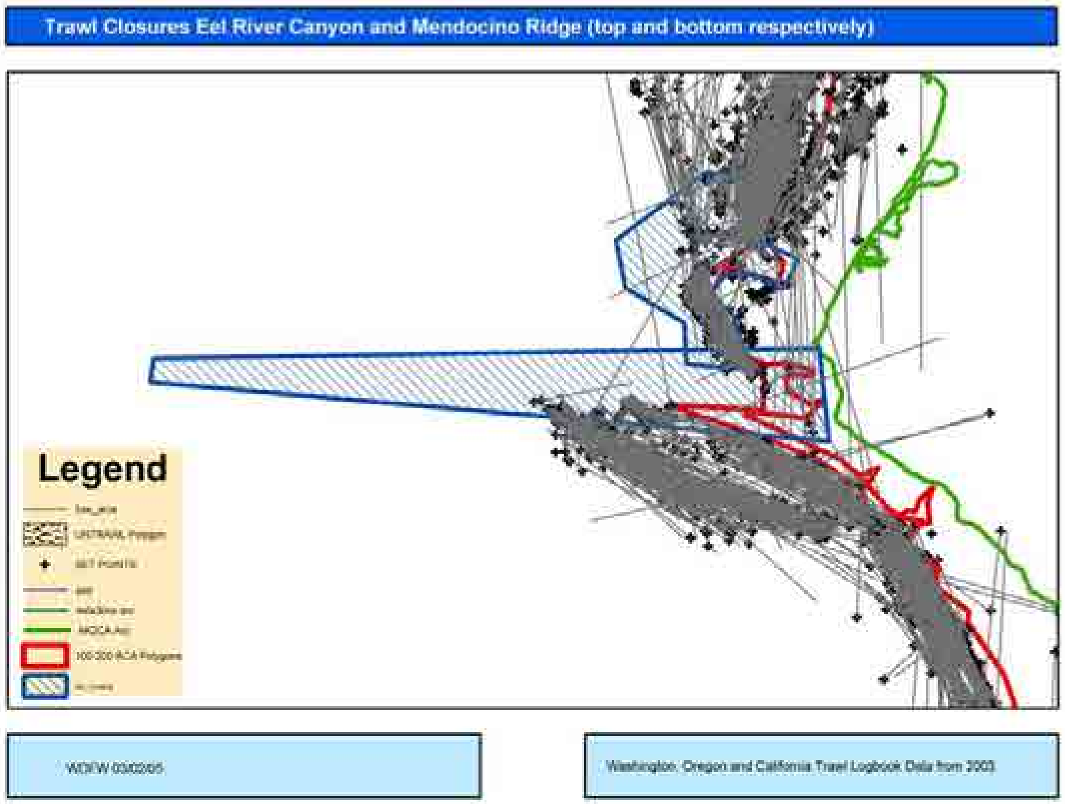

Figure P: 2003 bottom trawl logbook set points (courtesy WDF&W)

37. Delgada Canyon

Original Alternative C.12 estimated displaced revenue=N/A
Revised Alternative C.12 estimated displaced revenue= $79,978

This deep canyon begins close to shore on the Northern California coast (Figure 40). The proposed area contains 99 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). While no NOAA trawl surveys have sampled within the canyon itself, 7 records of sea pens and sea whips have been documented along the edge of the canyon. To our knowledge, the canyon has not been explored by scientific surveys, but scuba divers have noted some fantastic sights in the canyon head:

> *I have never seen areas of filter feeding organisms so thick in one spot in my life. Strawberry anemones so thick that it would make Amentos Reef in Monterey look barren…. As I shined my light into the cracks more I was seeing all sorts of baby rock fish of 6-8 different species laying inverted on the shelves…. It was essentially nothing more than a giant maternity ward for sea life…. I wonder if any marine scientists know about this place?*

http://diver.net/seahunt/fend/f_ericdelgada.htm

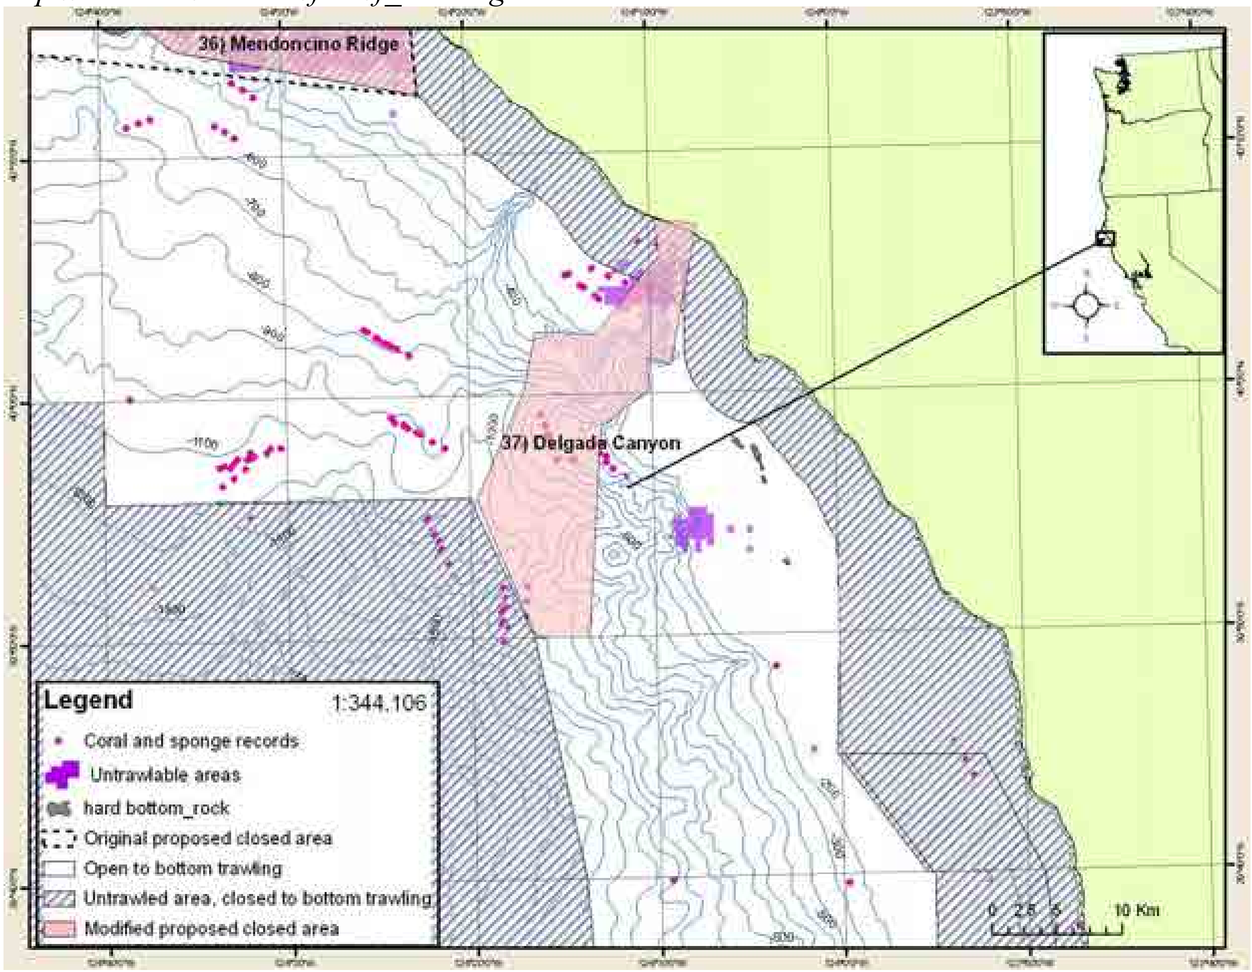

Figure 40: Delgada Canyon

38. Fort Bragg Canyon

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $51,128

This canyon begins offshore of Fort Bragg and extends into deep water outside the bottom trawl footprint (Figure 41). While no NOAA trawl surveys have sampled within the canyon itself, two records of sea pens and sea whips have been documented along the edge of the canyon.

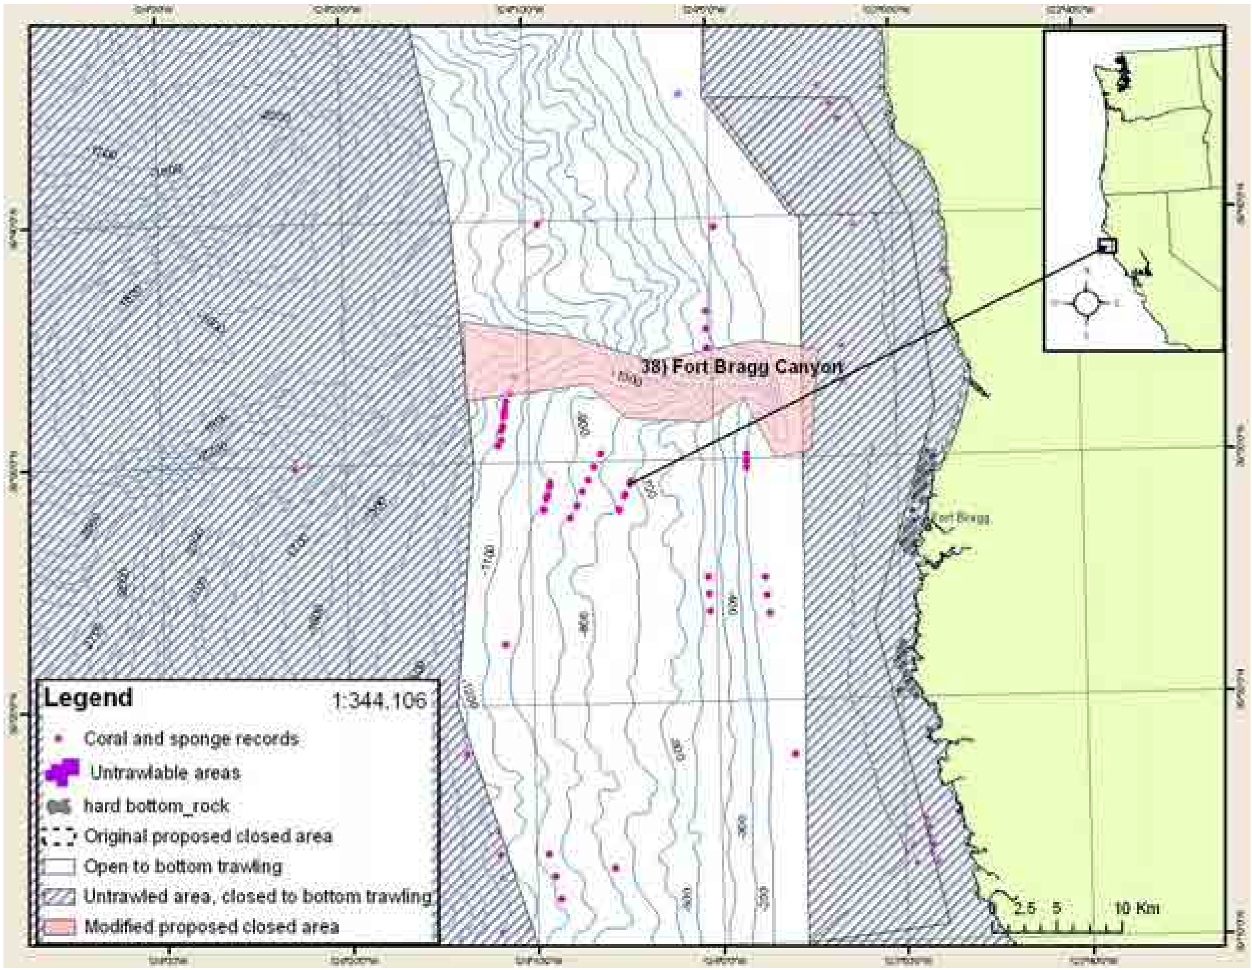

Figure 41: Fort Bragg Canyon

39. Point Arena offshore

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $47,324 (likely overestimated, trawl tracks fall outside of area, see Figure below)

This rocky shelf area is located offshore of Point Arena (Figure 42). Trawl logbook information indicates that no activity occurred in the area (Figure Q), and the area is located outside of the bottom trawl footprint. Minimal bottom trawl effort should be displaced by this suggested closure and the displaced revenue reported here is likely overestimated.

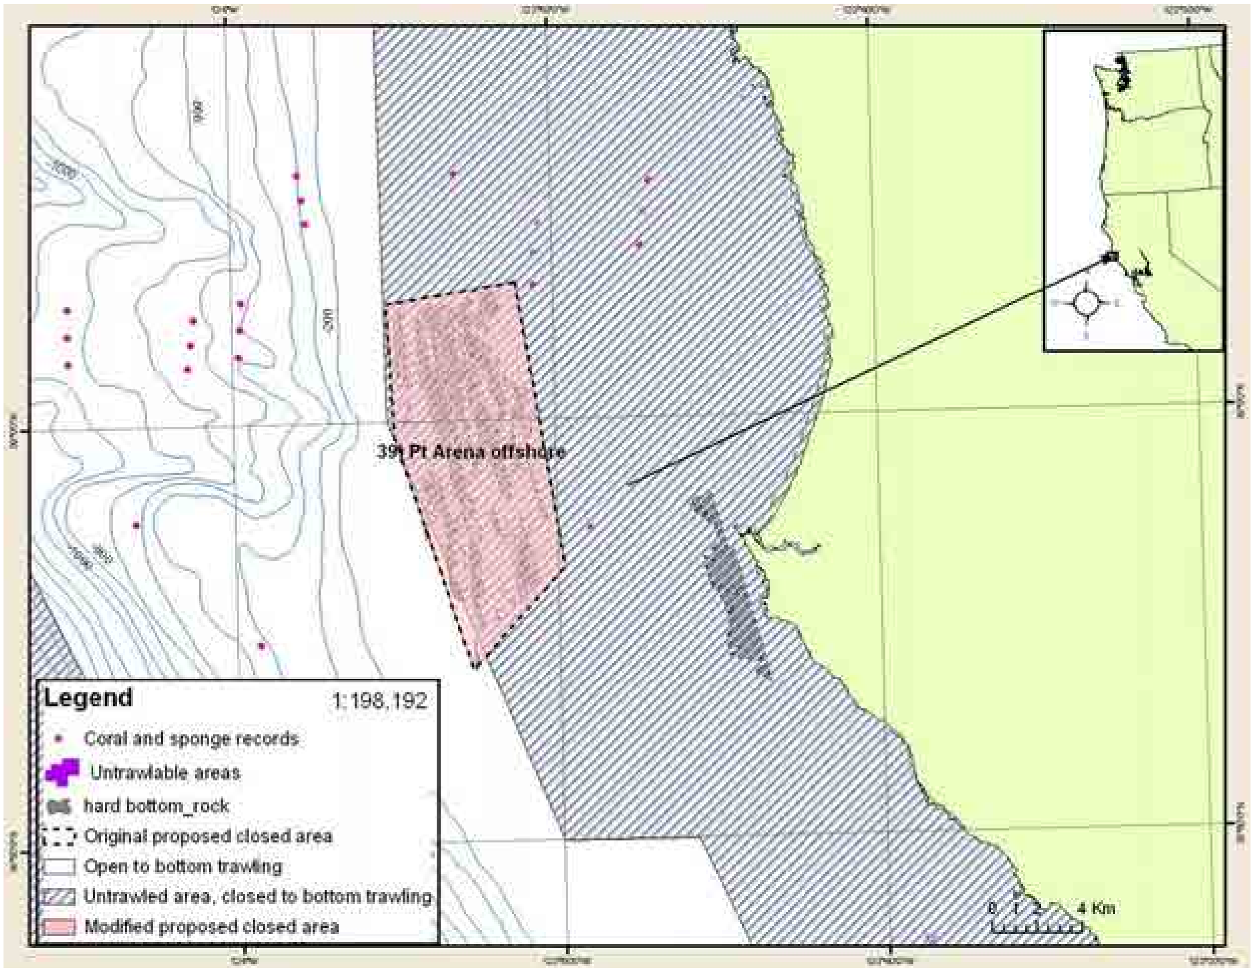

Figure 43: Point Arena offshore

40. Biogenic_ 12

Original Alternative C.12 estimated displaced revenue= $109,117
Revised Alternative C.12 estimated displaced revenue= $61,321 (likely overestimated, trawl tracks fall outside of area, see Figure Q below)

This proposed closed area in Revised Alternative C.12 spans slope habitat from 300 to 1200 meters in depth (Figure 44). NOAA trawl surveys have documented 40 records of habitat-forming invertebrates, including gorgonian corals, sea pens, sea whips, and sponges. The proposed area contains 40 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). Logbook information indicates that little bottom trawling occurs in the area, and minimal bottom trawl effort should be displaced by this suggested closure (Figure Q).

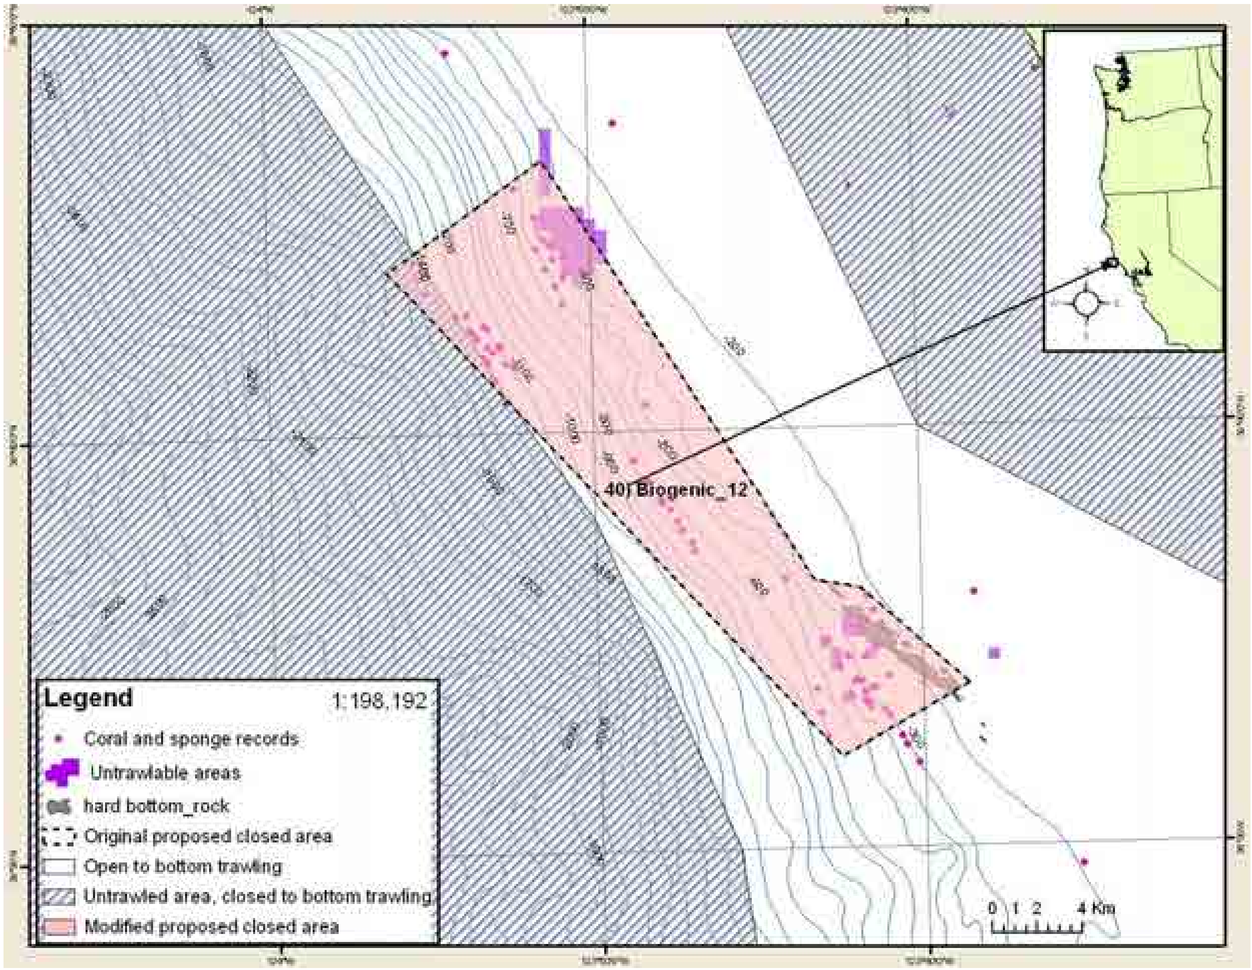

Figure 44: Biogenic_12

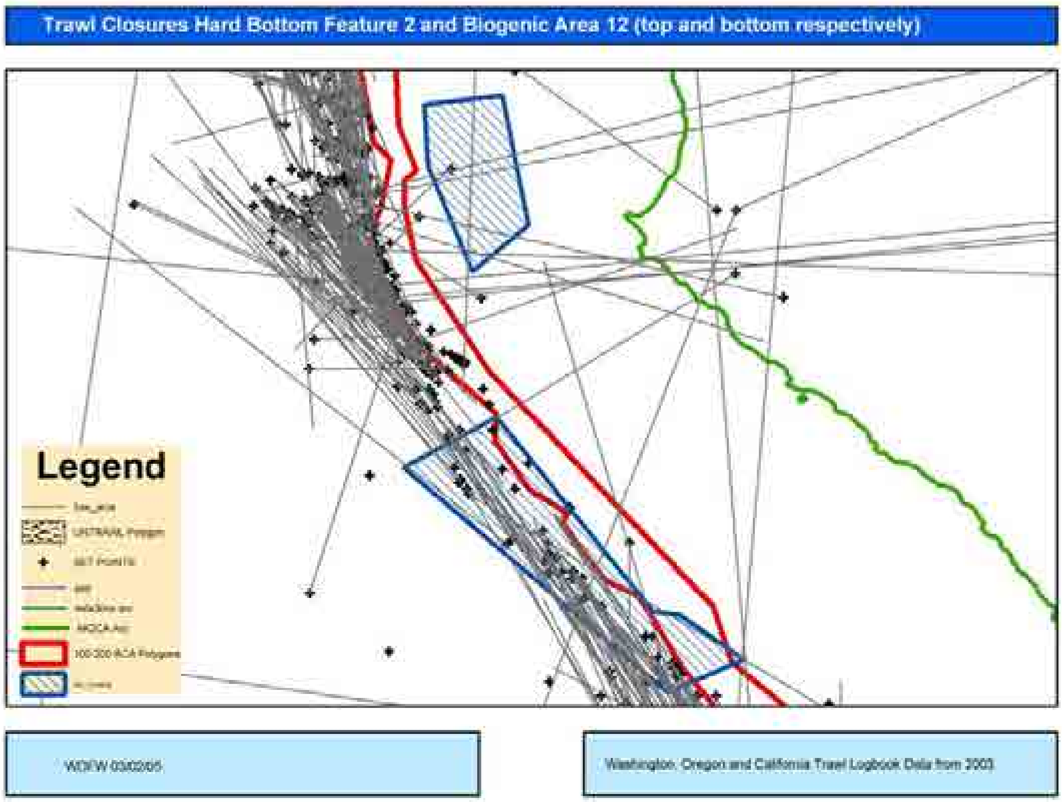

Figure Q: 2003 bottom trawl logbook set points (courtesy WDF&W)

41. Cordell Bank

Original Alternative C.12 estimated displaced revenue= $140,883
Revised Alternative C.12 estimated displaced revenue= $49,064 (likely overestimated, trawl tracks fall outside of area, see Figure R below)

Cordell Bank is an underwater island 7 km by 15 km surrounded by deep water on three sides. Due to a unique combination of topographic and oceanographic features, this area is extremely productive. At depths between 35 and 50 meters, the rocky habitats are carpeted with sponges, ascidians, hydrocorals, anemones, and sea stars. Fed by the productive currents, this seafloor habitat creates complex living structures for juvenile rockfish, lingcod, and many species of adult rockfish.

Designated as a National Marine Sanctuary in 1989, Cordell Bank is one of the most productive offshore areas in the United States. The combination of the California current, upwelling of nutrient rich ocean waters and the topography of the area provides for a flourishing ecosystem. This area is thickly covered by sponges, anemones, hydrocorals, and other invertebrates. It also hosts 180 species of fish, providing spawning habitat for lingcod. Finally this area hosts twenty six resident and migratory species of marine mammals.[6]

[6] Cordell Bank State of the Sanctuary Report. http://sanctuaries.nos.noaa.gov/oms/omscordell/omscordell.html

The boundary of area as it was proposed in Original Alternative C.12 was modified in Revised Alternative C.12 to avoid some trawled areas (Figure R) along the western slope and a south portion of the shelf. The Revised Alternative C.12 boundary closely follows the closed area boundary suggested by representatives of the bottom trawl industry (Figure 45). As such, minimal bottom trawl effort should be displaced by this suggested closure.

The ridges and pinnacles covered with structure forming invertebrates provides complex habitat which is sensitive to bottom tending gears. The proposed area contains 58 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). NOAA trawl surveys have documented 20 records of habitat-forming invertebrates, including gorgonian corals, sea pens, sea whips, and sponges.

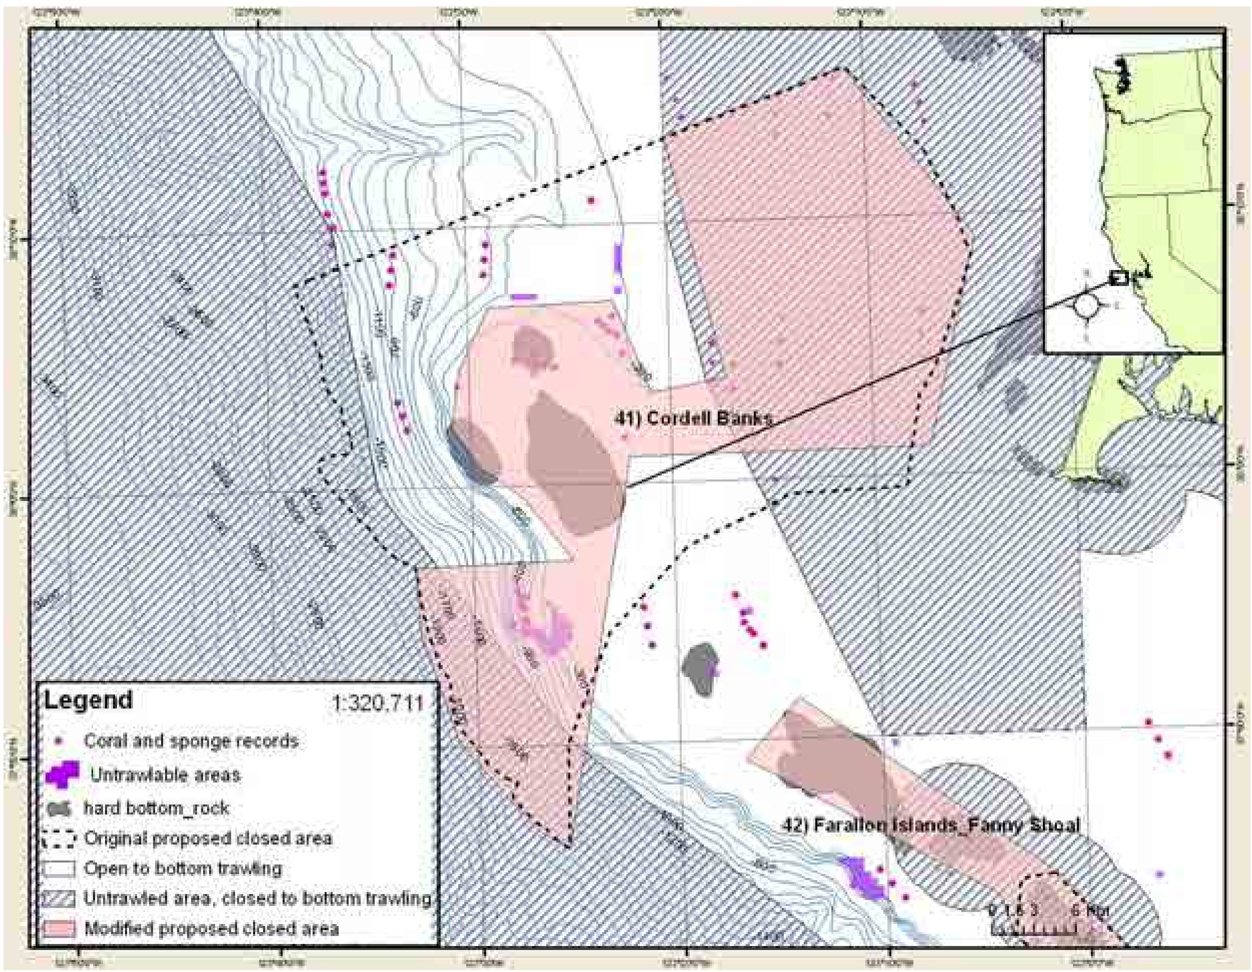

Figure 45: Cordell Bank

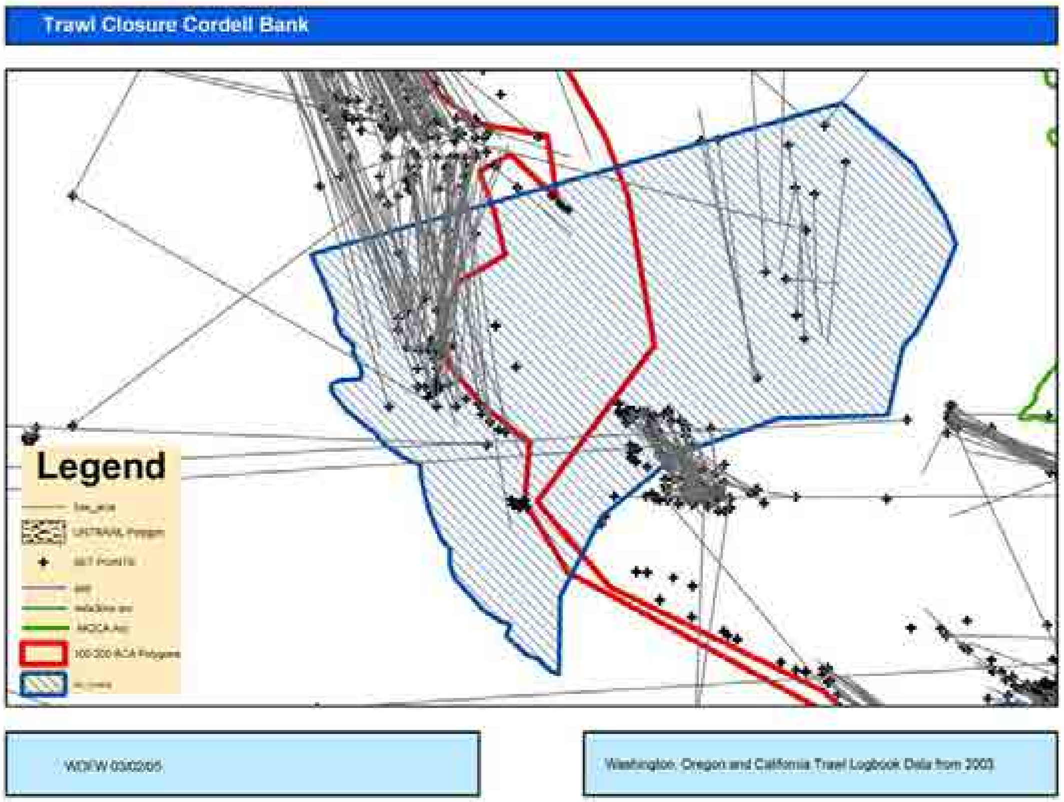

Figure R: 2003 bottom trawl logbook set points (courtesy WDF&W)

42. Farallon Islands_Fanny Shoal

Original Alternative C.12 estimated displaced revenue= $78
Revised Alternative C.12 estimated displaced revenue= $9,967 (likely overestimated, trawl tracks fall outside of area, see Figure S below)

This area was previously proposed as "*hard bottom feature_3*". The boundary of the proposed closure was modified to encompass more areas of hard bottom habitat to the north (Figure 46). Much of the proposed area falls within existing state of California bottom trawl closures. Trawl logbook information indicates little bottom trawl effort occurs in the area (Figure S), and minimal effort should be displaced by this suggested closure. The displaced revenue reported here is likely overestimated. This area around the Farallon Islands has not been well sampled by NOAA trawl surveys. The proposed area contains one record of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003). The California Academy of Sciences collected 3 specimens of coral in the area; the bubblegum coral *Paragorgia*, *Callagorgia*, and the stylasteridae coral *Stylantheca sp*.

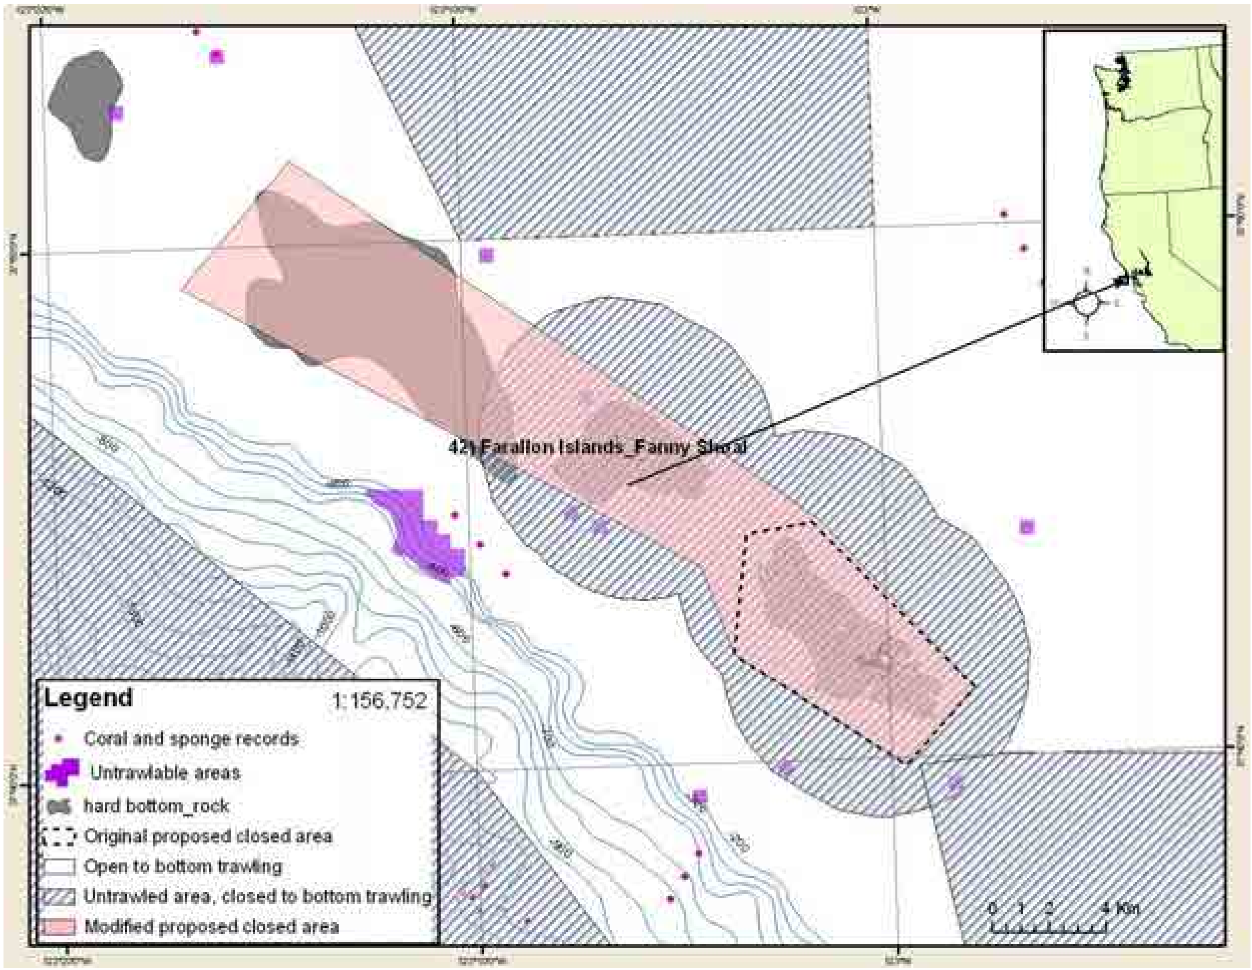

Figure 46: Farallon Islands_Fanny Shoal

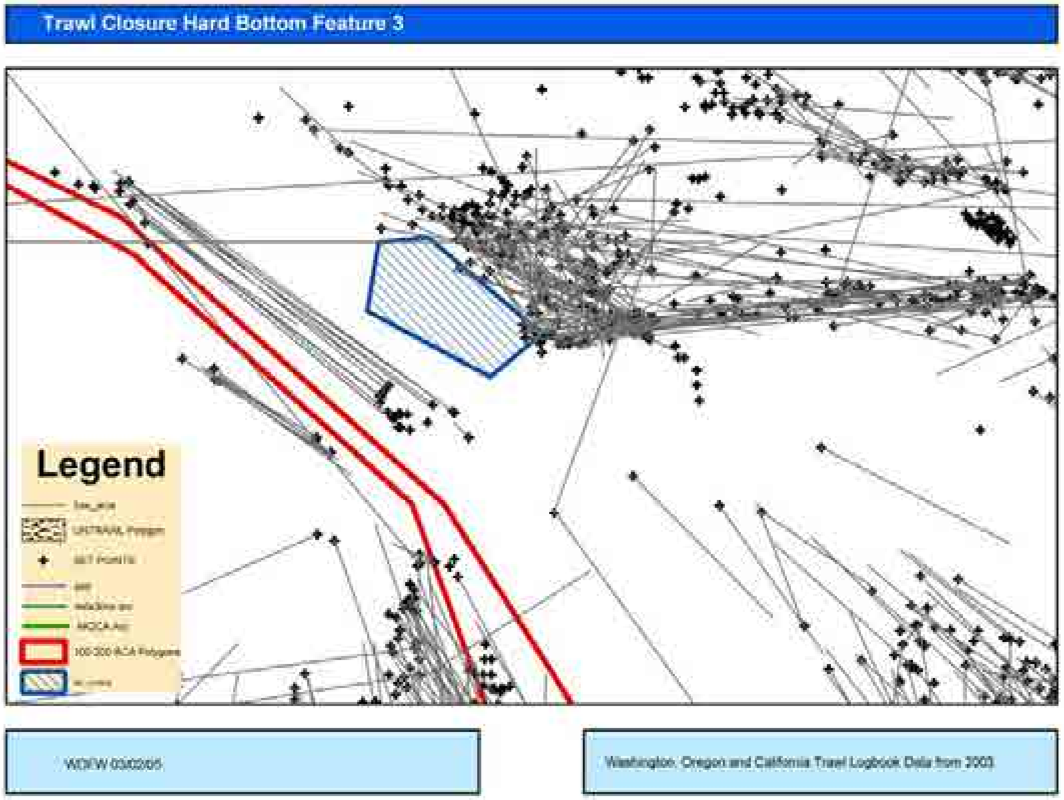

Figure S: 2003 bottom trawl logbook set points (courtesy WDF&W)

43. Half Moon Bay

Original Alternative C.12 estimated displaced revenue= $580
Revised Alternative C.12 estimated displaced revenue= $41,073 (likely overestimated, trawl tracks fall outside of area, see Figure T below)

This area was previously proposed as "*hard bottom feature_4*". This area of rocky shelf habitat is located offshore of Half Moon Bay (Figure 47). It is likely difficult to trawl in this area, and logbook information indicates that little bottom trawl effort occurred in the area. As such, the displaced revenue reported here is likely overestimated. The proposed area contains 6 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003).

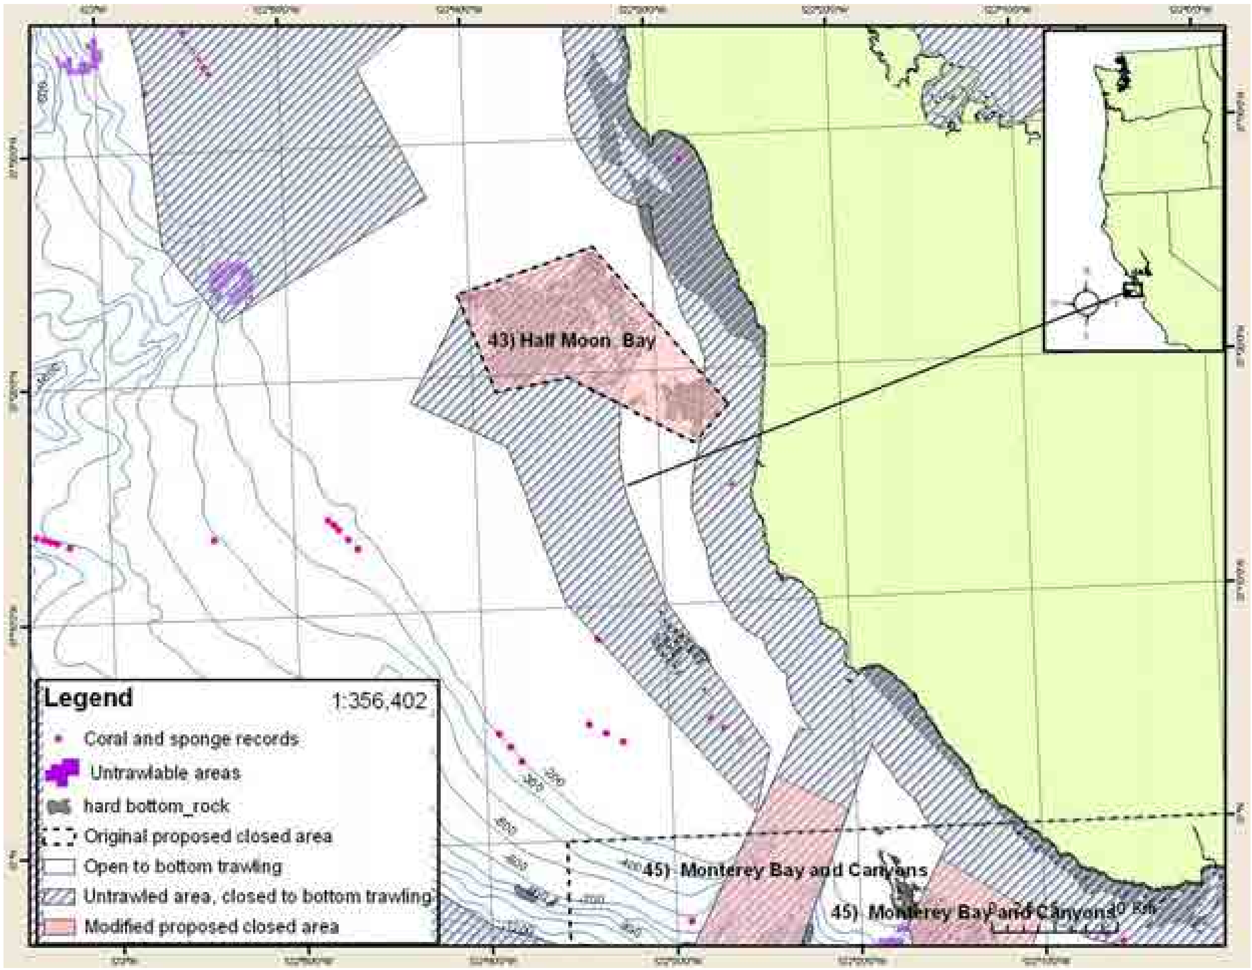

Figure 47: Half Moon Bay

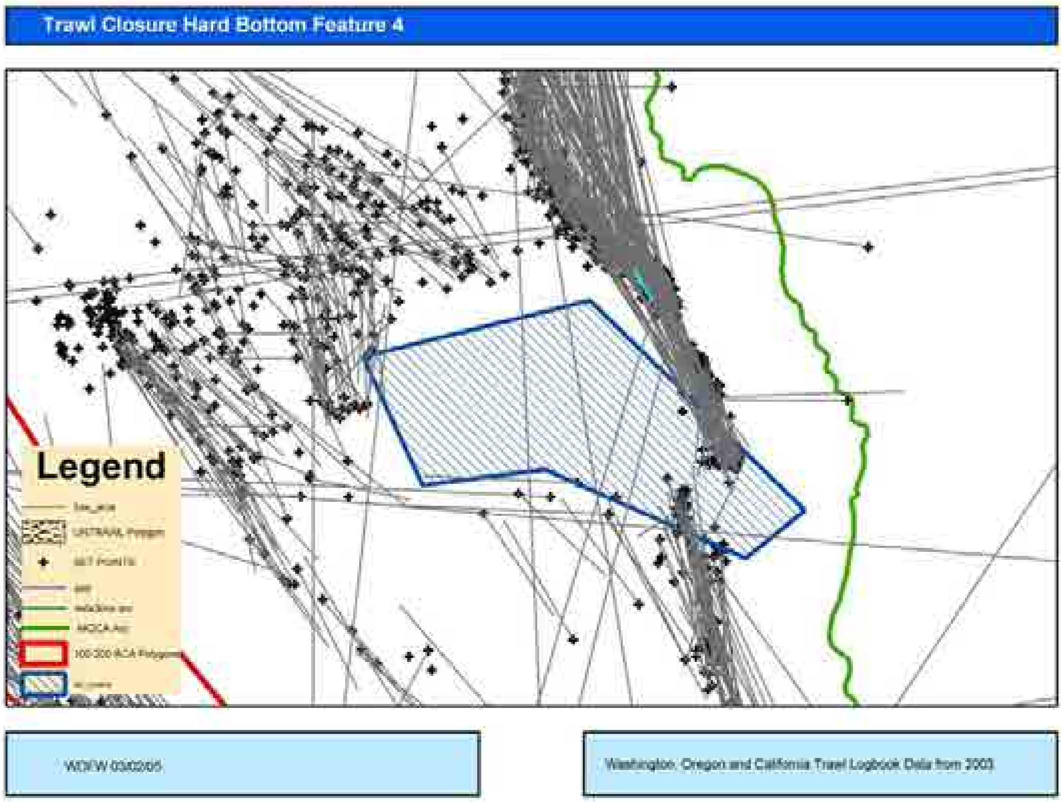

Figure T: 2003 bottom trawl logbook set points (courtesy WDF&W)

44. Point Sur_deep

Original Alternative C.12 estimated displaced revenue= N/A
Revised Alternative C.12 estimated displaced revenue= $10,173 (likely overestimated, trawl tracks fall outside of area, see Figure U below)

This area is located offshore in deep water, and was also suggested as an area for closure by the bottom trawl industry. A rocky escarpment rises 400 meters in the middle of the area, and the proposed area contains habitat from 1000 to 1400 meters depth (Figure 48). Eleven records of habitat-forming invertebrates, including sea pens and sea whips, have been documented in the area by NOAA trawl surveys. The proposed area is located outside the trawl footprint, and minimal effort should be displaced by this suggested closure.

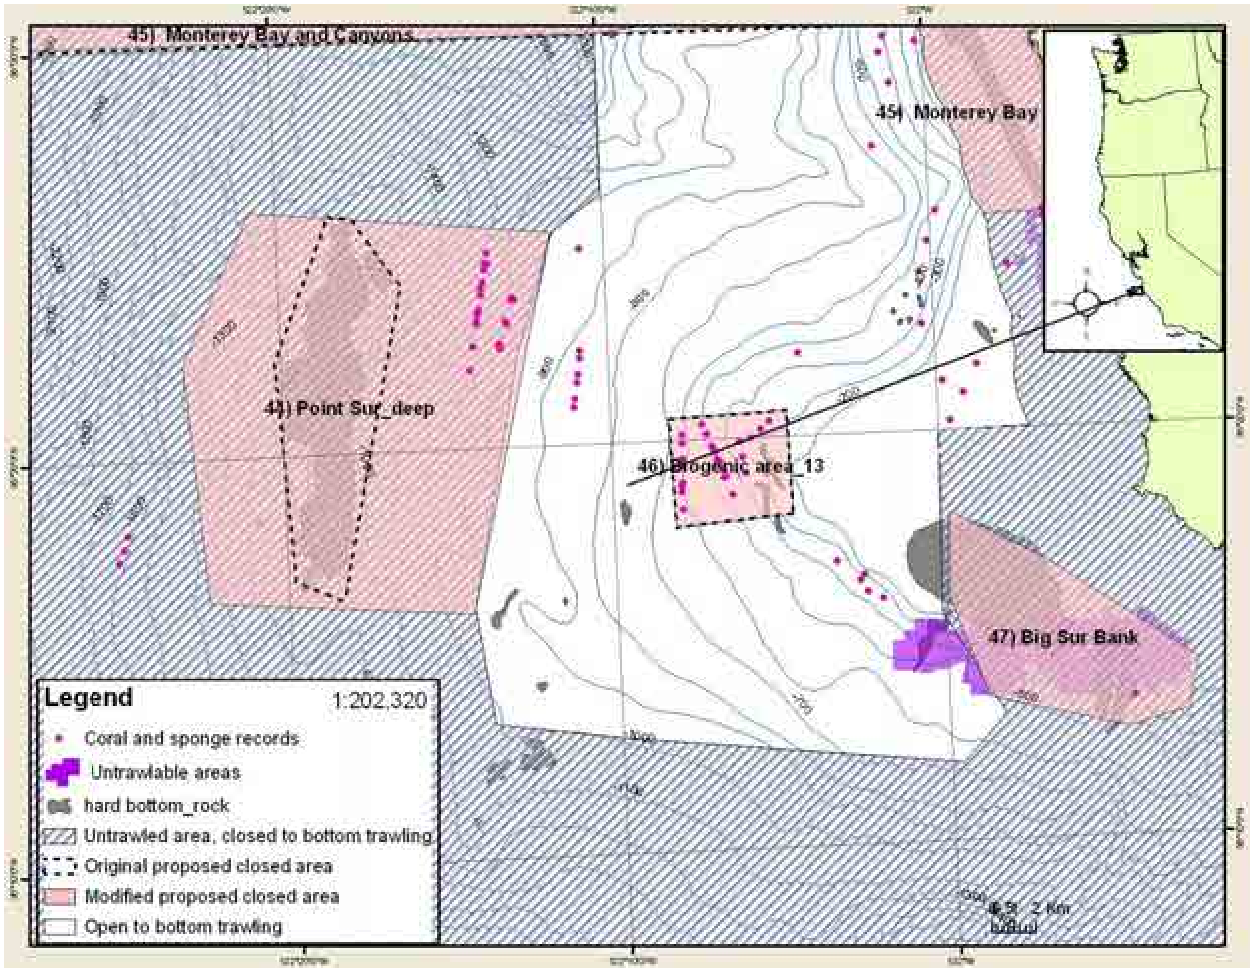

Figure 48: Point Sur_deep

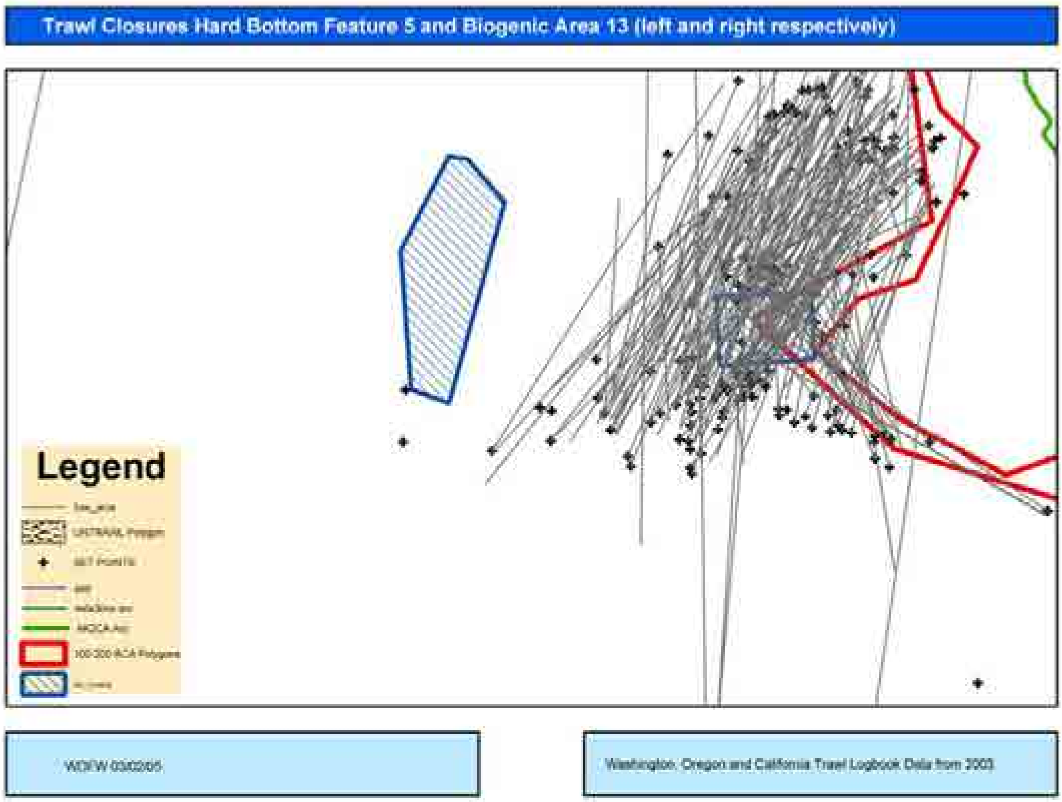

Figure U: 2003 bottom trawl logbook set points (courtesy WDF&W)

45. Monterey Bay and canyons

Original Alternative C.12 estimated displaced revenue= $645,196
Revised Alternative C.12 estimated displaced revenue= $191,468 (likely overestimated, trawl tracks fall outside of area, see Figure V below)

The deepest and largest submarine canyon on the coast of North America is the Monterey Canyon, just south of San Francisco, California (Figure 48). This canyon is 470 km long, approximately 12 km wide at its widest point, and has a maximum rim to floor relief of 1700 m, making it much larger than Arizona's Grand Canyon.

Monterey Bay and Canyon are part of the Monterey Bay National Marine Sanctuary designated in 1992. These areas contain a rich array of habitats from rugged rocky shores and lush kelp forests and one of the largest underwater canyons in North America. The sanctuary supports thirty three species of marine mammals, ninety-four species of seabirds, 345 species of fish, four species of sea turtles and thousands of species of invertebrates.[7] The area contains complex, canyon habitat and pinnacles. The proposed closed area in Revised Alternative C.12 contains 185 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003).

[7] State of the Sanctuary Report. Monterey Bay National Marine Sanctuary. http://www.mbnms.nos.noaa.gov

Trawl logbook information indicated that bottom trawling occurs in several discrete areas of the bay and off the slope (Figure V). The bottom trawl industry suggested a closure for the area that avoided closing any of these areas. As such, the boundaries of the original proposal were modified to avoid most of the trawled areas, and follows much of the boundary proposed by the trawl industry. Therefore, minimal displaced effort should result from the proposed closure and the displaced revenue reported here is likely overestimated.

The area is rich in records of habitat-forming invertebrates. NOAA trawl surveys have documented nine records of gorgonian corals, sea pens and sponges. Submersible dives by MBARI have documented 290 records of deep-sea corals in the proposed area, including bubblegum corals, black corals, and bamboo corals. The California Academy of Sciences has collected samples of hydrocorals, *Plumerella sp*., *Callogorgia sp*., *Paragorgia sp*., and bamboo corals.

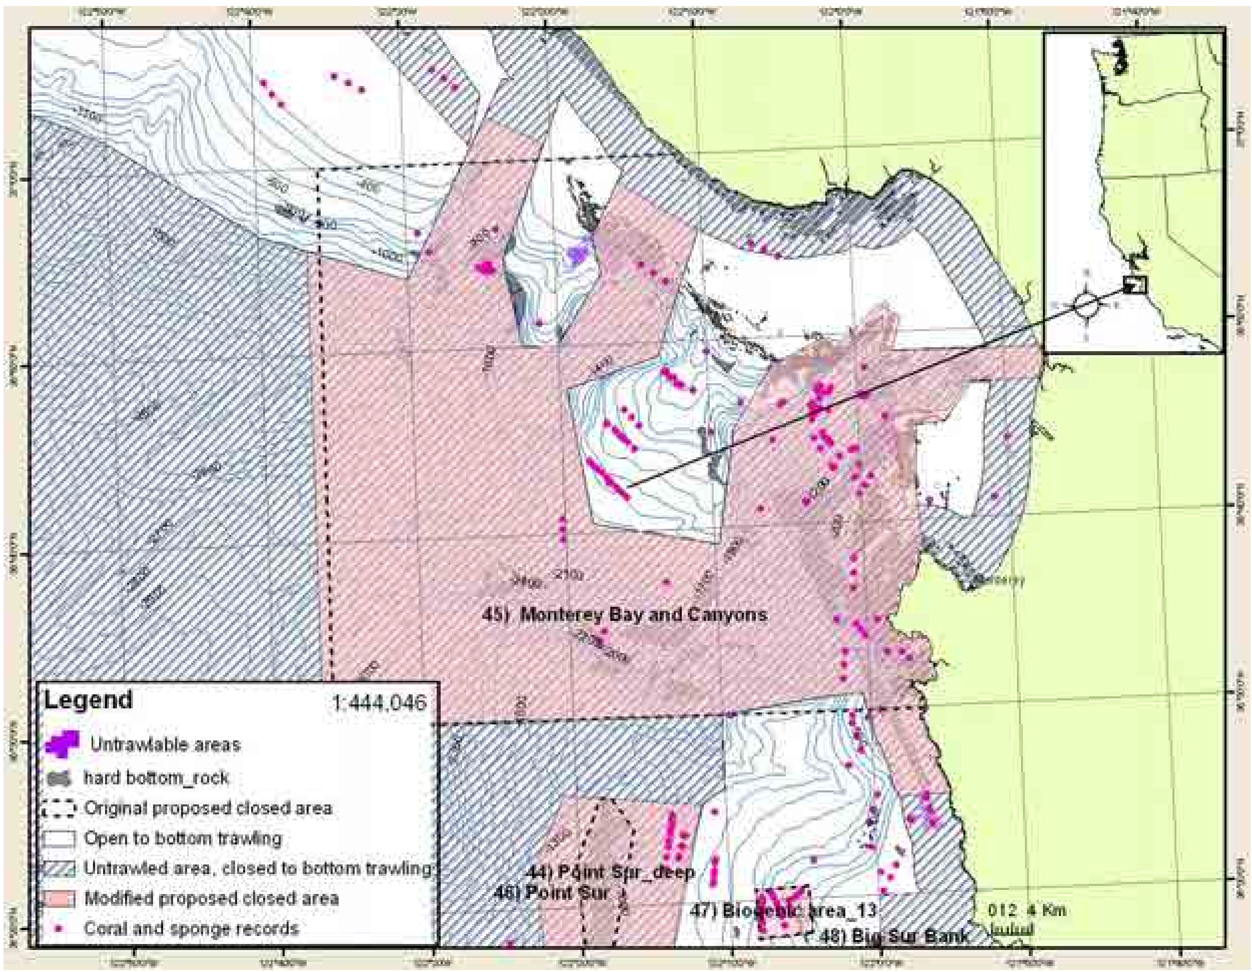

Figure 48: Monterey Bay and Canyon

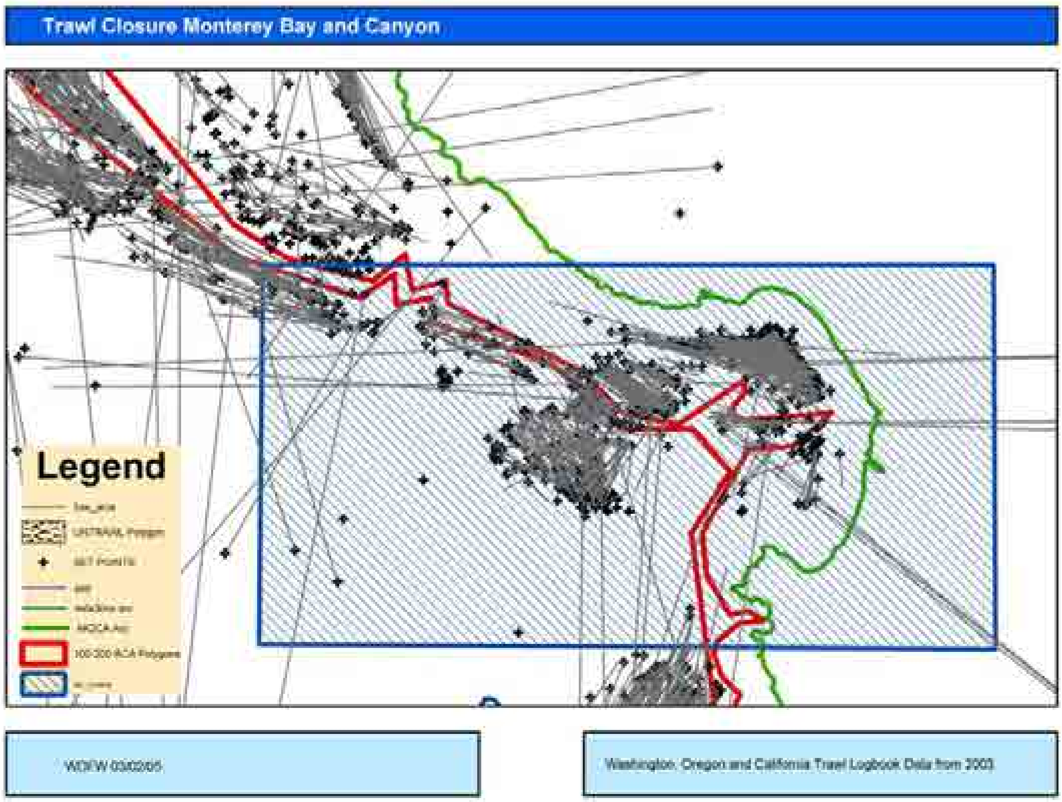

Figure V: 2003 bottom trawl logbook set points (courtesy WDF&W)

46. Biogenic_13
Original Alternative C.12 estimated displaced revenue= $26,257
Revised Alternative C.12 estimated displaced revenue= $11,282

The proposed area contains several rocky habitat features, and spans habitat from 300 to 700 meters depth (Figure 49). NOAA trawl surveys within the proposed area have documented 21 records of habitat-forming invertebrates, including black corals, gorgonian corals, sea pens, and sponges. Trawl logbook information indicates that trawling occurs across the proposed area (Figure U). However, the area suggested for closure is small relative to surrounding trawled area. This proposed area would be a good candidate for a control study site to assess the effects of bottom trawling on habitat.

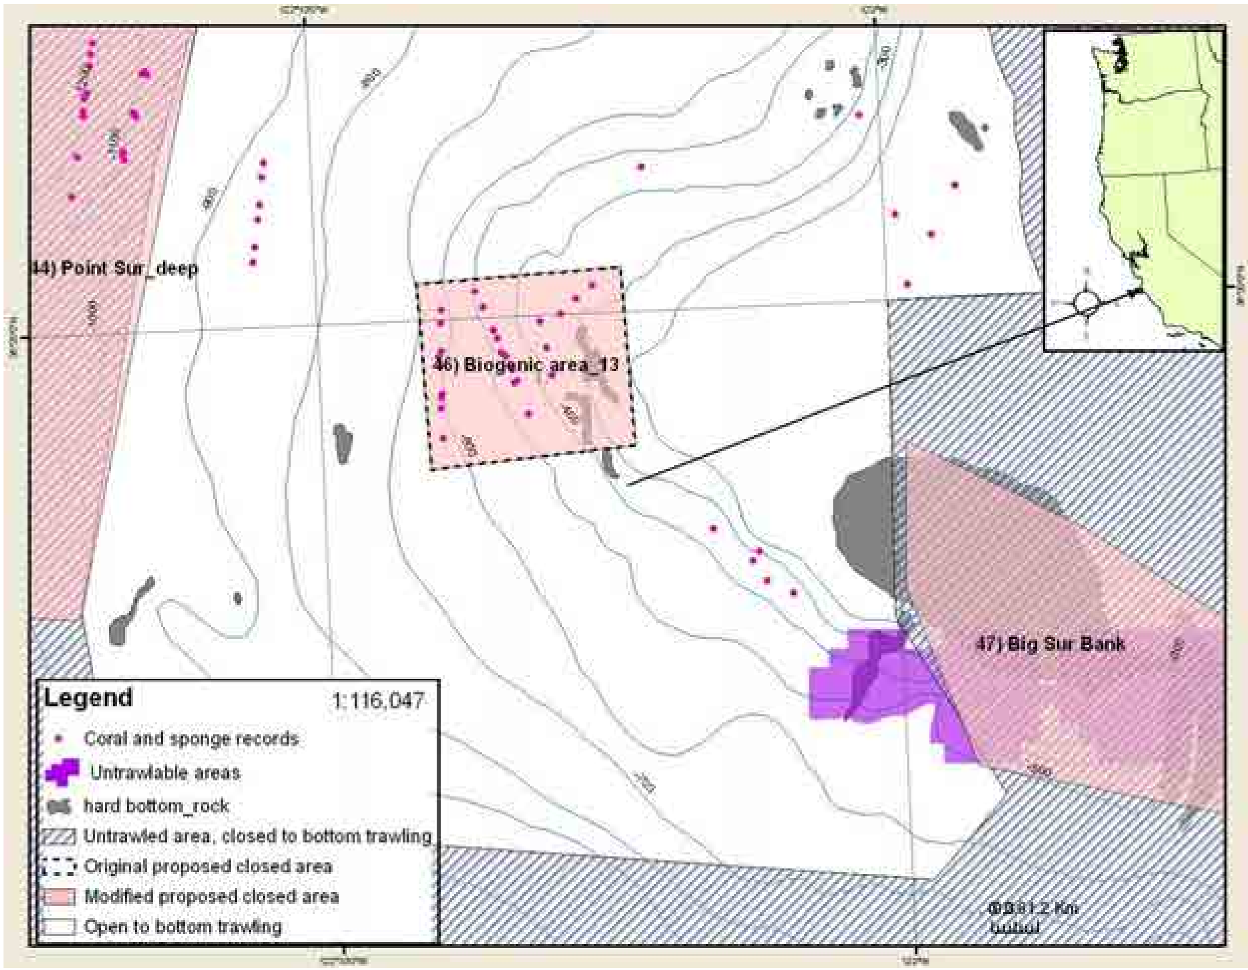

Figure 49: Biogenic_13

47. Big Sur Bank

Original Alternative C.12 estimated displaced revenue= N/A

Revised Alternative C.12 estimated displaced revenue= $41,694 (likely overestimated, trawl tracks fall outside of area, see Figure V above)

This area contains rocky shelf habitat under 200 meters depth off the coast of Big Sur point (Figure 50). Trawl logbook information indicates no trawl activity in the area, and the area is located outside the bottom trawl footprint. Therefore, minimal displaced effort should result from the proposed closure. The displaced revenue reported here is likely overestimated. The proposed area contains 175 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003).

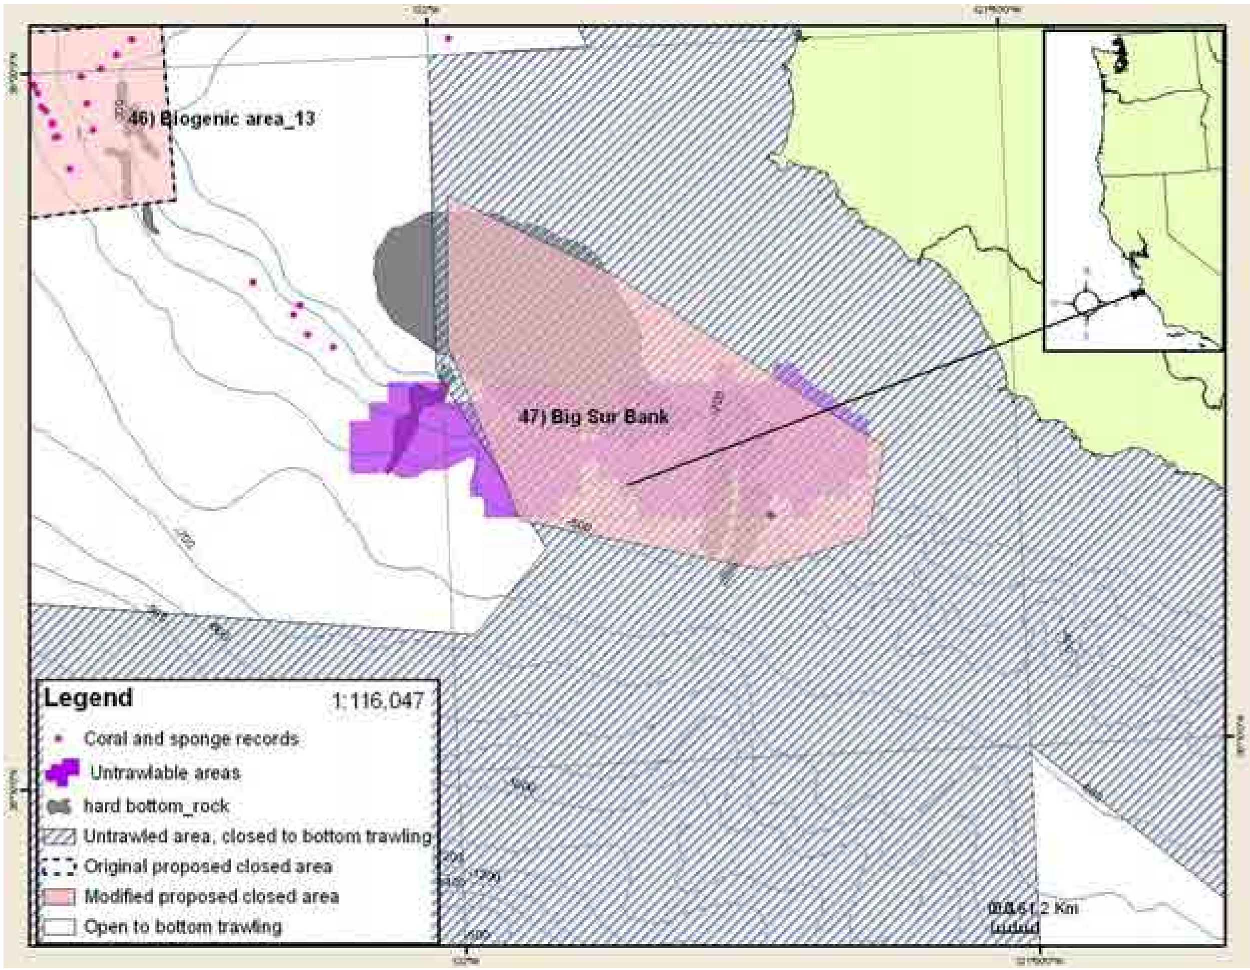

Figure 50: Big Sur Bank

48. Morro Ridge

Original Alternative C.12 estimated displaced revenue= $258,779
Revised Alternative C.12 estimated displaced revenue= $30,125 (likely overestimated, trawl tracks fall outside of area, see Figure W below)

Morro Ridge is a long ridge of hard substrate off the Central California coast (Figure 51). The southern portion of the ridge rises to 500 meters depth while the northern portion drops to 1000 meters. Trawl logbook information indicated that some trawl effort occurred along the eastern edge and south western point of the previously proposed closed area (Figure W). The proposed closed area for Revised Alternative C.12 avoids these areas, and minimal displaced effort should result from the proposed closure.

The Revised Alternative C.12 closed area contains numerous records of habitat-forming invertebrates from NOAA. NOAA trawl surveys have documented 81 records of gorgonian corals, sea pens, sea whips, and sponges. The proposed area contains 26 records of underwater obstructions, trawl hangs and areas where NOAA survey nets have hung up, identified by the "untrawlable" polygons determined by Zimmerman (2003).

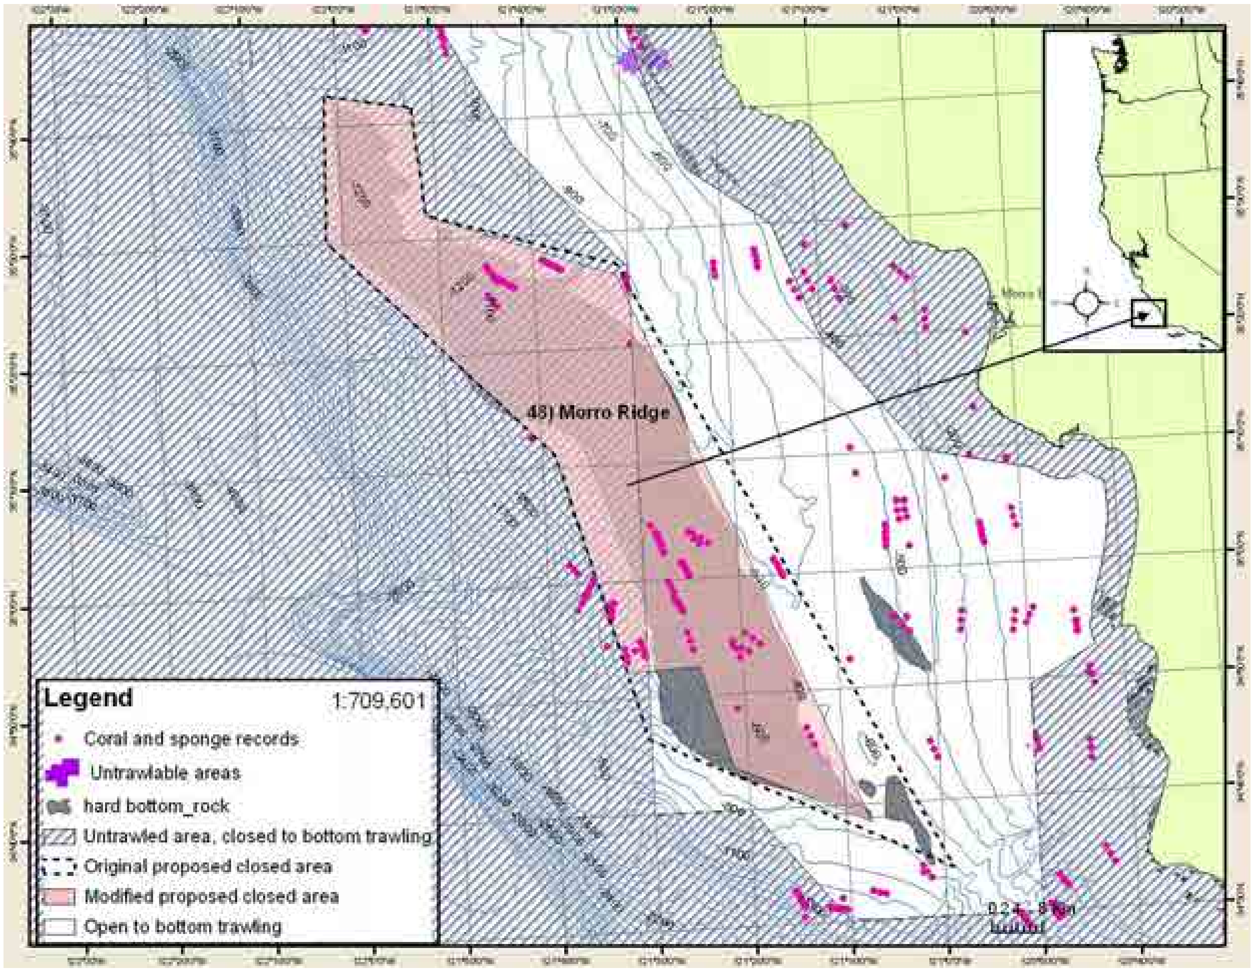

Figure 51: Morro Ridge

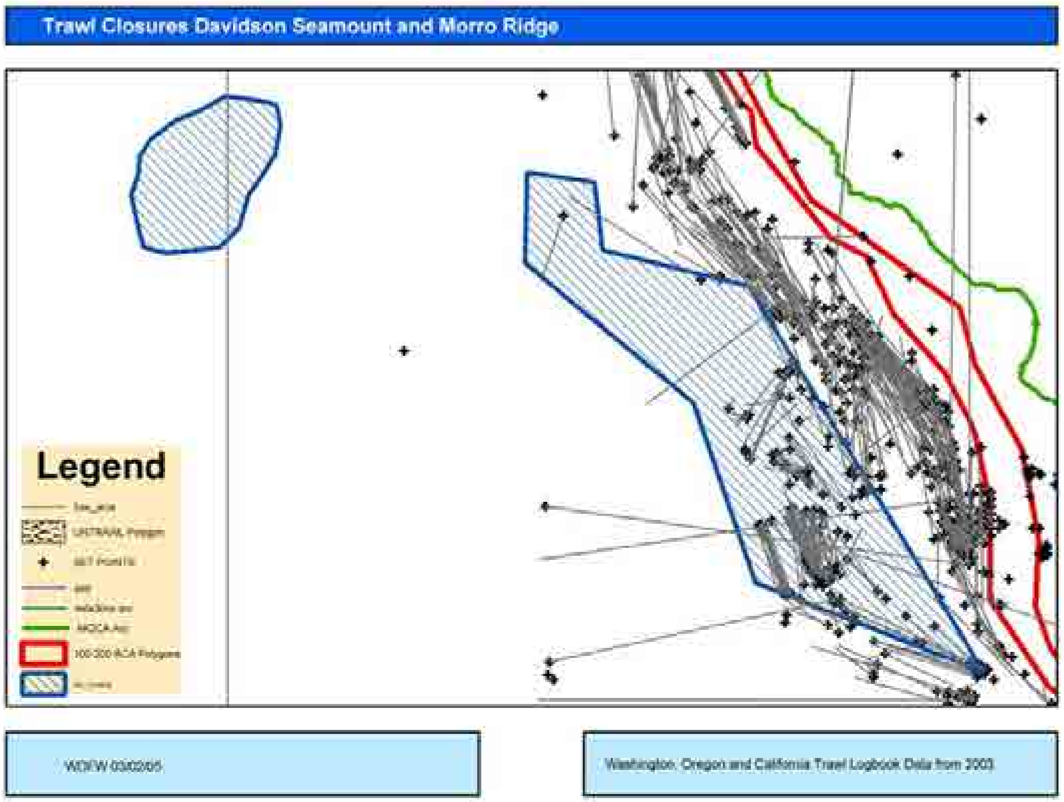

Figure W: 2003 bottom trawl logbook set points (courtesy WDF&W)

49. Channel Islands

Original Alternative C.12 estimated displaced revenue= 0
Revised Alternative C.12 estimated displaced revenue= $11,016 (likely overestimated, trawl tracks fall outside of area, see Figure X below)

The Channel Islands National Marine Sanctuary contains numerous records of biogenic habitat, particularly gorgonian corals (Figure 52). It is located at the meeting point between two major oceanographic currents, and therefore has a relatively high diversity of marine life from both tropical and temperate marine ecosystems. While the area has not been well sampled with trawl gear, NOAA trawl surveys within the proposed area have documented 6 records of Hexactinellid sponges at up to 296 kg per survey haul. The California Academy of Sciences has documented hydrocoral in the area. The Smithsonian Institution has documented three rare collections of the reef building deep-sea corals *Lophelia pertusa* and *Madrepora occulata.* Trawl logbook information indicates little trawl activity (Figure x). The proposed closed area encompasses existing state of California bottom trawl closures, therefore minimal displaced effort should result from the proposed closure. The estimated displaced revenue reported here is likely overestimated.

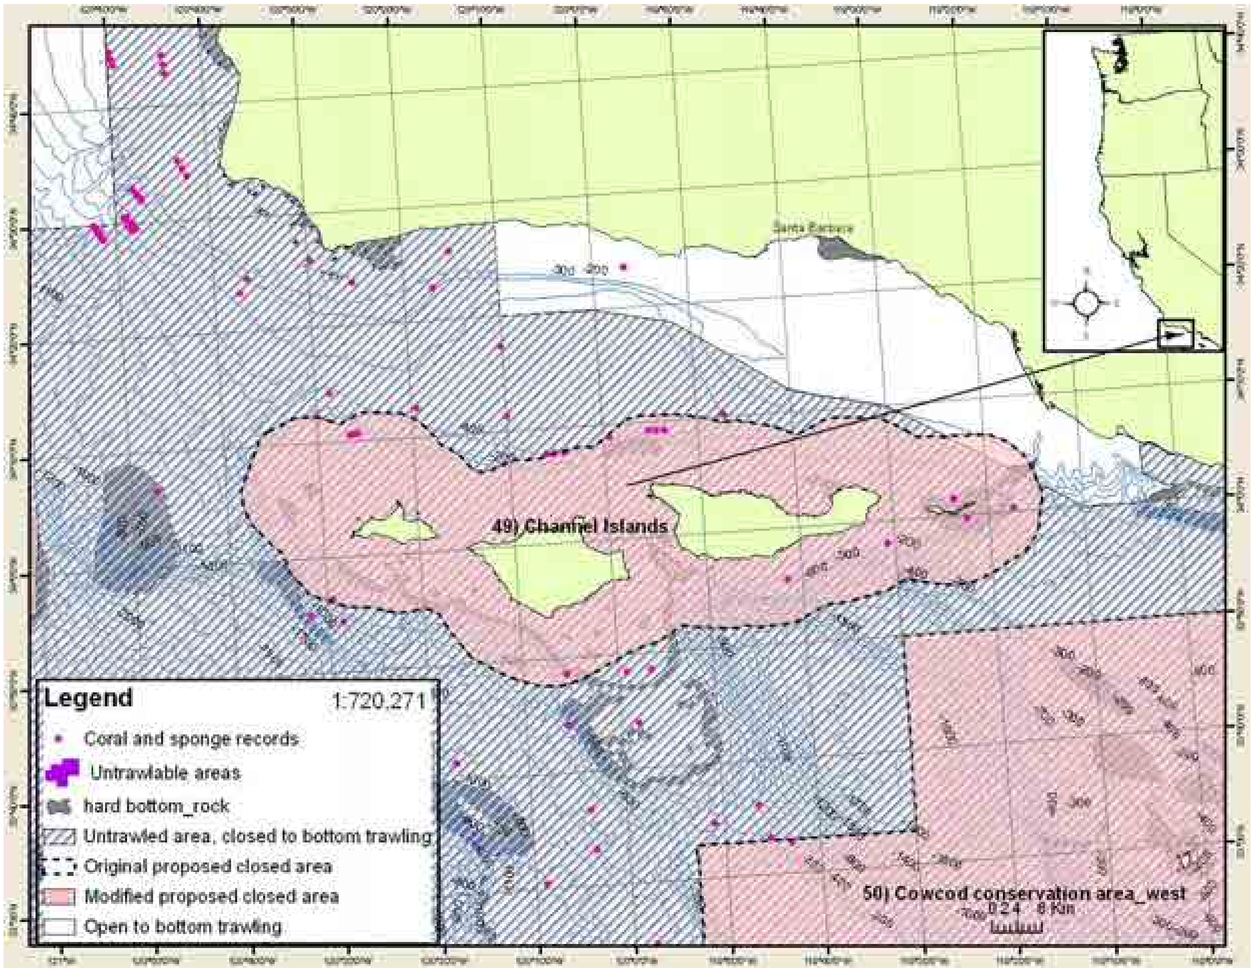

Figure 52: Channel Islands

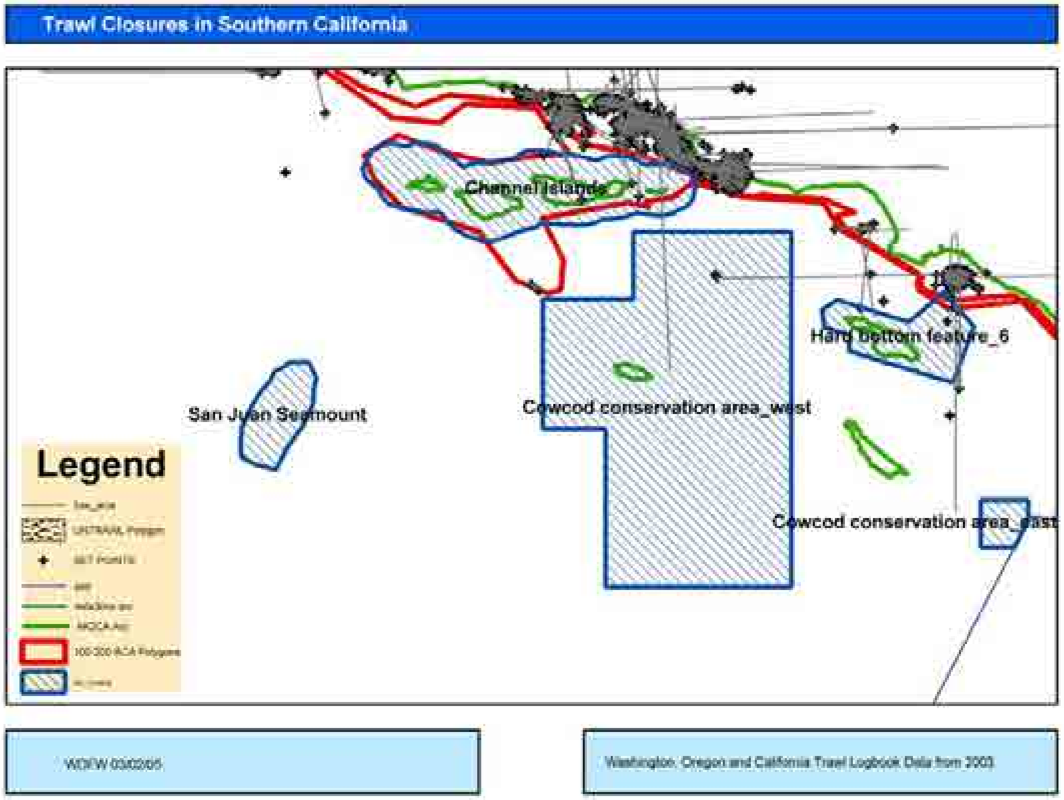

Figure X: 2003 bottom trawl logbook set points (courtesy WDF&W)

50. Cowcod conservation area_west
52. Cowcod conservation area_east
Original Alternative C.12 estimated displaced revenue=$0
Revised Alternative C.12 estimated displaced revenue= $0

The Cowcod Conservation Areas (Figure 53) were established by the Pacific Fishery Management Council and the National Marine Fisheries Service in 2001 to help protect and rebuild cowcod which have been driven down by 89 to 96 percent of unfished levels. Cowcod is a long-lived species with low productivity requiring almost a century to rebuild the population.[8] Due to the low levels of allowable mortality necessary to rebuild cowcod, the primary rebuilding strategy is avoidance.[9] These areas contain hard bottom habitats including a number of offshore banks.[10] While the area has not been well sampled with trawl gear, NOAA trawl surveys within the area have documented three records of Hexactinellid sponges. Submersible dives have also

[9] *Id*. at 45.
[10] Analysis provided by NMFS for the EIS Oversight Committee in Portland, OR on August 16-18, 2004.

documented occurrences of black corals.[11] The area is not trawled due to the current closure, and logbook information indicates that little trawling has occurred in the recent past (Figure X). Therefore minimal displaced effort should result from the proposed closure.

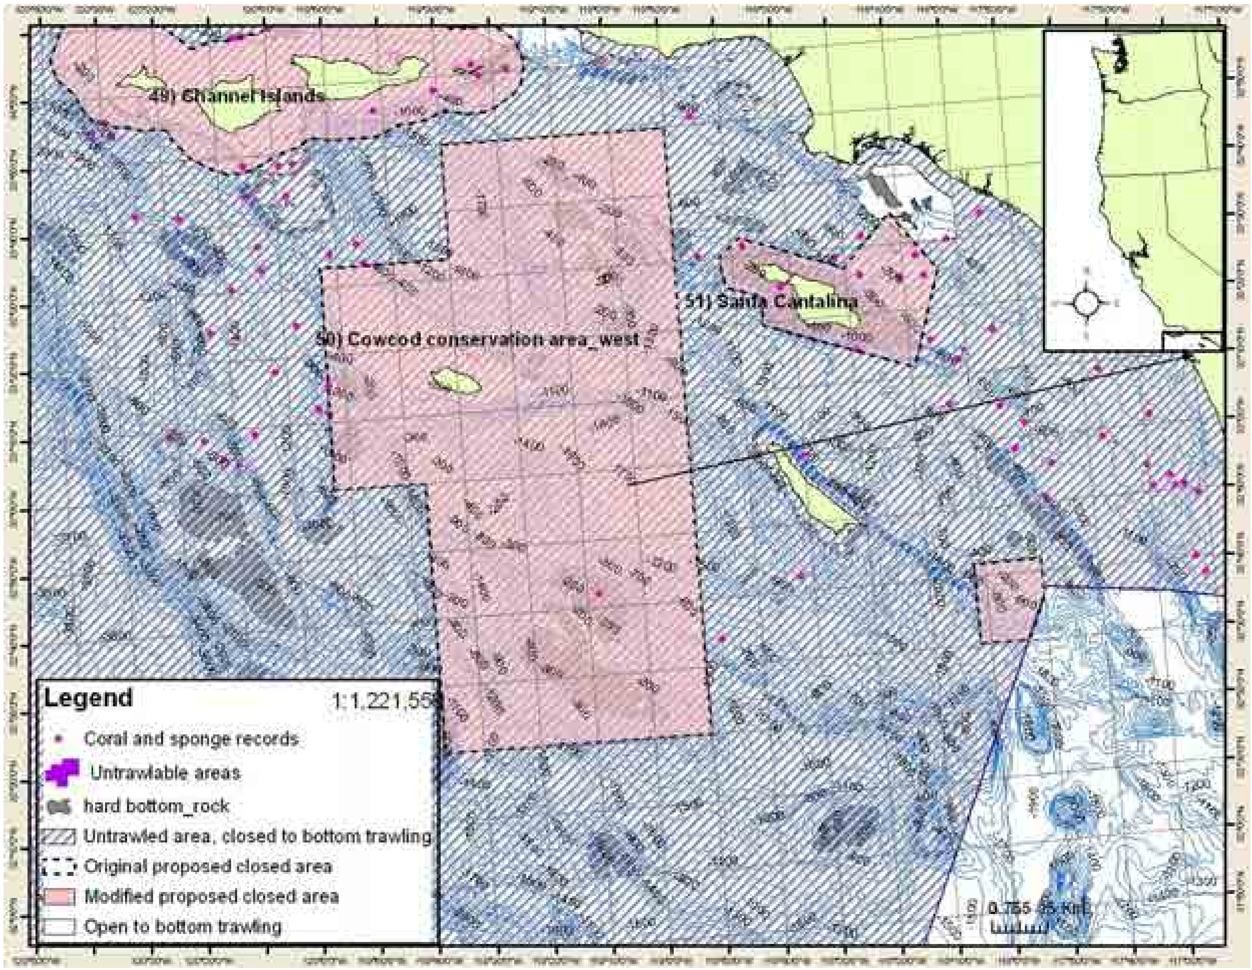

Figure 53: Cowcod conservation areas east and west

51. Santa Cantalina

Original Alternative C.12 estimated displaced revenue= $0
Revised Alternative C.12 estimated displaced revenue= $2,315

This area contains habitat around Santa Cantalina (Figure 54). This area had previously been proposed as "*hard bottom feature_6*". While the area has not been well sampled with trawl gear, NOAA trawl surveys within the area have documented 9 records of habitat-forming invertebrates including Hexactinellid sponges, sea pens, and black corals. The Santa Barbara Museum of Natural History has documented the rare reef-building deep-sea coral *Lophelia pertusa* in the proposed closed area. Trawl logbook information indicates that little trawl activity occurs in the proposed area, and most of the area is located outside the trawl footprint (Figure X). Therefore

---

[11] Preliminary Report on Occurrences of Structure-Forming Megafaunal Invertebrates off the West Coast of Washington, Oregon and California. Northwest Fishery Science Center. August 2004.

minimal displaced effort should result from the proposed closure and the displaced revenue reported here is likely overestimated.

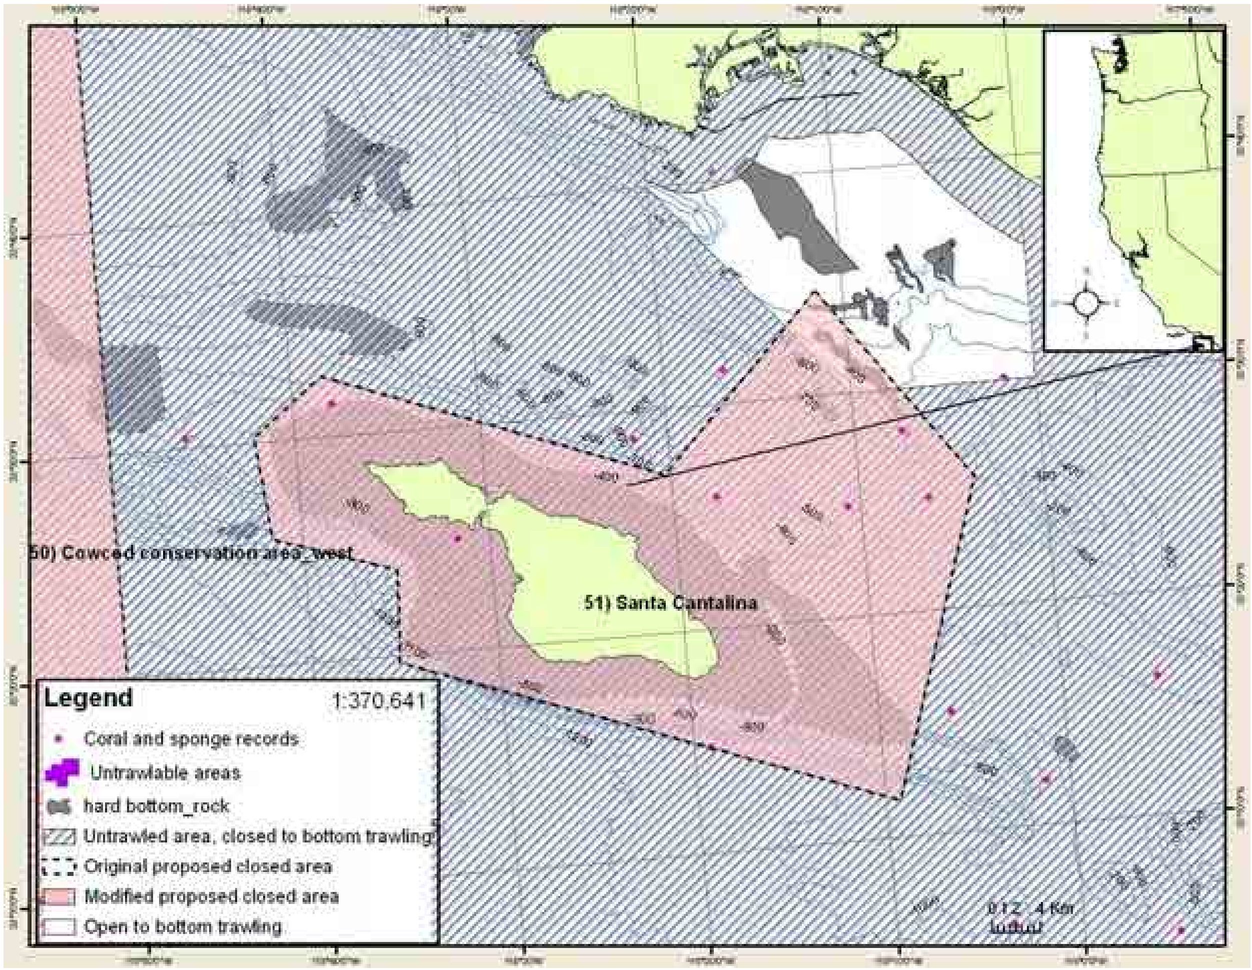

Figure 54: Santa Cantalina

Seamounts

Eight undersea structures of volcanic origin that meet the definition of seamount (those that rise up more than 1000 meters from the seafloor) have been identified within the jurisdiction of the PFMC. These are President Jackson, Thompson, San Juan, Guide, Pioneer, Gumdrop, Rodriguez, and Davidson Seamounts. The location and areal delineation of seven of the seamounts were plotted in GIS from data provided on the *Consolidated GIS Data, Volume 1, Physical and Biological Habitat data disk* (PFMC 2003). An additional seamount, Rodriguez Seamount, was not included in the GIS data disk, but was later identified and incorporated into the Revised Alternative.

Davidson Seamount has been the most well explored of the seamounts, and numerous records of bubblegum corals, black corals, and Hexactinellid sponges have been documented. DeVogelaere et al. (2003) found 24 coral taxa on Davidson Seamount and described numerous species associations, particularly that *Paragorgia sp*. were found in areas with highest species diversity. All of the seamounts off the Pacific coast have not been subject to bottom trawling and all are located outside the bottom trawl footprint. Logbook data documented no trawling on any seamounts on the U.S. West Coast. Therefore, there would be no economic impacts from bottom trawl closures that prevent future damage to these unique communities.

* Indicates areas in the revised Alternative C.12 proposal which were not identified in the original Alternative C.12.
\# Indicates areas in the original Alternative C.12 proposal which were split into component areas in the revised Alternative C.12.

As a result of analyses of the spatial distribution of trawl track information from logbooks, input from trawl fishermen, and comments from the SSC, areas of Alternative C.12 were revised to provide for expanded trawl grounds while protection of habitat areas. This revised Alternative C.12 reduces revenue displacement across the EFH area while maintaining integrity of protection/mitigation. The revised Alternative C.12 results in displacement of less than 15% and far less loss in any actual revenue.

The estimates of displaced revenue of the original Alternative C.12 proposal were provided by the WDF&G, who estimated displaced revenue by summing catch from 2003 trawl logbook set points contained within the closed area. The estimates of the revised Alternative C.12 were made by determining the proportional overlap of a closed area with 2000-2003 trawl effort data that was provided in 10 x 10 minute blocks. The proportional method assumes a uniform distribution of fishing effort across a block. However, the revised closed area boundaries were made with the spatial distribution of trawl tracks

DETAILED SUPPORT AND JUSTIFICATON OF REVISED ALTERNATIVE C.12

While perfect information is not available for the designation of Essential Fish Habitat, or the determination of adverse impacts to that habitat, the potential for long-term and perhaps irreversible adverse impacts demands that precautionary action be taken immediately to reduce the impact of bottom trawling on the U.S. West Coast seafloor. The literature on environmental policy generally concludes that higher uncertainty justifies stronger policy intervention to avoid damages than certainty-equivalent cases (i.e. Nordhaus 1994). The reason for this result is that the amount of damage is non-linear. In other words, the increases in damages are greater in the worst case scenario than the decreases in the best-case scenario. This result is highly applicable to the analysis of EFH designation and mitigation measures because of the severity of economic damages in the worst case scenario. For example, if it turns out that commercial fish productivity is strongly tied to the presence of biogenic habitat structures (as suggested in the literature), the long-term effects of continued damage to these habitats would be extremely severe and irreversible from a fisheries perspective. Therefore, even if there is a low probability of this outcome, a comprehensive policy analysis should pay strong attention to this outcome in the evaluation of different policy interventions to minimize adverse impacts to EFH.

While there continue to be uncertainties, a substantial amount of scientific studies and data are available, both to designate Essential Fish Habitat and mitigate the adverse effects of fishing to the extent practicable. Based on the information currently available, it is clear that bottom trawling is causing adverse impacts to Essential Fish Habitat on the U.S. West Coast and that the revised Alternative C.12 (presented in this document) is the most practicable solution to minimize these adverse impacts.

Designation of Essential Fish Habitat

Given the available information concerning designation of Essential Fish Habitat, the alternative most consistent with a precautionary, ecosystem-based management approach to fisheries is Alternative A.2 with the addition of seamounts. This alternative is also consistent with the EFH Final Rule, which speaks directly to the various levels of information which may be available to determine EFH. Section 600.815(a)(1) recognizes four levels of EFH information for each life stage of each species:

(*1*) *Level 1: Distribution data are available for some or all portions of the geographic range of the species.*
(*2*) *Level 2: Habitat-related densities of the species are available.*
(*3*) *Level 3: Growth, reproduction, or survival rates within habitats are available.*
(*4*) *Level 4: Production rates by habitat are available.*

Based on the information presented in the EFH DEIS, it is clear that EFH information is currently at or below Level 1 for most groundfish in the Pacific Coast groundfish fishery. The EFH Final Rule describes how "habitat use" is to be inferred when information is Level 1:

In the event that distribution data are available only for portions of the geographic area occupied by a particular life stage of a species, habitat use can be inferred on the basis of distributions among habitats where the species has been found and on information about its habitat requirements and behavior. Habitat use may also be inferred, if appropriate, based on information on a similar species or another life stage.

This section also defines the burden of proof standard to be used by the Councils:

Councils should interpret this information in a risk averse fashion to ensure adequate areas are identified as EFH for managed species. Level 1 information, if available, should be used to identify the geographic range of the species at each life stage. If only Level 1 information is available, distribution data should be evaluated (e.g., using a frequency of occurrence or other appropriate analysis) to identify EFH as those habitat areas most commonly used by the species.

Use of the term "risk averse" in this context makes clear that the law and regulations do not require proof of causality before designating EFH, but rather use of whichever level of information is available. When information is at Level 1, any habitat that fish are associated with should be designated as EFH.

Observations of fish outside any given habitat type does not provide evidence that these habitats are not EFH. First, habitat use does not need to be obligate to affect the population of fish. For example, facultative and fortutious habitat use has been shown to enhance fish populations even if the habitat use is not obligate (Mumby et al. 2004). Second, there may be various forms of complex habitat in a given area, giving fish several options to use as shelter, for example. In this case, removal of some of the complex habitat (i.e. corals) decreases the availability of suitable habitats, even though other suitable habitats still remain. Basic ecological theory states that reduction in the availability of suitable habitat reduces the carrying capacity of the species that uses the habitat, even if other suitable habitat remains. This theory is supported by Rubec et al. (1999). Fishery management science in the U.S. is based on the premise that carrying capacity is proportional to maximum productivity (i.e. MSY). Therefore, even if corals are not the only type of complex habitat available to fish, their removal may reduce the productivity of fish. Furthermore, even if biogenic habitat is only utilized by fish at certain times of the year, it may have a strong influence on survivorship or reproductive success. For example, a fish may depend on the presence of biogenic habitat only at specific events such as spawning periods. Even though these events may be infrequent, they have a strong effect on population dynamic processes that determine productivity. Therefore, the absence of fish in biogenic habitat at one specific moment in time is not evidence that the habitat is not linked to the survivorship or fecundity of commercial fish and invertebrates.

Seamounts provide an area of vertical relief from the relatively flat and featureless abyssal plain. As such, seamounts are sites of enriched biological activity with enhanced biomass of pelagic and benthic organisms relative to the surrounding waters (Mullineaux and Mills 1997; Dower and Perry 2001; Haury et al. 2000). Studies indicate that seamounts function as deep-sea islands of localized species distributions, dominated by suspension feeders like corals and sponges which can be easily damaged by fishing gear that makes contact with the bottom (Monterey Bay National Marine Sanctuary, Sanctuary Integrated Monitoring Network, URL: www.mbnmssimon.org/sections/seamounts/overview.php). Recent studies conducted by the Monterey Bay Aquarium Research Institute on West Coast seamounts have documented unique and diverse biological communities. (http://www.mbari.org/volcanism/seamounts/seamountsresearchtop.htm).

Along the crests and slopes of several seamounts, MBARI scientists observed long-lived coral and sponge habitats. DeVogelaere et al. (2003) found 24 coral taxa on Davidson Seamount off California and described numerous species associations, particularly that *Paragorgia sp*. were found in areas with highest species diversity. Guyots are a type of volcanic seamount with a flat top or plateau. Because the tops are flat, they may be particularly vulnerable to trawling due to the relative ease of setting trawl gear. The rarity and uniqueness of seamount faunal communities provides strong scientific justification for a highly precautionary approach. Koslow et al. (2001) conducted a survey of Tasmanian seamounts where 30% of species identified were new to science and 30-60% were endemic to particular seamounts.

Accordingly, we support Alternative A.2 with the addition of seamounts as the EFH Description and Identification alternative.

Importance of Structure-forming Megafaunal Invertebrates as Key Components of the Ecosystem and Essential Fish Habitat

Corals, sponges, and other habitat-forming invertebrates provide three-dimensional structure on the seafloor that increases the complexity of benthic substrates. While corals and sponges are the most conspicuous and easily observable biogenic structures, they generally occur in diverse biological communities with other invertebrates such as crinoids, basket stars, ascidians, annelids, and bryozoans. Henry (2001) found thirteen hydroid species collected from only four coral specimens, suggesting that northern corals support highly diverse epifaunal communities. Beaulieu (2001) observed 139 taxa associated with deep-sea sponge communities in the northeast Pacific. Buhl-Mortensen and Mortensen (2004) found 17 species of Pandalus shrimp, isopods, amphipods, copepods, and decapods associated with *Paragorgia arborea* and *Primnoa resedaeformis* in Nova Scotia, including an obligate associated copepod. Removal of habitat structure in relatively low-structure soft-sediment systems significantly decreases biodiversity, and consequently that of the wider marine ecosystem (Thrush et al. 2001). Therefore, protecting known areas of coral and sponge habitat inherently protects areas of high benthic diversity and a host of benthic organisms that provide habitat for fish in the form of food and shelter.

Deep sea corals and sponges provide three dimensional structures that form habitat for commercial groundfish, shellfish, and other marine life (Husebo et al. 2002; Krieger and Wing 2002; Malecha et al. 2002; Heifetz 2002). Deep sea corals and sponges are found at depths from 30 meters to over 3,000 meters (Krieger and Wing 2002). Many cup corals, hydrocorals, and *Metridium* anemones are found at depths as shallow as 15 m. Some larger species of deep sea corals, such as *Paragorgia sp*. can grow over 3 m tall. Because these long-lived filter feeders are attached to the seafloor, they may be important indicators of areas in the ocean that have consistently favorable ecological conditions, such as areas of high upwelling that are worth protecting for other reasons as well.

Based on the best available science, cold water corals and sponges are important Essential Fish Habitat that are vulnerable to the impacts of bottom trawling. In February 2004, over 1,100 scientists signed a consensus statement declaring that "In short, based on current knowledge, deep-sea coral and sponge communities appear to be as important to the biodiversity of the oceans and the sustainability of fisheries as their analogues in shallow tropical seas." This statement is corroborated by numerous scientific studies documenting the importance of cold-water corals as habitat for fish and invertebrates. Here are 12 examples:

1. A recent study in the Olympic Coast National Marine Sanctuary (Hyland et al. 2004) corroborates the conclusion reached in other regions that coral and sponge ecosystems are valuable habitat for demersal fisheries on the U.S. West Coast and important "reservoirs of marine biodiversity" (Hyland et al. 2004). This study documented bottom trawl marks in the vicinity and a large proportion of dead or broken corals.
2. Krieger and Wing (2002) identified 10 megafaunal groups associated with *Primnoa sp*. deep sea corals, that use the corals for feeding, breeding, and protection from predators. Six rockfish species were either beneath, among, or above the coral colonies. Shrimp were among the coral polyps and a pair of mating king crabs was hiding beneath the coral. The authors conclude that removal of these slow-growing corals could cause long-term changes in associated megafauna.
3. Dr. Milton Love (pers. comm.) identified large schools of juvenile rockfish (including widow and squarespot rockfish) closely associated among the branches of the newly-discovered "Christmas tree coral", likely using the coral for protection. This deep sea coral species was named based on the numerous associated species that clung to the branches like Christmas ornaments (Opresko 2005).
4. Mortensen et al. (1995) identified megafauna associated with deep sea coral bioherms in Norway, including redfish, saithe, squat lobsters, sponges, and gorgonians (*Paragorgia arborea*, *Paramuricea placomus*, *Primnoa resedaeformis*).
5. Buhl-Mortensen and Mortensen (2004) documented 17 crustacean species associated with cold-water gorgonian corals off Canada, most of which were using the habitat as protection from predators and some were obligate to the corals. This suggests corals provide habitat for commercial fish prey.
6. Husebo et al. (2002) found that the largest catches of redfish (*Sebastes marinus*) were made with long-line fleets set in deep sea coral reef habitats. Ling and tusk were also most numerous in coral habitats, although not statistically significant. Fish caught in coral habitats tended to be larger in size than in non-coral habitats. Reasons for the associations were feeding and physical structure.
7. Christiansen and Lutter (2003) cite evidence that commercially caught demersal and pelagic fish species, mainly redfish, saithe, ling and tusk, have a higher abundance near deep sea coral reefs and patches.
8. Costello et al. (2003) found that fish species and abundance was greater on the deep sea coral habitat than surrounding seabed; 69% of species and 79% of abundance was associated with the reefs.
9. Koenig et al. (2003) state that important predatory fish species have been seen aggregating around the larger coral structures of *Oculina sp*. deep sea corals off Florida, and small fish have taken up residence inside the modules.
10. Scott and Risk (2003) found abundant fish associated with *Primnoa* which are not common in areas where coral is absent. The authors state that deep sea corals off Canada are being rapidly depleted by bottom trawling, which in turn appears to have an impact on fish stocks.
11. Sulak et al. (2003) listed economically important fish species observed in deep sea coral habitat, several of which were restricted to this habitat. The authors also found several poorly known fish species associated with deep sea corals.

12. Brodeur (2001) documented Pacific Ocean perch using sea whip forest habitat in the Pribilof Canyon in the Bering Sea on a diel cycle as resting areas.

Sponges represent a major component of biogenic fish habitat that has not received the level of attention as corals. However, sponges are a diverse group of large, slow-growing seafloor animals that provide habitat for fish and invertebrates on the U.S. West Coast. There are two major groups of sponges on the U.S. West Coast: hexactinellid (glass) sponges and demosponges. Sponges can reach sizes of 3 meters high and provide complex three dimensional structure on the seafloor. Large glass sponges found off the coast of British Columbia have been age dated to be 220 years old, and the average size based on current knowledge of growth rates is 35 years (Leys and Lauzon 1998). Several studies worldwide have documented the importance of sponges as fish habitat:

1. Freese and Wing (2003) documented that Aphrocallistes sponges provide habitat for juvenile red rockfish in the Gulf of Alaska. The authors state that the fish observed in the study benefited from the sponges through predator avoidance and that bottom trawl damage to sponge communities would be expected to have a negative impact on juvenile red rockfish survival rates.
2. Eastman and Eakin (1999) documented fishes of the genus Artedidraco are associated with sponge beds in the Ross Sea of Antarctica.
3. Tokranov (1998) described the association of the sponge sculpin (*Thyriscus anoplus*) with sponge beds in the northern Kuril Islands.
4. Konecki and Targett (1989) found that cod icefish (*Lepidonotothen larseni*) lay their eggs on the biogenic substrate provided by the spongocoel of the hexactinellid sponge *Rossella nuda* off Antarctica. The authors state that glass sponges serve as important nesting and refuge sites for Antarctic fishes and that destruction of sponge communities by bottom trawling could have an adverse impact of the fish ecology of the region.
5. Moreno (1980) and Daniels (1978) documented several species of fishes known to utilize sponges as spawning and nesting sites and for predator avoidance.
6. Munehara (1991) established that the silverspotted sculpin (*Blepsias cirrhosus*) uses the sponge *Mycale adhaerens* as a spawning bed and that the eggs benefit from the association through predator avoidance, oxygen supply, and the antibacterial and antifungal properties of the sponges.
7. Herrnkind and Butler (1994 identified sponges as “benthic juvenile shelter” for spiny lobster in Florida Bay that were found to be one of the most productive sites for survival of postlarvae.
8. Rocha et al. (2000) found that sponges are habitat 'oases' in a desert of rubble and flat rocky bottoms in Brazil. The study identified fish associations with shallow and deepwater sponges, including several obligate associations and and four endemic species of fishes associated with deepwater sponges.

The following species are known to associate with corals and sponges: rougheye rockfish, redbanded rockfish, shortraker rockfish, sharpchin rockfish, Pacific Ocean perch, dusky rockfish, yelloweye rockfish, northern rockfish, shortspine thornyhead, several species of flatfish, Atka mackerel, golden king crab, shrimp, Pacific cod, walleye pollock, greenling, Greenland turbot, sablefish, and various non-commercial marine species (Freese 2000; Krieger and Wing 2002;

Heifetz 1999; Else et al. 2002; Heifetz 2002). Red tree corals (*Primnoa sp.*) are known to provide protection from predators, shelter, feeding areas, spawning habitat, and breeding areas for fish and shellfish and are found throughout the U.S. West Coast (Krieger and Wing 2002). Stone (preliminary data, 2004) found an 87% rate of association between adult Alaskan FMP species and biogenic habitat and a 100% association rate for juveniles. Kaiser et al. (1999) found that biogenic habitat structure is an important component of demersal fish habitat, and observed higher densities of gadoid fish species associated with structural fauna such as soft corals, hydroids, bryozoans, and sponges in the southern North Sea and eastern English Channel. Husebo et al. (2002) found that the largest catches of redfish (*Sebastes marinus*) were made with long-line fleets set in deep sea coral reef habitats. Rocha et al. (2000) found that sponges are habitat 'oases' in a desert of rubble and flat rocky bottoms in Brazil. Reed (2002) in a study of deep water *Oculina* reefs along eastern Florida, noted extensive areas of *Oculina* rubble in part as the result of bottom fishing and major declines in commercial fish populations in the reefs from 1970-1990. Prevention of damage by bottom trawls to corals and other "living substrates" may increase the amount of protective cover available to slope rockfish to escape predation, increase survival of juvenile fish and thus have a positive impact on the stocks (Alaska Region EFH EIS).

Managed fish species in the PFMC management region using structure-forming invertebrates (such as corals, basketstars, brittlestars, demosponges, gooseneck barnacles, sea anemones, sea lilies, sea urchins, sea whips, tube worms, and vase sponges) as biogenic habitat include: Arrowtooth flounder, big skate, bocaccio, California skate, cowcod, Dover sole, flag rockfish, greenspotted rockfish, lingcod, longspine thornyhead, Pacific ocean perch, quillback rockfish, rosethorn rockfish, sablefish, sharpchin rockfish, shortspine thornyhead, spotted ratfish, starry rockfish, tiger rockfish, vermilion rockfish, yelloweye rockfish, and yellowtail rockfish (Pacific EFH DEIS).

Bottom Trawling Causes Adverse Impacts to Essential Fish Habitat

Adverse impacts to essential fish habitat from fishing that are more than minimal and not temporary is the legal trigger requiring mitigation measures. Based on the information included in the EFH DEIS and additional studies not considered in the document, it is clear despite the present uncertainties that bottom trawling taking place under the current Groundfish Fishery Management Plan is having adverse impacts on Essential Fish Habitat that are more than minimal and not temporary.

There is general scientific consensus that bottom trawling has wide ranging effects on habitats and ecosystems. According to the National Research Council (2002) Report on the Effects of Trawling and Dredging on Seafloor Habitat, these adverse impacts include:

- changes in physical habitat of ecosystems
- changes in biologic structure of ecosystems
- reductions in benthic habitat complexity
- changes in availability of organic matter for microbial food webs
- changes in species composition

• reductions in biodiversity.

These statements are corroborated by numerous scientific studies from around the world corroborate the conclusion that bottom trawling causes adverse impacts to biogenic habitat. Here are 31 examples of these studies:

1. Hyland et al. (2004) documented bottom trawl marks in the vicinity of coral and sponge beds in the Olympic Coast National Marine Sanctuary and observed a large proportion of dead or broken corals.
2. Engel and Kvitek (1998) compared heavily trawled and lightly trawled areas in otherwise similar regions off Big Sur, CA, finding lower epifaunal invertebrate densities at the more heavily trawled site. The authors conclude that intensive trawling significantly decreased physical habitat heterogeneity and biodiversity.
3. Grehan et al. (2003) found evidence that deep sea corals are being destroyed by trawling, as evidenced by trawl scars, flattened coral rubble, barren sediment, and lost trawl gear. The authors state that this provides irrefutable proof of a serious threat to the marine ecosystem caused by fishing that warrants immediate emergency measures to protect the remaining corals.
4. Conway et al. (2003) studied the environmental conditions where sponge reefs are found and discovered that like deep-sea coral reefs, many of the hexactinosan sponge reefs in British Columbia have been damaged or destroyed by the groundfish trawl fishery.
5. Hall-Spencer et al. (2002) document widespread trawling damage to cold-water coral reefs at 840-1300 m depth along the West Ireland continental shelf break and at 200 m off West Norway. The trawled coral matrix was at least 4550 years old. The authors discuss the need for urgent conservation measures to protect these corals.
6. Lundalv and Jonsson (2003) found about 50% of investigated coral sites in the Kosterfjord area to be destroyed by recent bottom trawling, while the remaining areas exhibit major signs of trawl damage.
7. Mortensen et al. (2003) found signs of fishing impact such as broken live corals, tilted corals, and scattered skeletons. Broken or tilted corals were observed along 29% of the transects.A total of 4 % of the coral colonies observed were impacted.
8. Fossa et al. (2002) developed an estimate of 30-50% of the deep sea coral *Lophelia* reefs in Norway have been damaged by bottom trawling and that fishermen claim that catches are significantly lowered in areas where the reefs are damaged.
9. Koslow et al. (2001) sampled the benthic fauna of Tasmanian seamounts finding high abundance and diversity of hard and soft corals, hydroids, sponges, ophiuroids, and sea stars, a large fraction of which were new to science. This study also found that heavy trawling has completely removed the reef aggregations.
10. Wassenberg et al. (2002) documented direct removal of sponges caused by trawling, accompanied by long-term changes in species composition over time.
11. Ardizzone and Pelusi (1983) and Ardizzone et al. (2000) found bottom trawling to reduce the quality and quantity of Posidonia oceania beds, a biogenic habitat in the Mediterranean Sea.
12. Hall-Spencer and Moore (2000) found a 70% reduction in maerl thalli habitats, which have important ecological functions, with no recovery after four years.
13. Kaiser et al. (1996) conducted a multivariate analysis showing that both beam trawling and dredging reduce the abundance of most epifaunal species in the Irish Sea.

14. Kaiser et al. (2000a) found that chronic fishing has caused a shift from communities dominated by relatively sessile, emergent, high biomass species to communities dominated by infaunal, smaller-bodied fauna. Removal of emergent fauna has thus degraded the topographic complexity of seabed habitats in areas of high fishing effort. The authors note that communities within these areas currently may be in an alternative stable state.
15. Ault et al. (1997) found conspicuous long-term damage to sponges and soft corals after one pass of a trawl and that the sponge *Ircina felix* and corals of the genus *Pseudoplexaura* appeared to be the taxa most vulnerable to breakage or dislodgement by trawling.
16. Collie et al. (1996), Collie et al. (1997), and Collie et al. (2000) found conspicuously and significantly reduced abundance of colonial epifaunal species that provide complex habitat for shrimp, polychaetes, brittle stars, and small fish at sites disturbed by bottom fishing in Georges Bank, and found that many species whose abundances were reduced were also prey for commercial fish.
17. DeAlteris et al. (2000) discuss physical impacts and biological alterations in community structure caused by trawling in New England and recommended closure areas to reduce the impact of mobile fishing gear on habitat and biodiversity.
18. Magorrian (1995) found otter trawling to remove emergent epifauna and reduce the structural complexity of mussel beds in Strangford Lough, and recommended marine reserves as a management tool.
19. McAllister and Spiller (1994) found that trawling and dredging have major impacts on marine habitats by removing protruding invertebrate animal life including sea anemones, sponges, sea squirts, crinoids and many others which provide shelter and food sources for juvenile fish and shellfish. Specific trawling effects in the study included shearing off higher hummocks, filling in low spots, changing the configuration of the bottom, removing areas more exposed to or protected from the current, exposing shellfish, worms and other sediment dwelling species to predation, and stirring up clouds of mud and other sediment that plug gills and similar structures of filter feeders. The authors recommend closures, control areas, and conversions to less damaging gear types.
20. Norse and Watling (1999) state that trawling damages refuges from predation and feeding places for demersal fish, which are correlated with species diversity and post settlement survivorship of some commercial species.
21. Pitcher et al. (2000) found that total annual removal of benthic fauna ranged from very low to over 80% in areas of highest trawl intensity in Australia's Great Barrier Reef. They found that highly vulnerable populations of epifaunal species may be depleted by about 55% overall and there will be a substantial alteration in most trawled grids with a shift to less vulnerable species.
22. Reed (2002) in a study of deep water Oculina reefs along eastern Florida, noted extensive areas of Oculina rubble in part as the result of bottom fishing and major declines in commercial fish populations in the reefs from 1970-1990.
23. Rumohr et al. (1994) found reductions in abundance of epifauna and absence of inner structures (feeding burrows, living chambers, tubes) in areas impacted by trawling in the German Bight.
24. Bavestrello et al. (1997) found fishing damage to gorgonian corals in the Ligurian Sea, found slow recolonization and recovery rates for these corals, and recommended special protection for these corals as a Natural Marine Park.

25. Stone and Malecha (2003) state that "gardens of corals, sponges, and other sessile invertebrates" were similar in structural complexity to tropical coral reefs with which they shared several important characteristics including complex vertical relief and high taxonomic diversity. The authors note the particular sensitivity of these habitats to disturbance and observed anthropogenic disturbance to corals.
26. Wheeler et al. (2003) found broken coral rubble and dead coral in areas of higher trawl intensity, whereas untrawled areas had a much higher abundance of undisturbed upright coral colonies.
27. Van Santbrink and Bergman (1994) documented 70% mortality to anthozoans after two passes of a beam trawl in the southern North Sea.
28. The NMFS Alaska Fisheries Science Center website (NMFS 2004) shows several underwater video clips taken with a Remotely Operated Vehicle. Clip 9 shows heavily trawled coral habitat containing "broken-up coral debris in this area -- heavily damaged". (http://www.afsc.noaa.gov/race/media/videos/vids_habitat.htm)
29. Anderson et al. (2003) documented high levels of coral and sponge bycatch in the New Zealand orange roughy trawl fishery.
30. MacDonald et al. (1996) made several estimates of habitat sensitivities to physical disturbance, concluding that fragile, slow recruiting animals are the most susceptible to disturbance.
31. Van Santbrink and Bergman (1994) documented mortality rates of several benthic species as a result of two passes of a trawl.

Bottom trawling is the leading, most widespread cause of reduced habitat complexity that is taking place among major fishing grounds along the North American continental shelf. As trawl gear can crush, displace, expose and bury marine life on the sea floor, habitats that are trawled are far more likely to have reduced overall species diversity. Those organisms remaining after extensive periods of trawling tend to be "comprised of large numbers of a few opportunistic species" (Norse and Watling 1999). The study found that the extent of the disruption of a habitat's complexity is dependent upon how long the area has to recover between trawls, how extensive the damage is from the trawling gear, and whether the habitat is constituted primarily of quick-recovering short-lived species or of slow growing, long-lived species.

The National Research Council (2002) Report concludes that the impacts of trawling can lead to measurable changes in benthic habitats over time, with the greatest impact on those communities which are ecologically most complex. Extended trawling over the same habitat can lead to "a shift from communities dominated by species with relatively large adult body size towards dominance by high abundances of small-bodied organisms." More significantly, areas of intense trawling activities have the potential to be permanently affected and will lead to the emergence of short-lived organisms which are "readapted to conditions of frequent physical disturbance." (NRC 2002).

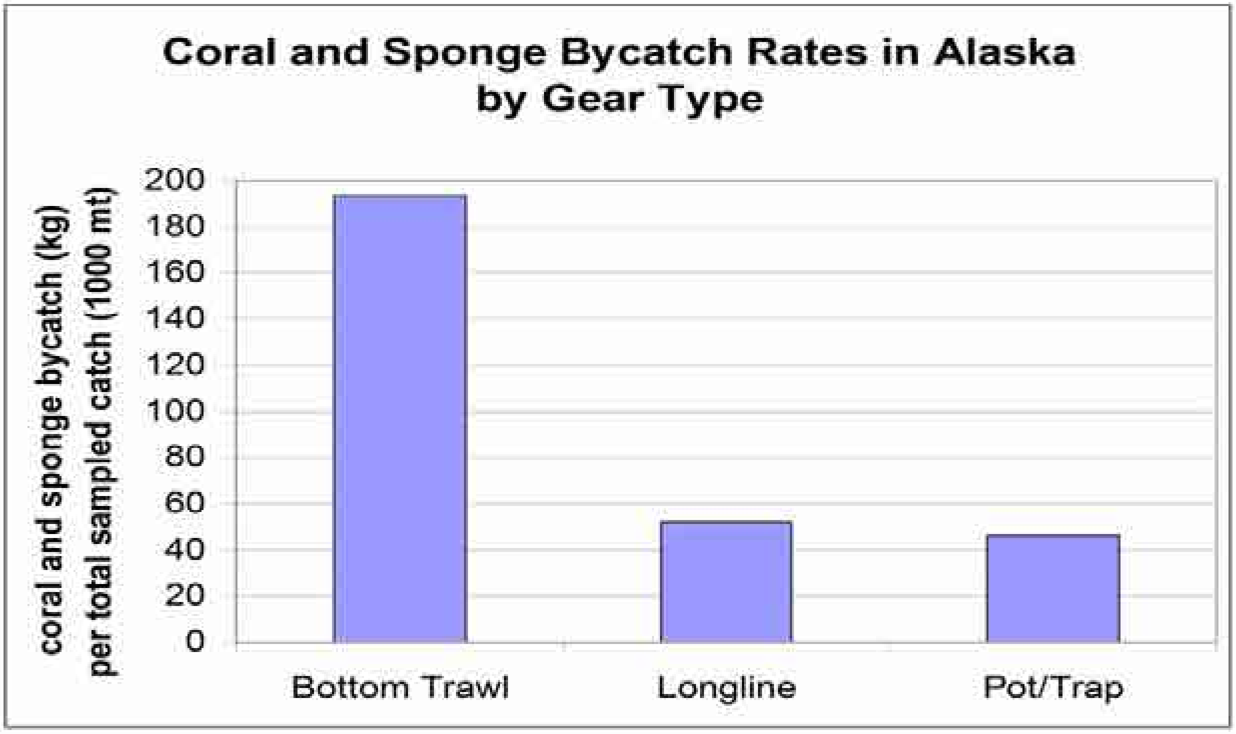

Figure 1: Bycatch rates for groundfish fishing gears in Alaska, based on data from 1990-2002. Bycatch rates are defined as the weight of reported bycatch divided by the weight of total sampled catch. These rates may not reflect actual damage to seafloor since fishing gears may not retain all corals and sponges that are impacted. However, they are useful for looking at relative impacts of different gears in a Benefit-Cost Analysis. Data source: NMFS (from Shester and Ayers 2005)

Bycatch of habitat-forming invertebrates constitutes direct evidence of adverse impacts of fishing to biogenic habitat (i.e. reduction in quality and quantity). The West Coast groundfish observer program (WCGOP) was established to obtain more precise estimates of fishery discards and total catch (NMFS 2003). For the same reasons that the data from the WCGOP improves the accuracy of catch estimates for overfished groundfish, observer data can and should be used to both evaluate the impacts of fishing on EFH and develop mitigation measures in the EFH EIS. In fact, a repeated criticism of the Alaska Region EFH DEIS by the Center for Independent Experts was that coral, sponge, and bryozoan bycatch from observer records were not analyzed, utilized, or incorporated (Drinkwater 2004).

Trawling will have the greatest impact upon marine flora and fauna that has adapted to exist in areas of low natural disturbance. Ecological disturbance theory suggests that the extent to which an organism within a habitat can recover from an anthropogenic disturbance (i.e. bottom trawling) is dependent upon the overall stability of the habitat prior to that disruption taking place. Organisms living in habitats that consist of easily dispersed sediments are far more likely to adapt more quickly to the new conditions following a trawl than would those organisms that normally do not experience extensive disruptions. Conversely, a habitat that consists of deep-water boulders or corals is far less likely to have extensive natural disruptions. Such "epifaunal communities that stabilize sediments, reef-forming species, or fauna in habitats that experience low rates of natural disturbance have been observed to be particularly vulnerable" to disruptive activities such as commercial bottom trawling (NRC 2002). This is especially important given that confluence of various advances in fishing technology – such as larger boats with more powerful engines, more robust mobile fishing gear and fish-finding technologies – has allowed fishers to seek out groundfish in areas, such as the deepwater slopes of the continental shelf, that just decades ago would have been impossible to reach.

These findings, taken together, indicate that the effects of highly-destructive fishing gears such as trawls will have a disproportionate impact upon structurally complex, interconnected ecosystems as found in shallow and deep-water coral habitats. These habitats which have grown over the period of several hundred years or more and exhibit a low capability to adapt to increased levels of disruption. That is, as trawling tends "to eliminate competitively dominant, long-lived but disturbance-sensitive structure-forming benthic species" and frees "up food and space for shorter-lived, disturbance-insensitive opportunistic (weedy) species" it represents a critical threat to corals, sponges, and other biogenic seafloor habitats that are clearly Essential Fish Habitat within the Pacific Fishery Management Region based on the best available science. (quotations from Watling and Norse 1999).

Adverse Fishing Impacts on the U.S. West Coast

This section outlines the rational basis for the determination that the adverse impacts of bottom trawling on U.S. West Coast Essential Fish Habitat are "more than minimal and not temporary".

The EFH Final Rule includes "site-specific or habitat-wide impacts" in its definition of adverse impacts on EFH. (50 CFR 600.810(1)). The Risk Assessment conducted in Appendix A of the EFH DEIS contains an analysis of the effects of fishing on Essential Fish Habitat. The main document includes the various data sources that were used in the analysis (p. 73-74). The strength of the model in its current form is that it provides generalized comparisons of different habitat types and fishing gears. Page 77 of the Appendix A main document states that

In terms of major habitats, biogenic habitats are more sensitive than hard bottoms (although we note that the former may occur on the latter) and these are much more sensitive than soft bottoms.

In terms of the major gear types, dredges are most impacting, followed by bottom trawls, and these are much more impacting than nets which are more impacting than pots & traps and hook & line (including longlines).

Therefore, consistent with the global literature, the model successfully identifies biogenic habitats and hard substrates as focus areas for mitigation measures and bottom trawls and dredges as the gear types with the greatest effect. Where the model stops short is in its estimation of actual impacts caused by the current groundfish management regime.

While the analysis overall has some merits, Appendix A of the EFH DEIS claims that there are two main limitations to current understanding of the impacts of fishing on habitat: 1) the relationship between fishing effort and habitat modification, and 2) the relationship between habitat modification and ecosystem productivity (including fish productivity). (Appendix A Risk

Assessment Main Document p.74). The document claims that "[p]resently there are very little data to fill either of these gaps". These "gaps" are used to justify the used of relative indices rather than actual numbers. These statements are simply unreasonable in a document that is intended to provide the public with a detailed understanding of the environmental impacts of federally authorized actions. Further, the reference to fish productivity unlawfully limits the inquiry and analyses:

"It is not appropriate to require definitive proof of a link between fishing impacts to EFH and reduced stock productivity before Councils can take action to minimize adverse fishing impacts to the extent practicable. Such a requirement would raise the threshold for action above that set by the Magnuson-Stevens Act."

67 Fed. Reg. 2343, 2345 (Jan. 17, 2002).

The EFH DEIS provides no justification that the two main limitations described in the Risk Assessment are valid nor does it provide a rationale for using relative indices rather than best estimates from the literature. On the contrary, there have been numerous studies providing direct quantifications of the relationship between trawl effort and habitat modification. Further, even were productivity an appropriate measure, there are also many methodologies in the literature that can be used to estimate the relationship between productivity and habitat features even in cases of high uncertainty.

Swallow (1990) presented a dynamic model for assessing the impacts of a renewable resource, fish, as a result of reductions in a non-renewable resource, habitat. The model result is that if habitat impacts are not considered in the coupled resource management system, the adverse impacts to habitat are systematically higher than the economic "optimal". This confirms the theoretical result that fish habitat damage externalities systematically increase the habitat damage above the optimal outcome, reducing the productivity of the renewable resource. Thus the failure to account for the externality causes a market failure. Due to the long recovery times of corals and sponges (approaching consideration as a "non-renewable resource", this model is appropriate and applicable to answer the question about fisheries productivity. Another example is provided in Mangel (2000), which developed a model based on Beverton-Holt and Ricker-like recruitment functions showing that loss of spawning habitat is equivalent to additional fishing mortality of the adult stock; or in other words, productivity loss.

Mangel's (2000) model indicates that there may be a lag time in habitat-mediated changes in fish productivity between when habitat damage occurs and fish productivity declines. This may occur based on demographic features of fish stocks, such as long life spans and/or lag times in the effects of density dependence on mortality. Mangel (2000: p 672) states that "…neither catch nor stock is a good indicator of what is happening to the habitat: the decline lags behind habitat destruction and the recovery lags behind habitat restoration. Habitat itself must be monitored." Mangel (2000) backs this statement through a mathematical model based on modern fishery models used in fishery management.

The use of indices rather than expected values is the fundamental flaw in the impacts model. When indices are used, impacts can only be determined relative to each other. While this may be a useful way to identify the most harmful activities, relative indices eliminate the ability to assess or evaluate the absolute impacts. While it is clear that there may be uncertainty with expected values, the data exists to provide numerical best estimates and standard deviations from available literature. In fact, the Alaska Region EFH DEIS contained an impacts model that compiled available information into "best estimates" of actual numerical figures based on literature on the impacts of trawling. While the ultimate conclusion in the Alaska EFH EIS was based on an unlawful definition and interpretation of the mitigation threshold, the model remains instructive. For example, Table B.2-4 in the Alaska EFH DEIS contains estimates of habitat sensitivity to each gear type as a percentage of the habitat in the affected area that is damaged with each unit of fishing effort. This clearly shows that it is not necessary to convert to an arbitrary relative scale of 0-3, as was done in the Pacific Region EFH DEIS. In particular, the use of a percentage in the Alaska model specifically allowed the analysts to develop absolute quantitative estimates of the loss of each habitat type as a result of current patterns of fishing effort, and eliminated the need to introduce an arbitrarily-defined "k-value" to estimate absolute impacts. This was precisely the problem pointed out by the PFMC Scientific and Statistical Committee which prevented the Pacific Region EFH DEIS impacts model. It is unclear why best estimates of percentages were not used in the Pacific Region model, when they were used successfully in the Alaska model based on the same literature.

In addition, another example of a quantitative model for incorporating sensitivity and recovery times is presented in DeAlteris et al. (1999). This study was aimed specifically at developing a methodology to identifying adverse impacts to EFH that are more than minimal and temporary and was not considered in the EFH DEIS. MacDonald et al. (1996) developed sensitivity indices for different benthic habitat types, and found that fragile, slow recruiting animals are most susceptible to fishing disturbance. Another study to add to the information on sponge sensitivity is Heifetz et al. (2003), which documented 50% damage to sponges in Eastern GOA one year after a trawl pass.

Furthermore, the EFH DEIS Risk Assessment (Appendix A) identifies category 3 Sensitivity Index score to be:

Major changes in bottom structure, such as re-arranged boulders; large losses of many organisms with differences between impact and control sites greater than 50% in most measured metrics.

Based on this statement alone, it would be unreasonable to claim that the "major changes" caused by gears that have a Sensitivity Score of 3 could be considered minimal.

Recovery rates for habitat types are the most important parameters to consider when determining whether known losses of habitats are "minimal and temporary". The Recovery Index used in the EFH DEIS omits several key studies and published information on the recovery of corals and sponges. The table on Page 16 in Appendix A-10 indicates the estimated recovery time for slope corals is "7.0+" years based on a study that showed no evidence of recovery for corals damaged by trawling in the Gulf of Alaska. However, it is clear that corals and sponges have growth rates on the order of millimeters per year, living to be hundreds of years old. In its Effects of Fishing model, the Alaska EFH DEIS used 100 years as its central estimate of the recovery time of hard corals (low estimate = 50 yrs; high estimate = 200 yrs) (Alaska Region EFH DEIS, 2004, Appendix B, Table B.2-5). In addition, the following studies justify a much higher estimate of coral and sponge recovery times (hence slower growth rates) than was presented in the Recovery Index, both on the continental slope and shelf.

1. Andrews et al. (2003) found growth rates of 1.74 cm/yr for Primnoa, 1 cm/yr for Corallium, and ages of 30 to over 200 years for deep-sea coral species of Davidson Seamount.
2. Cordes et al. (2001) found ages of 25-30 years for the deep sea coral *Anthomastus ritteri* in California's Monterey Bay, noting that the results agree with the general notion that growth rates are reduced and longevity increased in deep-sea species.
3. Roark et al. (2003) sampled corals from Hawaii and the Gulf of Alaska and dated a living *Gerardia* sp. to be 2700 years old and a black coral to be 2200 yrs old, using radiocarbon dating techniques.
4. Leys and Lauzon (1998) found large deep water Hexactinellid sponges to be 220 years old with average growth rates of 1.98 cm/year.
5. Probert et al. (1997) found recovery times greater than 100 years for deep sea corals.
6. Jones (1992) review of trawl impact literature revealed that recovery time for deep sea benthos with little natural disturbance is on the scale of decades.
7. Koslow et al. (2000) discusses the higher longevity and vulnerability of deepwater ecosystems to trawling, particularly on seamounts, which are known to have benthic fauna (i.e. corals) with high levels of endemism.
8. Risk et al. (2002) found ages of over 300 years for *Primnoa resedaeformis.*
9. Heikoop et al. (2002) found deep sea corals (*Primnoa*) in Alaska and elsewhere have lifespans of several centuries. The authors describe the potential of these corals to contain extended records of surface productivity, deep ocean temperature and chemistry of value to climatologists and fisheries managers.
10. Reed (2002) in a study of deep water Oculina reefs along eastern Florida, noted extensive areas of Oculina rubble in part as the result of bottom fishing and major declines in commercial fish populations in the reefs from 1970-1990. Coral growth rates averaged 16.1 mm/yr.

In addition, use of estimated ages of biogenic habitats as their recovery time is likely to be a significant underestimate of actual recovery because it omits the time necessary for recolonization. Specifically, if corals and sponges take a long time to settle and begin growth in damaged areas, overall recovery is much longer. Evidence for long recolonization times is presented in Koenig et al. (2003), which found no evidence of recolonization of Oculina deep sea corals into denuded areas and offered two explanations: continued trawling and the rubble areas do not provide suitable substrate for planular settlement of coral larvae. Additionally, the Krieger (2002) study cited in the EFH DEIS found no evidence for recolonization of corals seven years after trawling.

It is unclear why the recovery index distinguishes between gear types in its estimates of habitat recovery. Recovery should be based on the estimated time it takes for a fully damaged habitat to return to a pre-impacted state, independent from the source of damage. The differences between gears should be limited to the sensitivity of each habitat type to each unit of effort with different gear types. For example, whether a deep sea coral was removed by a bottom trawl or a researcher, the growth rate of each corals is the same. Furthermore, since age does not include recolonization time between impact and settlement of new biogenic structures, all recovery times used in the EFH DEIS that were derived from literature on ages are systematically underestimated.

It is also unfortunate that the Risk Assessment was not able to utilize the extensive trawl logbook data for the U.S. West Coast showing thousands of start and end points for recent years of trawl effort.

However, a simple calculation of habitat sensitivity and trawl effort illustrates that by any measure in the Pacific groundfish fishery, the more than minimal and not temporary threshold has been crossed. The following example represents a thought experiment to demonstrate the severity of habitat impacts using parameters from the Risk Assessment and scientific literature. The Risk Assessment states that the sensitivity of corals and sponges to one unit of bottom trawl effort is Sensitivity Level 3.0, which is defined on p. 75 to be a 50-100% loss of habitat-forming organisms. If we use the low value of 50%, this means that each area loses half of its habitat features every time it is trawled. Let's say an area containing corals is trawled once per year. This means in five years, the amount of available habitat will be reduced by $(0.50)^5$, which equals 3.1% of the original habitat. Even if we add in a rate of 1% recovery each year (which is equal to saying the recovery time for corals is 100 years), there is still only 5.1%. An optimistic (best case scenario), dynamic equation for this would be:

$$H_{t+1} = 0.5H_t + 0.01H_0, \qquad (1)$$

where H_0 is the initial amount of habitat and H_t is the amount of habitat after t years.

Note that this model contains a highly optimistic assumption that habitat recovers at a fixed rate regardless of how much is remaining. This ignores any potential delays in habitat recovery from recolonization, Allee effects, or ecological succession.

The following graph (Figure 2) shows 5 example trajectories of available habitat remaining in an area subject to one pass of a trawl per year and assuming a Sensitivity Rate of 50%. The first case, shown in pink is the trajectory for a habitat that does not recover from damage. The second case is shown in red (triangles) is the trajectory for a habitat with a recovery time of 100 years (1% recovery per year). If trawling stops at the end of year 4 due to a trawl closure, the habitat ceases to decrease and begins a slow trajectory toward total recovery (shown in green circles). For a case where habitat recovers in 10 years, the habitat is lost at a slower rate because it is compensated by recovery (shown in orange diamonds). If trawling continues, the habitat remaining at equilibrium is 20%. However, with a trawl closure enacted at the end of year 4, the habitat with a 10 year recovery time nears full recovery at year 14 (shown in blue squares).

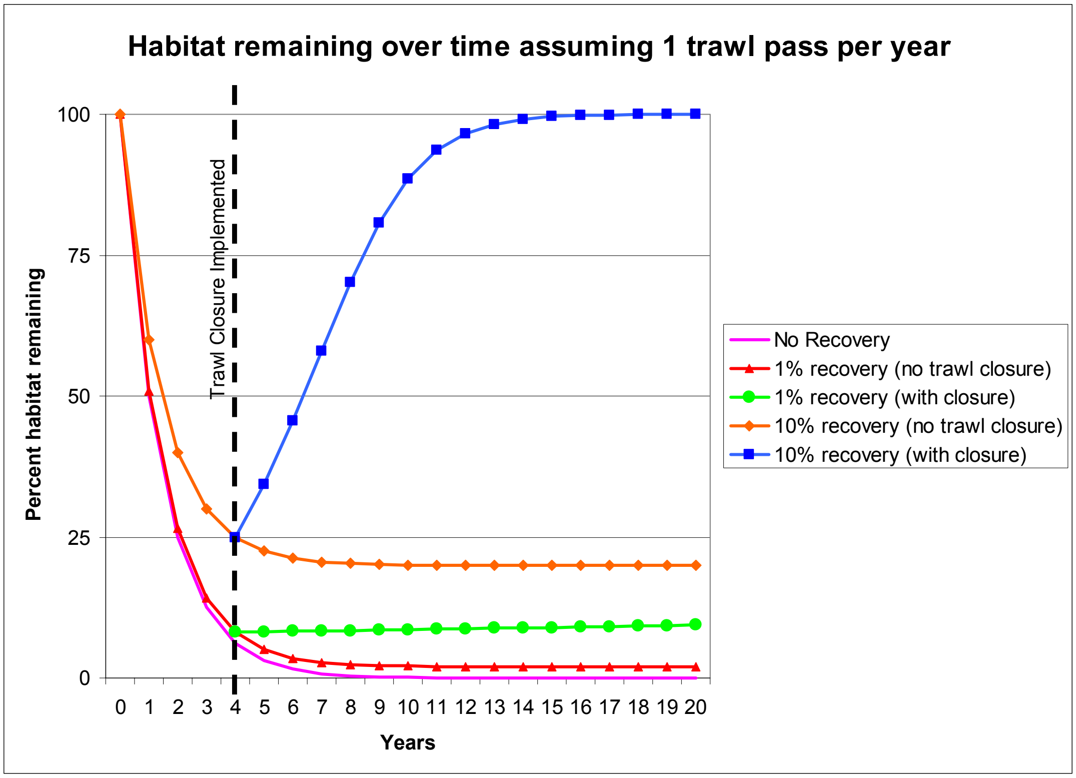

Figure 2: Results of hypothetical habitat damage model using actual parameters from the EFH DEIS and scientific literature on recovery rates. (Refer to text for further discussion).

For the case of many deep sea corals found off the U.S. West Coast, the recovery time is at least 100 years (see citations earlier in this Section). This recovery time (100 years) was used in the Alaska Region EFH DEIS "Effects of Fishing" habitat loss model. Using this estimate, all coral and sponge habitats where trawling occurs at least once per year with a 50% impact per pass, there will be less than 5% of this habitat type remaining after 5 years. (This is precisely the reason why the Alaska Region EFH DEIS showed long-term losses of corals on the order of 50-100% in all areas containing trawl effort. There is no reasonable way to justify that a 95% loss of corals and sponges at any specific biogenic habitat site is minimal (recall the EFH Final Rule's reference to "site-specific" adverse impacts and the CIE Report (Drinkwater 2004) reference to "localized impacts to corals and sponges"). Nor could any reasonable person justify that a 100 year recovery time is temporary from the standpoint of a fishery. Since there are many known areas of corals and sponges that are repeatedly trawled (i.e. observer bycatch data from WCGOP and overlay of trawl tracks on known records of corals and sponges documented in trawl surveys), these habitat features have been substantially reduced in both quantity and quality for the long-term. Therefore, it is clear based on the Sensitivity Level of >50% presented in the EFH DEIS for bottom trawling on corals and sponge and based on the published recovery times over 100 years that adverse impacts to biogenic coral and sponge habitats by bottom trawling authorized under the current Fishery Management Plan are occurring in a manner that is more than minimal and not temporary. This conclusion triggers the legal requirement to minimize adverse impacts of bottom trawling to the extent practicable.

The results of this simple thought experiment indicate that the first few passes of a trawl account for the biggest fraction of the total damage to habitats with long recovery times. The EFH DEIS (Ch.3, p. 3-16) confirms this result in its statement that:

Corals, anemones, sponges, sea pens, and sea whips are a highly sensitive habitat that may be substantially modified with relatively little fishing effort (NRC 2002). It may be that initial contact (i.e., the first time gear is deployed) is the most important due to the high sensitivity of the habitat to impact.

Therefore, even a single pass of a bottom trawl in sensitive habitat areas constitutes adverse habitat impacts that are more than minimal. This suggests that the most effective trawl closures are located in areas that are lightly-trawled or have not yet been trawled. Therefore, the best available scientific understanding of biogenic habitat sensitivity and recovery provides strong justification for closing all areas outside the trawl footprint.

Additional considerations beyond the EFH legal mandate

This section discusses the current state of scientific theories regarding the linkage between marine habitat and fisheries productivity and is simply designed to illustrate the potential effects of the adverse impacts described in the previous section. It is not intended to imply that productivity should be a consideration in the determination of adverse impacts. In fact, the linkage between EFH and commercial fish productivity is irrelevant from the standpoint of the law (see 67 Fed. Reg. at 2354), and from a factual standpoint, since corals and sponges constitute a component of EFH and we are nowhere near EFH Information Level 4 for these habitats and most others. However, the potential effects of habitat loss on fish productivity may be useful to consider.

Several ways to conceptualize this linkage are presented in the scientific literature. Many studies assume a one-to-one linear relationship between habitat availability and fish production (i.e. Naylor and Drew 1998; Costanza et al. 1997). Under this logic, a loss of 95% of habitat would result in a 95% loss in production. Another way to consider the issue is to assume that the habitat type only accounts for a certain proportion of the productivity of a fishery, say 20% as an arbitrary example. Under this logic, the damage to habitat would result in a loss of 19% of the landings produced in the trawled area (assuming all other habitat features are not impacted by trawling). Whether this would be considered "minimal" is an open question, but it suggests that management measures to mitigate the loss of coral and sponge habitat would pass a simple Benefit-Cost test from the fishermen's point of view as long as they represent less than a 19% economic loss to the trawl fleet due to increased fishing cost. While this is a simplified example, it represents the basic logic justifying habitat protection measures in a fisheries management regime that aims to maximize the value of the fisheries harvest.

The basic theory underlying the need to protect habitat from the perspective of the fishermen is that habitat damage may reduce the productivity of fish that are associated with the habitat. One way to illustrate this effect is to consider a basic Schaefer logistic growth equation:

$$dN/dt = rN(1-N/K) \quad (2)$$

where dN/dt is the production, r is the intrinsic rate of increase, N is the stock size, and K is the carrying capacity. Most fishery models view the r and K parameters as exogenous, determined by environmental factors. However, if habitat damage caused by fishing reduces r or K, the overall production decreases for any given stock size. Figure 3 shows potential effects of harvest with a destructive gear on the logistic production of a fishery, where the the amount of fishing effort (or harvest) reduces K by (represented by different production functions at equilibrium). The basic effect is that fishing effort increases (destroying more habitat) the entire productivity curve becomes smaller, particularly the apex of the curve, which is the maximum sustainable yield (MSY). Depending on the degree to which the fishing gear destroys habitat (determined by Sensitivity and Recovery Rates), this framework suggests that there can be quite significant reductions in MSY as the result of destructive fishing. This demonstrates the general result that reducing habitat impacts of fishing leads to an increased fishery yields and/or prevents further decreases in productivity.

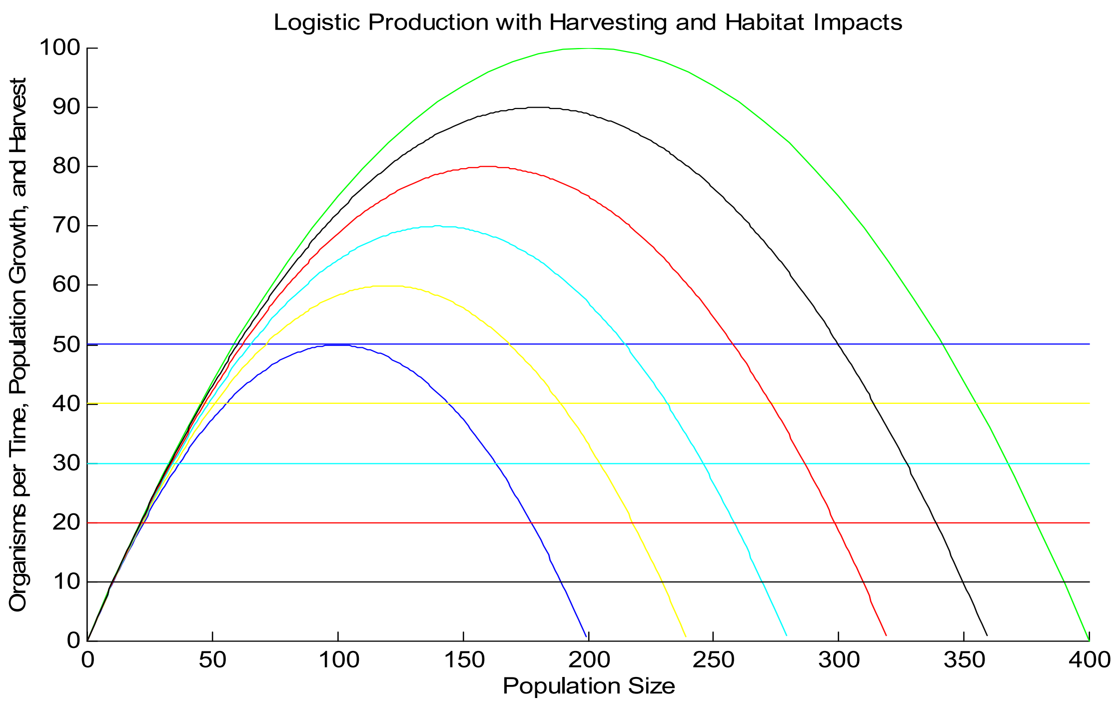

Figure 3. Effect of harvest on the logistic production function for the case where carrying capacity, K, is reduced by 4 times the level of harvest. Harvest rates (horizontal) correspond to production functions of the same color. The unfished carrying capacity is 400 with an potential MSY of 100 (green), while a harvest rate of 50 decreases the carrying capacity to 200 with an actual MSY of 50 (blue).

The time of managing fish stocks on a single-species basis without regard to their habitat is over. The inclusion of Essential Fish Habitat measures of the Sustainable Fisheries Act are a major step toward ecosystem-based fishery management. We now know that fish habitat is an essential driving force behind the production of commercial fish and maintenance of healthy ecosystems.

The "natural capital stock" of biogenic habitat must be managed explicitly. The Pacific Fishery Management Council has jurisdiction over which habitat areas are subjected to trawl impacts. From the standpoint of the Magnuson-Stevens Act and common sense, the Pacific Fishery Management Council must implement regulations that mitigate the adverse impacts of bottom trawling on Essential Fish Habitat in its final decision on this Environmental Impact Statement.

Mitigation Measures to Minimize Adverse Impacts to the Extent Practicable

The Sustainable Fisheries Act requires that if fishing activities are causing adverse impacts to EFH, Councils and NMFS must enact mitigation measures to minimize those adverse impacts to the extent practicable. It is clear from the above discussion that the adverse impacts of fishing on U.S. West Coast EFH are more than minimal and not temporary. Therefore, mitigation measures are required by law.

The US Commission on Ocean Policy, the PEW Oceans Commission, and many other scientists and administrative bodies have recognized the need to protect both the fish and the ecosystem in which the fish thrive. Current fishery management tools have largely focused on fishery conservation in its narrowest sense: avoid overfishing a species or a group of species. Gradually, the need to protect the fish *and* their associated habitat is being recognized. This need is imperative in Pacific Coast Groundfish management, given the legal mandate to minimize adverse impacts to the extent practicable.

As discussed in the Pew Oceans Commission Final Report, the goods and services from coastal and marine ecosystems, especially corals, sponges, and other biogenic habitats that are commonly damaged by benthic fishing gears are difficult, if not impossible, to replace. This suggests that if we destroy our nation's healthy ecosystems, we may well risk economic and social stability. In other words, there are costs associated with habitat destruction that go beyond the financial displacement of bottom trawlers, and eco-values beyond single species money fish. The value of a healthy ecosystem far outweighs the short-term economic gains of destructive bottom trawling.

Externalities in the Pacific Groundfish Trawl Fishery

An "externality" is generally defined as:

"An effect of one economic agent's actions on another, such that one agent's decisions make another better or worse off by changing their utility or cost. Beneficial effects are positive externalities; harmful ones are negative externalities."

(www-personal.umich.edu/~alandear/glossary/e.html)

Externalities are important in natural resource policy analysis because they cause market failures, justify policy intervention into markets, and suggest appropriate types of policy tools to correct market failures. Fish stocks and ocean habitats are subject to four distinct externalities from Pacific coast groundfish bottom trawl fisheries, largely as a result of their status as public goods. The first type is the ***stock externality***, which is the effect of an individual vessel's fish removals on the catch per unit effort of the rest of the fleet. This negative externality arises because the lower the stock size, the more effort is required to obtain a specific amount of catch. If this externality is not regulated, overfishing will occur in any circumstance where the cost of fishing is low enough. The market failure caused by this externality can be corrected with policy instruments that limit catch, including trip limits and total allowable catch quotas, many of which are already in place as a result of PFMC management. However, due to the uncertainty of fisheries stock assessments and enforcement capabilities, the effectiveness of these limits on target species catch depends on the degree to which fishery managers are precautionary in their quota decisions. The current Pacific groundfish fishery management plan uses catch limits and quotas to limit this catch. However, overfishing has occurred for nine Pacific groundfish species and current plans for stock rebuilding are on the order of several decades, so it is doubtful that the stock externality has been fully corrected.

The second type of externality is the ***habitat externality***. This negative externality occurs when the habitat impacts of harvesting fish affect the intrinsic growth rate and/or the carrying capacity of a fish stock. In the case of trawling, this may occur in several ways. Trawling is known to reduce the structural complexity of seafloor habitats, which in turn reduces the shelters from predation for juvenile groundfish. Less shelter from predation leads to higher mortality rates for young life stages with the overall effect of reducing the intrinsic rate of growth. Furthermore, if vulnerable habitats such as sponges, kelp, deep sea corals, or other biogenic substrates support higher densities of adult fish then if they are damaged or removed, the carrying capacity of the fish stock will be reduced by the act of harvesting fish with destructive gear. Decreases in the carrying capacity and growth rate reduce both the maximum sustainable yield and the maximum economic yield proportionally. In a legal context, this externality reflects the reduction in fish habitat that is "necessary" or "essential" to "support a population adequate to maintain a sustainable fishery" (EFH Final Rule (50 CFR Part 600)).

Since the costs of such destructive activity are dispersed throughout the entire fleet, this externality prevents an incentive to reduce the damage. Conversely, if one fisherman reduced his rate of habitat damage, the benefit would be distributed throughout the entire fishery. This externality is inherently a "collective action problem" as described in Hardin's *Tragedy of the Commons* (1968), which to be corrected requires all vessels to collectively reduce their habitat damage rates. The most effective policy instruments available to reduce the habitat damage rates for the Pacific groundfish trawl fishery include permanent area closures and gear conversions which are the cornerstone mitigation measures of Alternative C.12.

The third externality in a destructive fishery is the ***ecosystem externality***, which results from reductions in the quality and/or quantity of habitat sufficient to support a healthy ecosystem. The consideration of this effect is mandated by the EFH Final Rule. This negative externality encompasses the various social and non-use costs of habitat damage. In practice, social costs may be expensive to quantify, but include reductions in existence value, biodiversity value, passive use value, option value, bequest value, scientific value, historical value, intrinsic value, or the value of the ecological services provided (other than the production of the target fishery). Brief descriptions and definitions of some of costs are provided in the EFH DEIS (Section 3.10.2 entitled "Non-Consumptive Non-Use Values"). Unfortunately, however, the EFH DEIS made no attempt to quantify these costs. However, these costs of habitat damage are real and evidenced in part by the tens of thousands of public comments that NMFS and the PFMC have received on this EFH DEIS.

The fourth externality in a destructive fishery is the ***technology externality***. This is a positive externality associated with the appropriability of innovations or technological improvements that reduce the damage rate of a fishery. The fact that this is a positive externality means that the a market failure is occurring because the current system does not sufficiently encourage technological improvements to reduce the impacts of bottom trawling. These technological innovations include developing new low cost gear types that catch fish without destroying habitat. The externality arises because the costs of technological innovation are born by an individual fisherman, but the benefits of the innovation are enjoyed by the entire fishing fleet. Therefore, the market failure is that there will be less technological innovation to reduce habitat impacts than there would be at the optimum for the fleet as a whole. Since this is a distinct externality from the habitat damage (negative) externality described above, the technology externality requires a distinct set of policy instruments to increase expenditures on technological innovation to economically efficient levels. The bottom line is that we need the motivation and incentive to develop ways to catch fish without destroying the habitat the fish depend on for survival.

These four externalities each lead to systematic biases preventing fishing activity from reaching its privately and socially optimal outcomes. Correcting these market failures in the Pacific groundfish fishery requires policy intervention to address each externality (see Table 1).

Table 1: Externalities addressed by the management tools proposed in Alternative C.12.

Management Measures	Externalities			
	Stock	Habitat	Ecosystem	Technology
Catch limits	X			
Area closures (incl. freezing trawl footprint)		X	X	
Gear conversions and restrictions		X	X	X
Research and Monitoring				X

As the table indicates, no single management tool can address all four externalities, suggesting the need for a combination of management tools. While the table shows which externalities can be addressed with each tool, the extent to which each tool fully corrects each externality depends on its specific application. The purpose of the table is to show how the proposed mitigation measures address the externalities that create a market failure of excessive habitat destruction.

One general rule in environmental policy development is that when designed properly, a combination of multiple policy instruments is a more cost-effective way to address the market failures associated with multiple externalities than any one management measure alone. On the U.S. West Coast, there are four distinct externalities with regard to EFH. By addressing these externalities on multiple fronts, the Comprehensive Alternative is the most cost-effective, precautionary, and practicable alternative that sufficiently mitigates the adverse impacts of fishing on EFH as required by the Sustainable Fisheries Act.

The Economic and Ecological Benefits of Bottom Trawl Closures

There has been substantially more effort focused on the potential costs of the trawl closures proposed in Alternative C.12 (and in fact all mitigation alternatives) than on its potential benefits. However, when making important decisions affecting the future of U.S. West Coast fisheries, it is essential that attention be focused on using the best available information to understand not only the short and long term fisheries benefits of protecting habitat, but also the long-term ecological costs of failing to do so. With regard to the former, several major scientific efforts have quantified the benefits of previous area closures. The EFH EIS should include a review of these studies to provide the public with a more complete understanding of the current state of knowledge on expected benefits of bottom trawl closures. With regard to the latter, any analysis of practicability must include a discussion of the long-term ecological costs and benefits of habitat protection.

The EFH EIS should include a discussion and estimation of avoided costs. Several studies found reductions in commercial fish populations as a result of habitat damage caused by trawling and/or increased landings in areas with un-impacted coral and sponge habitats (i.e. Reed 2002; Rellini et al. 2000; Rothchild 1994; Sainsbury et al. 1993; Thrush and Dayton 2002; Vassilopoulou and Papaconstantinou 2000; Husebo et al. 2002; Bradstock & Gordon 1983). These studies corroborate the hypothesis that biogenic habitats act as a component of "natural capital" that produces fish. The economic loss of a capital stock of habitat is calculated using the discounted present value of all future fish production that will no longer occur when the habitat is not available. Since the recovery rates of biogenic habitats in particular are so slow, the present value of all future losses can be quite significant. Therefore, the benefits of avoiding the loss of the habitat stock are the exact converse of the costs of the lost productivity if the habitat is lost. As such, benefits of habitat protection can be calculated by the avoided cost of habitat damage. Rudd et al. (2003) states that "Fully accounting for the value of ecological services flowing from marine reserves requires consideration of increased size and abundance of focal species within reserve boundaries, emigration of target species from reserves to adjacent fishing grounds, changes in ecological resilience, and behavioral responses of fishers to spatially explicit closures."

Second, there are several models available to estimate these avoided costs in the scientific literature. Specifically, Rodwell et al. (2003) developed a model whose results indicate that habitat protection in reserves can underpin fish productivity and, depending on its effects on fish movements, augment catches. The authors state that "Marine reserves increase total fish biomass directly by providing refuge from exploitation and indirectly by improving fish habitat in the reserve". Although Revised Alternative C.12 does not propose marine reserves, this type of model could and should be used to evaluate the effects of management measures. Conover et al. (2000) discusses the potential benefits of marine reserves including protecting critical habitats that have been depleted, conserving marine biodiversity, and enhancing the harvest of stocks outside the reserve. Soh et al. (2001) used GIS analysis and found that marine reserves can greatly protect shortraker and rougheye rockfish populations from habitat impacts, discards, and serial overfishing of substocks without reducing catch levels. White et al. (2000) showed that the costs of a marine reserve for tropical coral protection were greatly outweighed by the benefits from higher catches. Koslow et al. (2001) found that heavy trawling has completely removed the deep sea coral and sponge aggregations and that benthic biomass was 106% greater and species richness was 46% greater on unfished seamounts than fished seamounts. Wheeler et al. (2003) found broken coral rubble and dead coral in areas of higher trawl intensity, whereas untrawled areas had a much higher abundance of undisturbed upright coral colonies. The authors state that even small coral thickets provide "cover" for fish and that destructive removal of this cover may have major implications for local fish stocks and coral associated biodiversity. The authors recommend using the precautionary principle by implementing fisheries technical measures to prevent further damage to coral until more is known about the relationship between fish and corals.

In particular, a great deal of literature has attempted to quantify the economic value of the fishery production services provided by tropical mangrove habitats. While this specific habitat type does not occur on the U.S. West Coast, the valuation techniques provided by these studies are directly relevant to the valuation of all fish habitat types. The most common technique found in this literature is to identify all fisheries directly or indirectly associated with mangrove habitat and attribute the entire ex-vessel values of each fishery to the associated habitat (Naylor and Drew 1998, Ruitebeck 1988, Christensen 1982, Hamilton & Snedaker 1984, Gren & Soderqvist 1994, Ronnback 1999, Sathirathai & Barbier 2001, Ruitenbeck 1988; Costanza et al. 1997; Swallow 1990). For example, Naylor and Drew (1998) assumed one-to-one habitat fishery linkages for surgeonfish, rudderfish, jacks, parrotfish, grouper, squirrelfish, snapper, rabbitfish, mullet, emperorfish, goatfish, and octopus, based identifying either direct reliance of these fish species on mangroves for food, reproduction, or protection or indirect reliance on mangroves for nutrient supplies that flow into the near-shore zone. These studies establish the precedent that until higher levels of habitat-fishery linkages are known (i.e. EFH Level 4), the EFH EIS should assume a one-to-one relationship between fish productivity and associated habitats.

Adaptive Management and the Future of Pacific Coast EFH Protections

The Revised Alternative C.12 lays the groundwork for future improvements to the management of Essential Fish Habitat off the U.S. West Coast for generations to come. The following section discusses potential options and policy directions that NMFS and the PFMC will have the opportunity to take in the future as a result of implementing Alternative C.12 through the current EFH EIS process. The statements made in this section are not to be interpreted as additional components of Alternative C.12 for consideration in the current EFH EIS process, but rather as a long-term vision of the possibilities for future ecosystem-based fishery management actions that may be taken subsequent to the implementation of Alternative C.12.

Incentives to Minimize Trawl Impacts in Remaining Open Areas

With the proper incentives, fishermen can control many factors that determine the degree to which their activities impact the seafloor. The additional monitoring required as part of Alternative C.12 will provide baseline data with a tremendous potential to evaluate individual performance and enact performance standards to achieve additional conservation incentives in the Groundfish Fishery Management Plan. The placement (physical location) of trawl set locations and the degree of impact on the seafloor are largely at the discretion of individual vessel captains. The various factors that play into this decision may include the likelihood of catching valuable target species and the likelihood that they will damage fishing gear. While some seafloor types cause major damage to trawl nets, such as large, sharp boulders, there is little evidence that biogenic habitat types such as living substrates damage trawl gear. Therefore, there exists no immediate incentive to avoid such habitats in the pursuit of fish, particularly if there are higher abundances of fish in these areas.

In addition to technology-based standards, such as gear restrictions, there are ways to create disincentives to fish in ways that cause damage to ocean habitats. By establishing performance standards that either mandate or reward more desirable fishing behavior, fishery managers can leave it to the experts, the fishermen, to determine the locations and gear types with which they fish. The benefit of such performance standards are that they give fishermen more flexibility in terms of the manner through which they meet a given conservation objective, and therefore, fishermen can determine for themselves the most cost-effective way of doing so. The disadvantage, conversely, is that performance standards generally cost more to monitor and enforce than command and control regulations such as gear restrictions.

One example of a performance standard that would create a disincentive to destroy vulnerable habitat features is a hard limit on habitat bycatch. Since trawl nets will retain a portion of structural living habitats, such as sponges, bryozoans, anemones, corals, and tunicates, the bycatch of these invertebrates can be used as an indicator of damage to vulnerable seafloor habitat. The limitation of these indicators is that they represent a limited set of habitat types and may not reflect structural damage to physical substrates such as rocks, boulders, sand, and the many small invertebrates that are too small to be retained in the net. Moreover, there have been few studies examining how much actual damage to seafloor invertebrates by bottom trawling is reflected in bycatch samples. However, structural invertebrate bycatch has the benefit of showing actual damage to the seafloor and may be a more direct indicator of damage than other approaches, such as effects of fishing models that assume homogenous distribution of habitat types.

Such bycatch limits should provide opportunities for fishermen, scientists and stakeholders to provide their input concerning setting appropriate bycatch limits, altering bycatch limits over time, whether to apply bycatch caps by fleet, sector, or individual vessel, the appropriate spatial scale at which to apply bycatch caps, consequences of exceeding bycatch caps, and rewards for avoiding bycatch. Table 2 (below at the end of this section) provides an example framework of decision points that could be considered in a future process to establish and implement habitat bycatch limits.

Conversely, rewarding "clean" fishing can provide a positive, and potentially profitable, incentive for habitat conservation. Such rewards must be based on accurate information about the performance of fishing vessels, which is precisely the rationale for enacting the monitoring regime described as part of Revised Alternative C.12.

Another idea for the future that may be considered after the implementation of the current EFH EIS is the concept of Spatially-Explicit Dedicated Access Privileges (SEDAPs). SEDAPs could be tradeable ***area-specific*** permits allocated to specific permit holders granting an exclusive privilege of a specified amount of annual trawl effort in a specified area. This SEDAP approach would be combined with effort reduction (buyout) and could include gear transfer considerations.

Potential Future Uses of VMS Data to Protect Essential Fish Habitat

In addition to providing monitoring of compliance, VMS data will also provide significant data to develop adaptive management measures in the future. VMS is a powerful tool that provides many additional management options to reduce habitat impacts. Once they are in place, fishery managers can better understand how fish habitats are being affected and can develop performance standards that create incentives to reduce the overall footprint of each trawl vessel. Habitat impact monitoring can be used to identify areas where bycatch rates are highest within areas that remain open. Additionally, they may also reveal more spatially explicit information on which areas have higher and lower relative effort. These data may be used to develop additional closed areas based on areas of higher bycatch rates and/or areas that are outside the future footprint of the bottom trawl fishery. As enforcement and monitoring capabilities improve with technological innovations, the scale of management, or the size of the grid blocks, should decrease so that management can take place at a resolution that better fits the patchiness of the seafloor habitat types and the spatial resolution of fishing effort.

Conclusion

In summary, these comments have outlined the clear evidence that Essential Fish Habitat on the U.S. West Coast is being adversely impacted by bottom trawling in a manner that is more than minimal and not temporary. Ecosystem-based fishery management and the Sustainable Fisheries Act demand that Essential Fish Habitat be explicitly managed and protected. The Revised Alternative C.12 is a compilation of over three years of an iterative, constructive process to develop a practicable and precautionary habitat management regime that meets the standards of the law. Oceana has gone to great lengths to conduct extensive literature reviews and obtain the highest quality data to develop a comprehensive policy solution. Revised Alternative C.12 is explicit regarding its use of the best available data given the uncertainties and most up-to-date understanding of this complex interdisciplinary challenge. Ideally, the selection and implementation of Revised Alternative C.12 will broaden the management scope of the Pacific Fishery Management Council to explicitly include considerations of Essential Fish Habitat in the overall ecosystem-based management of U.S. West Coast Groundfish Fisheries.

Oceana's Comprehensive Alternative has survived the scrutiny of the Council's Scientific and Statistical Committee, rigorous analysis by the state fishery management agencies, and has continually been improved as the direct result of constructive feedback from fishermen, fishery managers, scientists, and conservation interests. In implementing the Comprehensive Alternative, NMFS and the Council can rest assured that the Alternative offers substantial protection to known seafloor habitats that are vulnerable to bottom trawl fishing gear. In fact, based on the strong scientific evidence presented in these comments, protecting these areas will maintain and enhance the productivity of U.S. West Coast fisheries and the health of our ocean ecosystems. At the same time, Revised Alternative C.12 legitimates the economic needs of coastal communities and has been significantly refined based on comments from the SSC and trawl fishermen to improve its practicability. Revised Alternative C.12 shows that we can indeed conduct healthy, sustainable fisheries while adequately protecting the very habitats and ecosystems that are responsible for the high productivity and biodiversity of U.S. West Coast marine environments. Please adopt the Revised Alternative C.12 presented in these comments as the Preferred EFH Mitigation Alternative in the EFH Final EIS.

Scientists' Statement on Protecting the World's Deep-sea Coral and Sponge Ecosystems

As marine scientists and conservation biologists, we are profoundly concerned that human activities, particularly bottom trawling, are causing unprecedented damage to the deep-sea coral and sponge communities on continental plateaus and slopes, and on seamounts and mid-ocean ridges.

Shallow-water coral reefs are sometimes called "the rainforests of the sea" for their extraordinary biological diversity, perhaps the highest anywhere on Earth. However, until quite recently, few people - even marine scientists - knew that the majority of coral species live in colder, darker depths, or that some of these form coral reefs and forests similar to those of shallow waters in appearance, species richness and importance to fisheries. Lophelia coral reefs in cold waters of the Northeast Atlantic have over 1,300 species of invertebrates, and over 850 species of macro- and megafauna were recently found on seamounts in the Tasman and Coral Seas, as many as in a shallow-water coral reef. Because seamounts are essentially undersea islands, many seamount species are endemics - species that occur nowhere else - and are therefore exceptionally vulnerable to extinction. Moreover, marine scientists have observed large numbers of commercially important but increasingly uncommon groupers and redfish among the sheltering structures of deep-sea coral reefs. Finally, because of their longevity, some deep-sea corals can serve as archives of past climate conditions that are important to understanding global climate change. In short, based on current knowledge, deep-sea coral and sponge communities appear to be as important to the biodiversity of the oceans and the sustainability of fisheries as their analogues in shallow tropical seas.

In recent years scientists have discovered deep-sea corals and/or coral reefs in Japan, Tasmania, New Zealand, Alaska, California, Nova Scotia, Maine, North Carolina, Florida, Colombia, Brazil, Norway, Sweden, UK, Ireland and Mauritania. Because research submarines and remotely operated vehicles suitable for studying the deep sea are few and expensive to operate, scientific investigation of these remarkable communities is in its very early stages. But it is increasingly clear that deep-sea corals usually inhabit places where natural disturbance is rare, and where growth and reproduction appear to be exceedingly slow. Deep-sea corals and sponges may live for centuries, making them and the myriad species that depend on them extremely slow to recover from disturbance.

Unfortunately, just as scientists have begun to understand the diversity, importance and vulnerability of deep-sea coral forests and reefs, humans have developed technologies that profoundly disturb them. There is reason for concern about deep-sea oil and gas development, deep-sea mining and global warming, but, at present, the greatest human threat to coral and sponge communities is commercial fishing, especially bottom trawling. Trawlers are vessels that drag large, heavily weighted nets across the seafloor to catch fishes and shrimps. Scientific studies around the world have shown that trawling is devastating to corals and sponges. As trawlers become more technologically sophisticated, and as fishes disappear from shallower areas, trawling is increasingly occurring at depths exceeding 1,000 meters.

It is not too late to save most of the world's deep-sea coral and sponge ecosystems. We commend nations including Australia, New Zealand, Canada and Norway, which have already taken initial steps towards protecting some coral and sponge ecosystems under their jurisdiction. We urge the United Nations and appropriate international bodies to establish a moratorium on bottom trawling on the High Seas. Similarly, we urge individual nations and states to ban bottom trawling to protect deep-sea ecosystems wherever coral forests and reefs are known to occur within their Exclusive Economic Zones. We urge them to prohibit roller and rockhopper trawls and any similar technologies that allow fishermen to trawl on the rough bottoms where deep-sea coral and sponge communities are most likely to occur. We urge them to support research and mapping of vulnerable deep-sea coral and sponge communities. And we urge them to establish effective, representative networks of marine protected areas that include deep-sea coral and sponge communities.

The following 1,136 scientists have signed the *Scientists' Statement on Protecting the World's Deep-Sea Coral and Sponge Ecosystems*. Affiliations are for identification only, and do not imply endorsement by the signers' institutions.

Rachel T. Graham, Ph.D., University of York, York, UK
Gary D. Brewer, Ph.D., US Geological Survey, West Virginia, USA
Afifullah Khan, M.A., Department of Wildlife Sciences - AMU, Aligarh, India
Maria Joao Rodrigues, Ph.D. candidate, James Cook University, Queensland, Australia
Stephen van Leeuwen, Ph.D., Nickol Bay Naturalists' Club, Western Australia, Australia
Robert Davis, Ph.D. candidate, The University of Western Australia, Western Australia, Australia
Anne Salomon, Ph.D. candidate, University of Washington, Washington, USA
Carol Thornber, Ph.D., University of California at Davis, California, USA
Michael D. Noah, M.Sc., NOAA Fisheries & Ecosystems, Hawaii, USA
Joseph S. Ferris, Ph.D., AH Environmental Consultants, Inc., Virginia, USA
Adrain Gall, M.Sc candidate, Oregon State University, Oregon, USA
Veronica Estelle, M.Sc., Colorado State University, Colorado, USA
Clifton Ladd, M.Sc., Loomis Austin, Inc., Texas, USA
Terrance L. Breyman, M.Sc., Department of the Army, Washington D.C., USA
Matthew Perlik, M.Sc. candidate, Minnesota State University, Minnesota, USA
Horst Korn , Ph.D., Federal Agency for Nature Conservation, Putbus, Germany
Leah Gerber, Ph.D., Arizona State University, Arizona, USA
Steven R. Temple, Ph.D., University of California - Davis, California, USA
Camila Henriques, Ph.D. candidate, Aberdeen University, Aberdeen, UK
Tom Herman, Ph.D., Acadia University, Nova Scotia, Canada
Bhavani E Narayanaswamy, Ph.D., Scottish Association for Marine Science, Oban, UK
Giovanni Santangelo, Ph.D., Evolution University of Pisa, Pisa, Italy
Elizabeth Galley, Ph.D., University of Southampton, Southampton, UK
Birgit Luef, Ph.D. candidate, University of Vienna - Institute of Ecology and Conservation Biology, Vienna, Austria
Fanni Aspetsberger, Ph.D. candidate, Research Center Ocean Margins - University of Bremen, Bremen, Germany
Christine M. McConaghy, M.E.M., Duke University, North Carolina, USA
Ruth Howell, B.A., Gulf of the Farallones National Marine Sanctuary, California, USA
Filipe Mora Porteiro, Ph.D. candidate, University of the Azores, Horta, Portugal
Carole Conway, Ph.D. candidate, University of California-Davis, California, USA
Steve O'Shea, Ph.D., Auckland University of Technology, Auckland, New Zealand
Michael Mirigian, B.A., Instructor-Advanced Placement Environmental Science, California, USA
Marlin J. Atkinson, Ph.D., University of Hawaii- Hawaii Institute of Marine Biology, Hawaii, USA
Whit Sheard, M.Sc., The Ocean Conservancy, Alaska, USA
Katie Barnas, M.E.M., NMFS, Washington, USA
Lucy Keith, M.S., Florida Fish and Wildlife Conservation Commission, Florida, USA
Aleta Erickson, M.M.A./ M.S. candidate, University of Washington/ Jamestown S'Klallam Tribe, Washington, USA
Lloyd F. Lowry, M.Sc., Univeristy of Alaska- Fairbanks, Alaska, USA
Kathryn J. Frost, M.Sc., University of Alaska Fairbanks, Alaska, USA
Joseph J. Cech Jr., Ph.D., University of California- Davis, California, USA
Laurie Sindlinger, M.Sc., RSMAS- University of Miami, Florida, USA
Anna Bass, Ph.D., Allan Hancock College, California, USA
Nicole Milne, M.Sc. candidate, University of Washington- School of Marine Affairs, Washington, USA
Christoph Richter, Ph.D., Queen's University, Ontario, Canada
Lei Lani Stelle, Ph.D., Rochester Institute of Technology, New York, USA

Dorothy Dick, M.Sc. candidate, San Francisco State University, California, USA
David K. Mellinger, Ph.D., Oregon State University, Oregon, USA
Leslie A. Cornick, Ph.D., Connecticut College- Dept. of Biology, Connecticut, USA
Dário Alves, M.Sc., University of Tromso, Tromsø, Norway
David Stein, Ph.D., National Systematics Laboratory- NMFS, Washington DC, USA
Varvara Kandia, M.Sc., Univetsity of Crete, Hrakeio, Greece
Fabian Ritter, Dipl.-Biol. , M.E.E.R. e.V., Berlin, Germany
Sophy McCully, M.Sc. candidate, University of Wales- Bangor, Gwynedd, UK
John Woodside, Ph.D., Vrije Universiteit of Amsterdam, Amsterdam, Netherlands
Samantha Wellman, Ph.D. candidate, Newcastle University, NSW, Australia
Frank Veit, Ph.D., Int. Laboratory for Dolphin Behaviour Research, Eilat, Israel/Germany
Nan Hauser, Ph.D. candidate, Southern Cross University, Rarotonga, Cook Islands
Kym Collins, Ph.D. candidate, University of Sydney, Sydney, Australia
Kate McFadden, Ph.D. candidate, Columbia University, New York, USA
Dhugal J. Lindsay, Ph.D., Japan Marine Science and Technology Center/University of Queensland, Yokosuka, Japan/Australia
Tracey Sutton, Ph.D., Harbor Branch Oceanographic Institution, Florida, USA
David Scheel, Ph.D., Alaska Pacific University, Alaska, USA
Inge Werner, Ph.D., University of California Davis, California, USA
Janie Civille, Ph.D. candidate, Evolution and Ecology Section- University of California Davis, California, USA
Peter L. Chesson, Ph.D., University of California, California, USA
John Amos, M.Sc., SkyTruth, West Virginia, USA
Tara Wilkinson, M.Sc. candidate, McGill University, Montreal, Canada
Amy Mathews Amos, M.S., Turnstone Consulting, West Virginia, USA
Eric F.G. Hochberg, Ph.D., Santa Barbara Museum of Natural History, California, USA
Christina Stylianos, M.S. candidate, Nova Southeastern University, Florida, USA
Belinda Alvarez de Glasby, Ph.D., Museum and Art Gallery of the Northern Territory, Northern Territory, Australia
Jeffrey Mangel, M.S.; M.E.M., Pro Delphinus, Lima, Peru
Peter Kruse, Ph.D., Northern Territory Geological Survey, Northern Territory, Australia
Eduardo Infantes Oanes, M.Sc ., University of Plymouth, Devon, UK
Clementina Equihua, M.Sc. Instituto de Ecologia; UNAM, México City, México
Rob W.M. van Soest, Ph.D., Zoological Museum of the University of Amsterdam, Amsterdam, Netherlands
Isabel Sousa Pinto, Ph.D., University of Porto, Porto, Portugal
Raúl García Barrios, Ph.D., CRIM-UNAM, Mexico City, Mexico
Gesche Pluem, M.Sc., University of Hawaii at Manoa, Hawaii, USA
Virginie Stirbois, M.Sc. candidate, Marine Environmental Management - IUSC, Barcelona, Spain
Patricia Castillo-Briceño, M.Sc., PUCE, Manta, Ecuador
Ivette Rodriguez, M.Sc., Colegio de la frontera Norte, Baja California Norta, México
Efrain Alfonso Rubio Rincon, Ph.D., Departamento de Biologia-Escuela de Biologia Marina, Cali, Colombia
Helena Iturribarría, B.S., Pronatura NMC-Sonora, Sonora, México
Peter E. Miller, Ph.D., University of California - Santa Cruz, California, USA
Tamara Yunes, M.A., CETA, Buenos Aires, Argentina
Calhoun Bond, Ph.D., Greensboro College, North Carolina, USA
Vanessa Lauronce, M.Sc., Oceanography & Marine Biology, Toulouse, France
Erika Zavaleta, Ph.D., University of California - Santa Cruz, California, USA
Inge Armbrecht, Ph.D., Universidad del Valle, Cali, Colombia
Don Croll, Ph.D., University of California - Santa Cruz, California, USA
Detmer Sipkema, M.Sc., Wageningen University, Wageningen, The Netherlands
Elaine Espino-Barr, Ph.D., CRIP- Manzanillo, Colima, México
Stacy Philpott, Ph.D. candidate, University of Michigan, Michigan, USA

Simone Pfeifer, M.Sc., Institute for Applied Ecology, Neu-Broderstorf, Germany
Nelly de Paz Campos, M.Sc. candidate, National University of San Marcos, Lima, Peru
Bernie Tershy, Ph.D., University of California - Santa Cruz, California, USA
Salvador Contreras Balderas, Ph.D., Bioconservación - A.C. & Universidad A. de Nuevo León, Nuevo León, México
Elen Oneal, Ph.D. candidate, University of Michigan - Ann Arbor, Michigan, USA
Odalisca Breedy, M.Sc., Museo de Zoologia - Universidad de Costa Rica, San Jose, Costa Rica
Ann Knowlton, Ph.D., Western Washington University, Washington, USA
Henry M. Reiswig, Ph.D., University of Victoria and Royal British Columbia Museum, British Columbia, Canada
Teresa Bosques, M.Sc. candidate, Univesidad Nacional Autonoma de Mexico, Mexico City, Mexico
Antonio del Rio, Ph.D., National Autonomous University of Mexico, Cuernavaca, Mexico
Daniel E Roberts, Ph.D., Bioanalysis, Marine, Estuarine and Freshwater Ecology, New South Whales, Australia

Jeffrey Crooks, Ph.D., Tijuana River National Estuarine Research Reserve, California, USA
Leopoldo Moro Abad, Lcdo., Dirección General del Medio Natural - Gobierno de Canarias, S/C de Tenerife, Spain
Ronald R. West, Ph.D., Natural History Museum & Biodiversity Research Center, Kansas, USA
K. Kelly Hildner, Ph.D., University of California - Santa Cruz, California, USA
Beverly J. Rathcke, Ph.D., University of Michigan, Michigan, USA
Matthias Obst, Ph.D. candidate, University of Aarhus, Aarhus, Denmark
Julie Jedlicka, M.Sc. candidate, University of Michigan, Michigan, USA
Edward B. Cutler, Ph.D., Harvard University, Massachusetts, USA
Stephanie Huff, Ph.D., Harvard University, Massachusetts, USA
Raúl Sanchez Scaglioni, Ph.D., GEA PERU, Lima, Peru
Gerald R. Smith, Ph.D., University of Michigan, Michigan, USA
Salvador Ruiz Ramirez, M.Sc., Universidad de Guadalajara, Jalisco, Mexico
Carol Landry, Ph.D. candidate, University of Michigan, Michigan, USA
Alfredo Aretxabaleta, Ph.D. candidate, University of North Carolina at Chapel Hill, North Carolina, USA
Catherine Johnson, Ph.D., University of New Hampshire, New Hampshire, USA
Ella Vázquez Domínguez, Ph.D., Instituto de Ecologia - UNAM, México City, México
Gonzalo Giribet, Ph.D., Harvard University, Massachusetts, USA
Enrique Copeiro del Villar, Ph.D., free lance professional, Las Palmas de Gran Canaria, Spain
Theresa Sinicrope Talley, Ph.D., University of California - Davis, California, USA
Anja Schulze, Ph.D., Harvard University, Massachusetts, USA
Jun Bando, Ph.D. candidate, University of California - Davis, California, USA
Sally Leys, Ph.D., University of Alberta, Alberta, Canada
Dirk Van Vuren, Ph.D., University of California - Davis, California, USA
Jose Ignacio Fernandez Mendez, M.Sc., Instituto Nacional de la Pesca, México Ciry, México
Prosanta Chakrabarty, Ph.D. candidate, University of Michigan Museum of Zoology, Michigan, USA
Richard R. Vance, Ph.D., University of California at Los Angeles, California, USA
Antonio Mateo Solé Cava, Ph.D., Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil
Alan Cervantes, M.Sc. candidate, Universidad Nacional Autónoma de México - CIECO, México City, México
Naomi A. Rose, Ph.D., The Humane Society of the United States, Maryland, USA
Boury-Esnault Nicole, Ph.D., CNRS France, Marseille, France
Arthur A. Wolfson, Ph.D., International Biological Consultants, California, USA
James Saracco, Ph.D., Independent biologist, Alaska, USA
María Ordóñez, Ph.D., Centro Regional de Investigaciones Multidisciplinarias - UNAM, Morelos, México
Ardis Johnston, M.Sc., Harvard University, Massachusetts, USA
Lynn E. Carroll, Ph.D., TEDX, Inc., Colorado, USA

Tomas A. Carlo Joglar, Ph.D. candidate, University of Colorado, San Juan, Puerto Rico
Jose V. Lopez, Ph.D., Harbor Branch Oceanographic Institution, Florida, USA
Priscilla Winder, Ph.D. candidate, Harbor Branch Oceanographic Institution, Florida, USA
Drew M. Talley, Ph.D., University of South Florida, Florida, USA
Juliann E. Aukema, Ph.D., North Carolina State University, North Carolina, USA
Claudia Penaloza, Ph.D. candidate, Duke University, North Carolina, USA
Shaleyla Kelez, B.S., Grupo de Tortugas Marina-Perú, Lima, Perú
Gabriela García Rubio, M.Sc., ECOSUR, Quintana Roo, México
Ana Minerva Arce-Ibarra, Ph.D. candidate, El Colegio de la Frontera Sur, Quintana Roo, México
Patricia Balvanera, Ph.D., Centro de Investigaciones en Ecosistemas - UNAM, Morelia, México
Carol T. Stuart, Ph.D., University of Massachusetts - Boston, Massachusetts, USA
Dennis Lavrov, Ph.D., Universite de Montreal, Quebec, Canada
Juan J. Schmitter-Soto, Ph.D., El Colegio de la Frontera Sur, Chetumal, México
Todd J. McWhorter, Ph.D., University of Wisconsin-Madison, Wisconsin, USA
Carlos Ruiz, Ing., ECOSUR, Chiapas, México
Miriam Suárez, Licenciatura, UNAM, Chiapas, México
Alejandro Flamenco-Sandoval, Ph.D. candidate, UNAM, Morelia; Michoacán, México
Carolina Palacios Guevara, M.Sc. candidate, UNAM, México City, México
Carolyn Hedley, M.E.S. candidate, Dalhousie University, Nova Scotia, Canada
Kevin Crooks, Ph.D., Colorado State University, Colorado, USA
Gerald P. Rasmussen, M.S., Department of Environmental Conservation, New York, USA
Ana Claudia Nepote, M.Sc., Biotopia - A.C., Morelia, México
Richard P. Reading, Ph.D., Denver Zoological Foundation, Colorado, USA
Jorge E. Schondube, Ph.D., Centro de Investigaciones en Ecosistemas-UNAM, Morelia, México
Jose Ramón Delgado Padrçon, M.Sc., Unidad de Medio Ambiente - MRE, Caracas, Venezuela
Carlos Martinez del Rio, Ph.D., University of Wyoming, Wyoming, USA
Anna Soler Vila, M.Sc., Martin Ryan Institute - NUIG, Galway, Ireland
Simon Bicknell, M.Sc., Marine Institute, Galway, Ireland
Annika Mitchell, M.Sc.; Ph.D. candidate, Queen's University Belfast, Northern Ireland, UK
Ernesto Godelman, M.A., CeDePesca, Mar del Plata, Argentina
Beatriz Gimenez Reguera, M.Sc., Exotarium, Madrid, Spain
Jan Vanaverbeke; Ph.D., Ghent University, Gent, Belgium
Miltiadis-Spyridon Kitsos. Ph.D., University of Thessaloniki, Thessaloniki, Greece
Rafael Ph.D.; M.B.A.; Centre d'Estudis Avançats de Blanes, Girona, Spain
Milthon B. Lujan Monja, M.Sc.; Asociacion Aquacultura y Desarrollo; Chimbote; Perú
Laurand Sandrine, M.Sc.; University Paris 6; Paris, France
Harvey Tyler-Walters; M.Sc.; Ph.D., Marine Biological Association of the United Kingdom, Plymouth, UK
Jean Vacelet; Ph.D.; Centre d'Océanographie de Marseille, Marseille, France
Ward Appeltans; M.Sc.; Flanders Marine Institute; Ostend, Belgium
Yaiza Fernández-Palacios; Ph.D. candidate, Instituto Canario de Ciencias Marinas, Canary Islands, Spain
Maria Herminia Cornejo Rodriguez, M.Sc., Biologist School, Guayas, Ecuador
María Gómez Ballesteros, Ph.D., Instituto Español de Oceanografía, Madrid, Spain
Jhoni Ismael Quispe Becerra, Ph.D. candidate, University of Murcia, Murcia, Spain
Miguel Angel Garcia Campos, M.A., Engineer consulter, Las Palmas, Spain
David Barkin, Ph.D., Universidad Autonoma Metropolitana-Xochimilco, México City, México
Cristina Rodriguez-Cabello, M.Sc., IEO, Santander, Spain
Antonio Hernandez Matias, Ph.D., Instituto Español de Oceanografía, Santander, Spain
Jose Ignacio Fernandez de la Pradilla Villar, M.Sc., University of St. Andrews, St. Andrews, Scotland
Gidon Winters, Ph.D. candidate, Tel Aviv University, Eilat, Israel
Alberto Brito Hernández, Ph.D., Universidad de La Laguna, Canary Islands, Spain
Rafael Araujo, Ph.D, Museo Nacional de Ciencias Naturales, Madrid, Spain
Pilar Todo Vila, M.Sc., aquaculture consultant, Barcelona, Spain

Antonio García-Allut, Ph.D., Coruña University, A Coruña- Galicia, Spain
Xavier Pastor, B.S., Oceana, Madrid, Spain
Linda Lyshall, M.E.M candidate, Evans School of Public Affairs, Washington, USA
Gwen Goodmanlowe; Ph.D., California State University -Long Beach, California, USA
Jonathan L. Temte, M.Sc.; M.D., Ph.D., University of Wisconsin, Wisconsin, USA
Eliane Truccolo, Ph.D. candidate, Universidade do Vale do Itajai - Univali, Santa Catarina, Brazil
José Gustavo Natorf de Abreu, Ph.D. candidate, Universidade do Vale do Itajaí - UNIVALI, Santa Catarina, Brazil
Andre Silva Barreto, Ph.D., CTTMar - Universidade do Vale do Itajai, Itajai, Brazil
Jacqueline Savitz, M.Sc., Oceana, Washington DC, USA
Daphna Feingold, M.Sc. candidate, University of Haifa, Israel
Cecilia Rivas, M.Sc., Grupo de Estudios Ambientales del Perú and San Ignacio de Loyola Universitym, Lima, Perú
Jeremy Potter, M.E.M., NOAA Ocean Exploration, Washington DC, USA
Charlotte Gray Hudson, M.E.M., Oceana, Massachusetts, USA
Santi Roberts, M.Sc., Oceana, Washington DC, USA
Rhonda Kranz, M.Sc., Ecological Society of America, Washington DC, USA
Jo Marie V. Acebes, D.V.M., World Wide Fund for Nature- Philippines, Quezon City, Philippines
Bojan Lazar, Ph.D. candidate, Croatian Natural History Museum, Zagrab, Croatia
Joanna Alfaro Shigueto, M.Sc., Pro Delphinus, Lima, Perú
Jeffrey Firestone, Ph.D. candidate, University California - Davis, California, USA
Alexander von Hildebrand, M.A., VOARISOA - Observatoire Environnement et Produits Toxiques, Antananarivo, Madagascar
Jarrett Byrnes, Ph.D. candidate, University of Califronia - Davis, California, USA
Robert Wilcox, Ph.D., Northern Kentucky University, Kentucky, USA
Amber J. Mace, Ph.D. candidate, University of California - Davis, California, USA
Howard Daugherty, Ph.D., York University, Ontario, Canada
Catherine S. McFadden, Ph.D., Harvey Mudd College, California, USA
Andres Guhl, Ph.D. candidate, University of Florida, Florida, USA
Herbiet Patrice, M.A., UNAM, México, México
Michael Hiscock, Ph.D. candidate, Duke University, North Carolina, USA
Kifle Woldesilassie Hagos, M.A., Ministry of Fisheries, Eritrea
Tamara Shiganova, Ph.D., P.P.Shirshov Institute of Oceanology - Russian Academy of Sciences, Moscow, Russia
Francesc Giró, M.Sc., Fundación Natura, Barcelona, Spain

Dr. James Balsiger, Administrator
Alaska Region
National Marine Fisheries Service
709 West Ninth Street
Juneau, AK 99802-1668

Ms. Stephanie Madsen, Chair
North Pacific Fishery Management Council
222 Seward Street, Suite 200
Juneau, AK 99801

Dear Dr. Balsiger and Ms. Madsen:

Corals, sponges, and other living seafloor communities are important to the health of our oceans. The current Essential Fish Habitat Environmental Impact Statement process for the North Pacific provides the opportunity for the National Marine Fisheries Service (NMFS) and the North Pacific Fishery Management Council (NPFMC) to conserve corals, sponges, and other living seafloor communities that provide habitat for fishes from destructive fishing practices. We, the undersigned marine scientists and marine conservation biologists are concerned by the actions and rationale of the NMFS and NPFMC that fail to protect deep sea corals and sponges in North Pacific waters.

Presence of living benthic structure increases habitat complexity and sustains patterns of biodiversity in our ocean ecosystems. Cold water corals are among the most vulnerable and oldest seafloor habitats in Alaska. Many marine species, including commercially important species, utilize the vertical and three-dimensional structure provided by corals and sponges. Widely distributed in the Aleutians, Bering Sea, and Gulf of Alaska, these long-lived animals can protect fishes from strong currents and predators, as well as serve as nurseries for juveniles, and focal sites for feeding and reproduction.

Gorgonian corals, such as the red tree coral *Primnoa* spp. and the bubblegum coral *Paragorgia arborea,* are one of the most prominent groups of corals in Alaska. Both grow slowly, but can reach large sizes (3 m tall) and great ages (200+ years) if left undisturbed. Rockfish, Atka mackerel, walleye pollock, Pacific cod, sablefish, flatfish, crabs, and other economically important species in the North Pacific are found around red tree coral in the Gulf of Alaska (Krieger and Wing 2002). Among fish caught around corals during trawl surveys from 1975-1998, rockfish and Atka mackerel were most commonly caught around gorgonian, cup, and hydro- corals (Heifetz 2000). Eighty three percent of the rockfish observed during one study were associated with red tree coral (Krieger and Wing 2002). The removal or damage of red tree corals in Alaskan waters could have long term effects on associated faunal communities (Krieger and Wing 2002).

Video observation indicates that some managed fish species in the Aleutian Islands are highly associated with corals, sponges and other structure-forming invertebrates. One hundred percent of juvenile rockfish and eighty seven percent of all managed species counted in video from dives around the Aleutian Islands in 2002 were found within or very near these organisms (Stone, unpublished data). In recognition of their ecological importance and vulnerability to the adverse effects of fishing, coral, sponges, and other structure-forming seafloor communities have been identified as habitat areas of particular concern in Alaskan waters (Amendment 55/55/8/5/5 to the Fishery Management Plans for

BSAI Groundfish, GOA Groundfish, BSAI Crab, Alaska Scallop, and Salmon in the EEZ, pg 362-364, Jan.1999).

Bottom trawling destroys far more ocean habitat than any other fishing practice on the West Coast. The NMFS estimates about one million pounds of corals and sponges were removed from the seafloor of the Aleutian Islands and the Bering Sea annually between 1997 and 1999 by commercial fishing – over 90% by bottom trawlers (NMFS 2003). The impacts of this kind of destruction are neither minimal nor temporary. Both hard corals and soft corals can be extremely slow growing and sensitive to disturbance (*eg* Krieger 2001, Witherell and Coon 2000). For some species, it could take hundreds of years, if ever, for these animals to recover from the destruction of bottom trawling (*eg* Witherell and Coon 2000, Risk *et al.* 1998, Andrews *et al.* 2002). Vase sponges, morel sponges, and seawhips in deep, cold water habitats such as those in the Gulf of Alaska are also very vulnerable and slow to recover from bottom trawling (Freese *et al.* 1999, Freese 2001).

As documented in the National Academy of Sciences, National Research Council report of 2002, "Effects of Trawling & Dredging on Seafloor Habitat," bottom trawling reduces the complexity and biological diversity of seafloor habitats. The Academy recommends closures, gear modifications, and fishing effort reductions to mitigate the detrimental impacts of bottom trawling. Further, in February 2004, more than 1,100 of the world's foremost biologists signed a consensus statement calling for governments and the United Nations to protect imperiled deep sea coral and sponge ecosystems.

Currently in the North Pacific, NMFS is using the argument that bottom trawling in Alaska has no more than a "minimal" impact on habitat. The agency is using the rationale that in order to be more than minimal, habitat degradation must be so severe as to cause commercial fish stocks to collapse below sustainable levels. NMFS is measuring habitat effects by gauging the stock status of commercial fish, an inappropriate proxy as fisheries scientists cannot separate the effects of overfishing from those of habitat destruction on the status of fish populations. Rather, the effects on habitat should be directly measured, using observation and experiment.

NOAA scientists have said that the deep-sea corals in the Aleutians in particular are likely unparalleled in the world and that they have observed areas of damaged corals and associated organisms. Further, NMFS' own analysis shows that habitat-structuring organisms like corals, sponges, bryozoans, tunicates, crinoids, and anemones will be reduced 70-90% in thousands of square kilometers of habitat if current fishing practices continue. These losses are not inconsequential. Ecosystems are naturally resilient, but only to a point. Waiting to cross that threshold is dangerous. If the resiliency of a system is exceeded, the change can be irrevocable.

The time is now to protect Alaska's corals. We strongly urge the Council and NMFS to protect sensitive benthic habitat from destructive fishing practices.

Subject: Comment on 2005 Pacific Coast Groundfish EFH DEIS

Recreational fishermen have long been the stewards of ocean and fishery conservation. We support a healthy ocean environment, since without it we would not enjoy a meaningful recreational experience, either now or in the future.

The Coastside Fishing Club supports measures that will protect our Essential Fish Habitat (EFH). Our priorities are 1) public access and utilization of this public resource for recreational purposes before any commercial extraction. 2) That any fishing gear and techniques allowed in such an area must pose no threat to the environment. 3) That recreational fishing, and in particular mid-water and surface trolling for game species (e.g. salmon, tuna, etc), not be impacted by EFH restrictions except where there is strong scientific evidence that it would be harmful. We have consistently advocated that vertical hook and line fishing methods pose no threat to EFH. However, we acknowledge that essential bottom habitat is directly threatened by the commercial groundfish trawl industry, and that EFH protection must address the impacts caused by such destructive fishing practices.

The Coastside Fishing Club has reviewed the Essential Fish Habitat (EFH) DRAFT Environmental Impact Statement, and evaluated the various alternatives adopted by the PFMC. Of all the alternatives considered, only Alternative 12 represents a comprehensive approach towards protecting EFH, while preserving the publics right to access and utilize this public resource. Developed by Oceana and others, this alternative addresses all three objectives of the Sustainable Fisheries Act, is easy to comprehend, and is an effective response to the federally mandated protection of essential fish habitat. Our assessment of the alternative finds that the Oceana plan accurately identifies habitat areas sensitive to fishing impacts, and that the included maps and descriptions are complete. The Oceana plan, in accordance with findings from the NRC (National Academy of Sciences, National Research Council 2002: *The Effects of Trawling and Dredging on*

Seafloor Habitat) correctly identifies that ground trawl gear, practices, and operations are the primary threat to essential fish habitat; and proposes to mitigate those effects through closures, gear modification, and effort reduction. Finally, Alternative 12 proposes other reasonable and effective actions to encourage the conservation and enhancement of essential habitat areas.

The two variations to Alternative 12, Alternatives 13 and 14, unnecessarily restrict recreational fishing, without demonstrating a need for such restrictions or indicating how such restrictions would actually enhance EFH protection. While Alternative 13 does not specifically address recreational fishing, the language might be construed as doing so. Because of these restrictions we do not support either Alternative 13 or 14. The other 11 alternatives are not comprehensive and are therefore difficult to evaluate without knowing how they might be combined into an overall EFH protection package. Additionally, instead of doing a scientific analysis of biogenic habitat these other alternatives rely too heavily on identification of sites where fish are currently found, rather than embracing a broader ecosystem management approach. The Oceana analysis is habitat-based: they looked for places were corals, sponges, or other animal life exist and then drew lines around those areas – a more comprehensive ecosystem approach than found in the other 11 original alternatives.

The Coastside Fishing Club endorses the findings and proposed actions contained in Alternative 12. We encourage its adoption by the Council and by NMFS; either as the single preferred alternative, or fully incorporated into a new alternative that eliminates bottom trawling in EFH designated areas. Bottom trawling is the primary threat to essential fish habitat, and Alternative 12 specifically mitigates this threat while preserving recreational mid water, surface, and bottom fishing utilizing vertical hook and line gear.

RECEIVED
MAY 09 2005
PFMC

Mr. Donald Hansen, Chairman
Pacific Fishery Management Council
7700 NE Ambassador Place, Suite 200
Portland, OR 97220-1384

Dear Mr. Lohn and Mr. Hansen:

The California Coastal Commission works to protect, conserve, restore, and enhance environmental and human-based resources of the California coast and ocean for environmentally sustainable and prudent use by current and future generations.

The Commission supports precautionary approaches to managing federal fisheries to protect sensitive marine habitats. It is critical to protect important seafloor habitat like corals and sponges, and other special places such as seamounts and deep sea canyons, from damaging fisheries practices, such as bottom trawling, in order to protect ocean ecosystems while maintaining vibrant fisheries.

As you consider the Pacific Groundfish Essential Fish Habitat Environmental Impact Statement, we encourage the Pacific Fishery Management Council and the National Marine Fisheries Service to adopt a precautionary alternative to minimize adverse effects of fishing on essential fish habitat.

Sincerely,

Meg Caldwell

c/o Maryann Nickerson

7600 Sand Point Way, NE

Bin C15700

Seattle, WA 98115-0070 Comment on 2005 Pacific Coast Groundfish DEIS

Dear Mr. Lohn;

The lawsuit litigation that forced the Pacific Fishery Management Council to develop an Essential Fish Habitat Environmental Impact Statement did not challenge the content of the FMP but only the process used to develop the FMP. The judge ruled that the FMP fell short of following NEPA procedure and therefore the

Council needed to revisit the development of the FMP using correct NEPA procedures. However, the Council, fearing further lawsuits or perhaps even a directive from NMFS or by NOAA Fisheries Office of General Council, made the decision that NEPA compliance, or over-burdening the management system, is now a priority. This became obvious when Alternative 1, status quo, was eliminated from the Council's preferred options. What we should be asking is whether NEPA, and how NOAA Fisheries has started implementing it, fosters or hinders timely, high quality federal fisheries management and whether it could disrupt the intent and goal of the best management decisions for fishermen and conservation.

To quote attorney David Frulla's recent testimony to the U.S. House of Representatives Committee on Resources, "NEPA is a procedural statute. It imposes no substantive conservation obligations. That said, the environmental community has often used NEPA as a litigation device to attempt to force a substantive reconsideration of an agency action with which it did not agree. Accordingly, there are two elements of NEPA that should concern the Subcommittee: (1) whether it serves as an effective independent mechanism to ensure quality agency decision-making; and (2) whether it actually also serves to improve the quality of NOAA Fisheries decision-making. Regarding the first point, the litigation record shows that NEPA is, quite simply, over-rated as an enforcement tool. As to the latter, I submit that a wide array of substantive statutes independently help to ensure environmentally-aware decision-making. In fact, NEPA obligations may actually inhibit timely, science-based management."

While status quo for many may mean no change, business as usual, that is certainly not at all the case with our Pacific Fishery Management Council or the west coast fishing fleet. Status quo here means a continuation of heavy management measures while the resources continue to rebuilding. For the trawl fleet, this has meant: Fleet reduction via the buy-back program; Prohibited large roller gear use; Restrictions of use of large footrope gear areas; Implementation of small footrope gear and areas of use; Development of the selective flat fish net and restriction on deployment; Introduction and mandatory use of excluders in all shrimp trawls; Forced to carry observers for data collection activities; Coerced to operate under "house arrest" with the unfunded mandatary VMS program; Forced to develop the RCA and boundary modifications; Engaged in collaborative research to help improve the science; Current development of ITQ program to reduce discards with industry funding; Reduced time on the water by 75 to 80 percent; Reduced our earnings by at least 75%.

THE FACT OF THE MATTER IS THAT NO MATTER WHAT THE TRAWL FLEET DOES TO IMPROVE THE SITUATION, OCEANA AND NATURAL RESOURCE DEFENSE COUNCIL WILL NEVER BE SATISFIED. Look at either groups' website and you will see that their goal is to eliminate all net fishing. This is unreasonable. So how can any appeasement be made? We believe that you and the Council should take a stand against eco-terrorists by just saying no. Remember the judge didn't have a problem with the plan, just the technical NEPA procedure.

We encourage NMFS and the Council to select the following:

A. IDENTIFY AND DESCRIBE ESSENTIAL FISH HABITAT

CBTA preferred Alternative A.1 status quo

Second choice Alternative A.2 Depths less than 3500 meters

B. Designate Habitat Areas of Particular Concern

CBTA preferred Alternative B.1 status quo

Second choice Alternative B.2 Estuaries, 3 Canopy Kelp, 4 Seagrass, and 6 Rocky reefs combined

C. MINIMIZE ADVERSE IMPACTS ON EFH DUE TO FISHING

CBTA preferred Alternative C.1 status quo

Second choice Alternative C.4.1 Prohibit the geographic expansion of fishing for all bottom-tending gear and if other alternatives are also going to be adopted then it has to be the "Trawl Industry's Proposal" developed through meetings on the west coast with Pete Leipzig.

D. RESEARCH AND MONITORING

CBTA preferred Alternative D.1 status quo

Second choice has not been developed by anyone. But we would prefer status quo with added collaborative research on fishing impacts.

The expanded logbook program really does not need to be an alternative. The current logbook law requires all commercial fishermen to keep logbooks but the government has chosen to enforce it with only one group, the trawlers. If logbooks are going to be used in the future, one type should be produced for the entire coast that emphasizes total catch for both commercial and sport fishing.

VMS alternative is already in motion. However, CBTA is still against this system, especially because the government refuses to pay for this mandated equipment.

Fishermen feel that the Council is operating in fear of environmental group lawsuits and are willing to sacrifice every coastal community to appease them, all over of a question of NEPA procedure. The Council and its family of support agencies and committees have worked hard to manage our fisheries. The fleet in particular has made the most extreme sacrifices to ensure a healthy sustainable resource and to ensure the Council met compliance requirements of the management laws. We are very frustrated to see that NOAA is willing to flush it all down the toilet. Its our communities jobs at stake, not NMFS', that these environmental groups are willing to sacrifice.

The nation needs to address the frustration level environmental groups are placing on our fishing communities. The nation needs to weigh the stress these groups are placing on our hard working families against the donations these groups receive from their appeals to the public that the oceans are in crisis. The nation needs to address the fact that they are being duped by the desire to fund environmental groups effort to free the waters of nature loving fishermen.

Sincerely,

Steve Bodnar, Executive Director

Pacific Fishery Management Council

TO: Members of the Pacific Fisheries Management Council

In April, National Marine Fisheries hosted a public meeting in Bandon, Oregon on essential fish habitat and options being considered by the Council. It was very alarming and discouraging to learn from this meeting that the near shore area from Coos Bay to Bandon could possibly end up being closed to all fishing if option C14 were adopted. We were also very surprised to see that this was the only area on the Oregon Coast to be designated as a hard bottom habitat. That is most certainly not the case.

We understand that this map was prepared by Oceana, and when asked why this area was singled out, it was stated by the Oceana representative in attendance that it was the only data they had.

While we in no way endorse Oceana's proposal in Option C12, it could possibly be understood why the area was identified on the map as a no bottom trawl zone. It is an area already avoided by the trawlers due to the AT & T substation and the Bandon cable that runs offshore in that location. The trawlers receive mitigation not to fish there. We do not feel it is necessary for the area to be identified on the map for that reason. Under Options C13 and C14, the area designated as it is would have devastating effects on the rest of the commercial and recreational fleets in both Coos Bay and Bandon as well as both ports. The Port of Bandon strongly urges the Council to revisit this map and remove the hard bottom designation that we were singled out with.

Sincerely,

Alex Linke
Port Director

Re: Comment on 2005 Pacific Coast Groundfish DEIS

Dear Mr. Lohn,

These comments are submitted on behalf of Oregon Anglers and the Recreational Fishing Alliance (Oregon Group). We represent recreational fisherman in Oregon (Oregon Anglers) as well as at the national level (RFA). We appreciate the opportunity to present our views and concerns relating to Groundfish EFH

In the Magnuson-Stevens Fishery Conservation and Management Act we find a guideline for analyzing, and then choosing or suggesting alternatives relating to EFH. We are referring to the national standards, (Sec.301.)(a)(2) [*Conservation and management measures shall be based on the best scientific information available.*] (Sec.301)(a)(8) [*Conservation and management measures shall, consistent with the conservation requirements of this Act (including the prevention of overfishing and rebuilding of overfished stocks), take into account the importance of fishery resources to fishing communities in order to (A) provide for the sustained participation of such communities, and (B) to the extent practicable, minimize adverse economic impacts on such communities.*]

We find that many of the alternatives in the EFH DEIS do not comply with the standards mentioned above. Many are based on assumptions rather than applicable scientific information. Many have large economic impacts to the downside on fishing sectors and communities. The prevalent data sets come from one fishing sector while several alternatives affect all fishing sectors. All habitat interactions due to fishing are assumed to be detrimental to the marine ecosystem in this DEIS. While we support a precautionary approach to fishery management, we cannot support a zero human impact one.

Upon reviewing the EFH DEIS we find existing or modified alternatives that we do support. Our listing with modifications and explanations are as follows:

<u>Essential Fish Habitat Identification and Description</u>

Alternative A.2: Depths less than 3500m

We choose this alternative because it includes all habitat where groundfish have been observed. It would be, by default, the most accurate description of EFH based on current data.

<u>Habitat Areas of Particular Concern Designation</u>

Alternatives B.2 through B.8

Many of these alternatives have enough data to support designation. The rest relate to structural features which we can support on a precautionary management basis.

Alternative B.9 (modified) Process for new HAPC designation

It is our recommendation that this alternative be modified to include a process to remove a HAPC designation from an area. If the science used to support the original designation is no longer valid, then there should be an equivalent process to remove designation.

Minimize Adverse Fishing Impacts to EFH

Alternative C.8.1 (modified) Zoning Fishing Activities

Our support would be for this alternative with some changes. We believe that this alternative would be most in compliance with national standard; M-S Act(301)(a)(8). This alternative allows outcome-based management involving area closures. It allows fishers and management a process and some time to develop alternative gear to lessen EFH impacts. An incentive is offered to develop "clean" gear. Our suggested change concerns funding of gear development. *We recommend that funding for implementation of this alternative not be taken from that which is dedicated to any other fishing sector, nor cause a lowering of the percentage normally allocated to another sector.*

Research and Monitoring Activities

Alternative D.4 (modified) Research Reserve System

In our assessment of this alternative we believe that there is great value in a system of research reserves. They should encompass all habitat types designated as HAPC. All three zones of the EEZ should be included, nearshore, slope, and shelf. Reserves would need to be no larger in area than necessary to study the representative HAPC areas contained within. An allowance on shape would need to be made to comply with enforcement issues. Our addition to this alternative would be in the area of reserve management. *Management of research reserves shall be done only by NOAA Fisheries. All funding of reserve activities must be through federal tax revenues and/or fees. No private funding, as for instance grants from resource user organizations or from environmental organizations, may be used.Reserves must be reauthorized every 5 years through the Council process. No extractive activities will be allowed in a reserve except those necessary to conduct fisheries research.*

This alternative would allow for baseline and experimental data to be obtained in a controlled environment. Studies over time could help determine which habitat features are most important to a productive environment.

Summary:

Oregon Anglers and RFA believe that common sense can be used on this issue of EFH. We support an approach which relies on objective science and compliance with MSA national standards.

Thank you for considering these comments.

Ashland, OR 97520

These comments on the Groundfish Essential Fish Habitat Draft Environmental Impact Statement (DEIS) are submitted on behalf of the Rogue Valley Audubon Society, a chapter of the National Audubon Society with over 500 members in southern Oregon. We are concerned about the declining health of Oregon's fishery resources, and urge that management of groundfish on the Pacific coast be governed by the "precautionary principle." In other words, when data needed for informed decision-making are lacking, the most conservative alternative must be followed; the alternative that is most protective of the fisheries resource. Since there are many critical gaps in our understanding of groundfish ecology, this approach will necessitate significant changes in current management practices.

Specifically, we urge the Pacific Fisheries Management Council to take action in five critical areas:

* establish a network of reserves in order to better understand fishery impacts on all habitat types, * increase protection for sensitive habitat types such as kelp, corals and sponges that are essential to groundfish productivity,
* protect a representative sample of unique habitat types from all types of fishing impacts,
* make it easier for fishermen to change to less destructive gear,
* develop an ecosystem-based management plan that truly protects the long-term health of the marine environment.

Thank you very much.

Respectfully submitted,

Pepper W. Trail, Ph.D.

RE: Comment on 2005 Pacific Coast Groundfish Essential Fish Habitat Draft Environmental Impact Statement dated February 11, 2005.

Dear Mr. Robert Lohn,

Thank you for this opportunity to submit comments on the 2005 Pacific Coast Groundfish Essential Fish Habitat Draft Environmental Impact Statement dated February 11, 2005. The Audubon Society of Portland has 10,000 members throughout the state of Oregon who care deeply about the protection of coastal wildlife and habitat off of our coast. We applaud your efforts to compile the best available science, identify and designate essential fish habitat (EFH) and Habitat Areas of Particular Concern (HAPC), minimize adverse impacts that may result to EFH due to fishing, and identify further actions to encourage the conservation and enhancement of EFH. In the spirit of the PEW Ocean Commission Report of 2003 and the U.S. Commission on Ocean Policy Report of 2004, we believe this document seeks to incorporate the vital principles of ecosystem-based management into Pacific fishery management.

ALTERNATIVES TO IDENTIFY AND DESCRIBE EFH: ADOPT A.2

The Audubon Society of Portland recommends adoption of Alternative A.2, where EFH is identified as 100% of the area where the habitat suitability probability (HSP) is greater than zero for all species and any additional area in depths less than or equal to 3500 m (1914 fm).

We feel Alternative A.2 should be chosen as the Preferred Alternative because it is inclusive enough to cover all habitats where groundfish have been observed, with the addition of 100 m depth as a precaution for non-observed species and scientific uncertainty, but it is not so over-inclusive as to render the designation of EFH meaningless. Additionally, it will minimize restrictions to subsequent selections of HAPCs, which are to be subsets of designated EFH.

ALTERNATIVES TO DESIGNATE HAPC: ADOPT B.2, B.3, B.4, B.6, B.7, B.9

The Audubon Society of Portland recommends adoption of Alternatives B.2, B.3, B.4, B.6, B.7 and B.9. Although not required by the Magnuson-Stevens Act (MSA), Councils are encouraged to designate HAPCs, based upon the importance of the ecological function provided by the habitat, the extent to which the habitat is sensitive to human-induced environmental degradation, whether development activities are or will be stressing the habitat type and the rarity of the habitat type. These considerations are particularly germane in the context of the more than 80 species managed by the Pacific Fishery Management Council (PFMC). At a time when eight of the assessed 19 species of groundfish are declared overfished and offshore aquaculture and exploration activities are being hotly pursued on the federal level, the moment is ripe to move forward with designation of HAPCs in an effort to conserve and restore the most crucial habitat types, to be determined by the best available science.

In light of the importance of such designation, we recommend including Alternatives B.2, B.3, B.4 and B.6, which encompass essential estuaries, canopy kelp, seagrass and rocky reefs. These biologically productive areas have been shown to provide important habitat for many marine species, including groundfish, at various stages of life history, for reproduction, feeding and refuge. Although these habitat types are among the areas of highest productivity in the world, they can be particularly sensitive areas, due to proximity to the shoreline, inadequate mapping and vulnerability to certain gear types. Thus, designation as HAPCs would serve to concentrate attention on potential threats to these habitat types and would enable the PFMC to make informed future decisions regarding the management of Pacific groundfish.

Additionally, we recommend including Alternative B.7, a “catchall” designation for special interest areas that possess unique geological and ecological characteristics that may be critical for rockfish management. Seamounts and canyons supply a variety of unique ecological functions, perhaps the most important being the provision of high concentrations zooplankton, which is a principal food source for both juvenile and adult rockfish.

Finally, we recommend adopting Alternative B.9, which establishes a streamlined process for designating new HAPCs, based on proposals submitted to the PFMC. Based on the principles of adaptive management, this alternative recognizes that new future scientific information could call for inclusion of other critical habitat areas as HAPCs. It establishes a process for petition and PFMC consideration. This streamlined process will provide assurances that proposals submitted by organizations and individuals will be fully and fairly considered.

ALTERNATIVES TO MINIMIZE ADVERSE IMPACTS TO EFH: ADOPT C.4.2, C.6, C.7.2, C.9.5, C.9.6, C.10 AND A COMBINATION OF C.12, C.13 AND C14.

The Audubon Society of Portland recommends adoption of C.4.2, C.5, C6, C.7.2, C.9.5, C.9.6, C.10 and a combination of C.12, C.13 and C.14. Because Amendment 11 to the Fishery Management Plan did not include measures to minimize fishing impacts on EFH, it is essential to take steps to do so today. Although restrictions on the use of large footrope gear and Rockfish Conservation Areas have some mitigating benefits on the effects of fishing gear, these restrictions may only affect a small portion of habitat and are not necessarily determined by specific habitat type.

Under Alternative C.4.2, geographic expansion of fishing for all bottom-tending gear types would be prohibited, to protect areas that are potentially pristine. Because there is little data for areas in which there have historically been no fisheries, a precautionary approach should guide management in these unexploited areas, so as to truly adhere to the principles of sound science and provide valuable environmental baseline data for the future. As acknowledged by the DEIS itself, relatively little is known about organisms such as deep-sea corals that may occur in these areas and be particularly vulnerable to impacts associated with even a single fishing event. Recent discoveries such as new black coral species in close proximity to Los Angeles, multispecies aggregations of reproducing psychrolutid sculpins and deep-sea octopod, brooding eggs on the Gorda Escarpment off of California and methane seeps with associated carbonate rock structures and chemosynthetic communities along the shelf-break off of Oregon’s coast support this precautionary approach, suggesting there are diverse, yet scattered areas that warrant protection by limiting the expansion of existing fisheries. Thus, protecting presently undisturbed areas until better mapping information is available is critical. Additionally, applying the expansion limit to all bottom-tending gear types, not just trawl fisheries, is essential.

The PFMC should adopt Alternative C.5, which prohibits a krill fishery. Euphausiid shrimp are important prey for a wide range of species along the West coast and are inextricably linked to groundfish, both as primary prey for groundfish and in secondary ways through the food web. In the spirit of ecosystem-based management, we are supportive of preserving a healthy forage base for groundfish and their prey, and we encourage future actions by the PFMC to protect the full spectrum of currently non-managed forage species.

We recommend inclusion of Alternative C.6, which calls for closure of “hotspots,” as a Preferred Alternative for minimization of adverse impact on EFH. Used in conjunction with other alternatives, prohibiting trawling for the top 20% HSP areas associated with 50 or more species/lifestage combinations will ensure protection of the greatest possible number of groundfish populations.

Alternative C.7.2 closes off those special interest areas included under B.7 to all bottom-contacting activities, rather than just to the specific method of bottom trawling, thereby affording increased precautionary protection to these geographically unique and biologically productive areas.

Alternatives C.9.5 and C.9.6 prohibit the use of destructive dredge and beam trawl gear, which are being phased out anyway. Thus, these limitations will have little economic impact on fishing interests, but will seek to afford maximum protection to bottom habitat. That being said, we acknowledge that fishing gear is constantly evolving and that habitat protections envisioned may not be maintained through time as gear configurations change. We therefore support using gear restrictions in conjunction with the other protective measures to minimize adverse impact to EFH, as outlined above and below.

Alternative C.10 utilizes existing closed or unfished areas to eliminate bottom trawl gear. Through the use of public-private partnerships, private funds are used to buyout 50% of groundfish trawl permits, in concert with designation of no-trawl zones off the Central California coast. Progressive cooperative partnerships such as these are an essential and forward-thinking means of protecting habitat and fisheries for future generations, distributing the economic hardship of marine conservation more evenly onto a more diverse spectrum of interested stakeholders. Although geographically limited in scope, this alternative may have merit if the interested private parties (the Nature Conservancy and fishing interests) agree this is a productive proposal.

Alternatives C.12, C.13 and C.14 represent a broad spectrum of closures to ecologically important areas, either to just bottom trawl gear, all bottom-contacting gear or all fishing, respectively. We believe a combination of these alternatives should be utilized to achieve the PFMC's goals of protection and research. Integration of these approaches will also give the PFMC the opportunity to develop a network of research reserves, which can serve as a means to compare fishery management techniques and effects against benchmark data.

The Audubon Society of Portland recommends adoption of C.12, the "Oceana" alternative, in an effort to freeze the existing bottom trawl footprint. As stated by Oceana, the best science available from the National Academy of Sciences has found that bottom trawling reduces habitat complexity, causes shifts in benthic communities and reduces productivity of benthic habitats. By utilizing existing closed areas, denying expansion of trawling areas, closing sensitive areas within those currently being trawled, limiting roller gear size and engaging in ongoing research and monitoring, the PFMC can maintain healthy fisheries while protecting habitat and marine biodiversity. The Audubon Society of Portland also supports adoption of C.13, which limits use of bottom-contacting gear in ecologically important areas. Finally, we also recommend closure of specific ecologically important areas to all fishing. There is sound science to suggest that creating a network of discrete marine areas of biological significance that is off-limits to all fishing can allow adult fish to grow and reproduce in abundance, while their offspring help replenish populations outside closed boundaries where fishing is allowed. This alternative is supported by the principles of ecosystem-based management and moves fishery management into a broader ecological context.

RESEARCH AND MONITORING ALTERNATIVES: ADOPT A COMBINATION OF D.2.1 AND D.4

The Audubon Society of Portland recommends adoption of D.2.1. As stated above, one of the biggest challenges the PFMC faces today in the context of Pacific groundfish management is the relative lack of data, analysis and understanding of the species, their habitats and the effects of human disturbance. Data collected by fishing vessels can prove invaluable for gaining a future understanding of these complex interactions and gathering spatial data for future mapping. Thus, under this alternative, all fishing vessels will be required to maintain a logbook, recording information on fishing time, location and catch composition, similar to the current trawl logbook program. In addition, however, it is imperative that this data is not only collected, but also error-checked, entered into a database and analyzed in a meaningful way; one of the biggest complaints we have heard from fishing interests at public meetings related to this and other documents is that logbook data is gathered by individuals, but is not compiled and analyzed in a meaningful or timely manner.

We also strongly support Alternative D.4, which would restrict fishing in specific areas. These research reserves areas would not only minimize fishing impacts on habitat and marine wildlife, but would provide controlled benchmark data for determining extent of fishing impacts, differentiating natural versus human impacts and measuring the length of time necessary for habitat features and function to recover. By establishing a network of research reserves, the PFMC can engage in a comparative study of 1) areas open to and impacted by commercial and recreational fishing, 2) areas subject to only limited and controlled fishing disturbance and 3) areas not open to or impacted by any fishing. These areas should broadly represent all habitat types in which PFMC-managed groundfish occur, to allow comparison of the effects of fishing across these different types.

GUIDING PRINCIPLES

In general, we feel it is imperative for the PFMC to take a precautionary approach to management of Pacific groundfish, while we improve our limited understanding of the impacts of fishing on diverse habitats and the ability of habitats to recover from fishing impacts. In fact, the Oregon State of the Environment Report 2000 states, "the most significant risk to marine fisheries … is our insufficient understanding of the complex interactions of natural and human caused changes in stock health."[1] It is crucial, therefore, that the PFMC err on the side of caution in protecting and restoring Pacific groundfish and habitat.

We strongly encourage the PFMC to include a network of research reserves in its effort to designate, protect and understand present and future EFH. By monitoring and analyzing impacts and effectiveness in these reference sites, the PFMC can glean new

[1] **Oregon Progress Board.** 2000. Oregon State of the Environment Report, Statewide Summary, Salem, Oregon.

knowledge, engage in adaptive management and move forward more confidently with fishery management, basing its decisions on sound science.

Utilizing the principles of ecosystem-based management, the PFMC should develop an ecologically based management plan that considers the entire ecosystem, including humans, and protects the long-term health of the marine environment**.** This plan should think beyond protection of single species and should consider the inherently interrelated nature of all marine species and habitat types, as well as potential past, present, future and cumulative human impacts on these environments.

Finally, we feel it is important that all possible EFH protection measures be adopted in the near-term, rather than deferring measures for future understanding. This precautionary implementation should then be modified accordingly, based on the principles of adaptive management, as new information is gathered during the mandatory five-year review process.

CONCLUSION

In conclusion, we would again like to thank you for this opportunity to comment. As stated above, we applaud your efforts in creating this Draft Environmental Impact Statement and strongly support the designation and protection of EFH for Pacific groundfish. Specifically, we support the respective alternatives and general principles outlined above.

Thank you for considering these comments.

RE: COMMENT ON 2005 PACIFIC GROUNDFISH DRAFT ENVIRONMENTAL IMPACT STATEMENT

The City of Morro Bay treasures its fishing heritage and local commercial fishing fleet that provides fresh seafood for this country in a highly regulated and sustainable environment. Our harbor and its commercial fishing businesses depend on groundfish landings to support the harbor infrastructure, since many of our fishermen are mainly albacore, crab or salmon permittees with actual landings in the ports north of Morro Bay. Our City has suffered from the reductions in groundfish quotas, seasonal restrictions and area closures to the extent that the local groundfish market has almost collapsed and just a few of the traditional shore side support businesses are still hanging on.

Currently there are 5 Class A permittees who operate out of our port. That represents trawl fishing effort over two hundred miles of coastline between Santa Barbara Harbor and Monterey Harbor. Each Class A permittee generally fishes between 5-8 days to make their 60 day quota; so on most of the days of the year there IS NO LONGER EVEN ONE DEEP WATER COMPLEX TRAWLER OPERATING ON THIS TWO HUNDRED MILES OF COASTLINE. Yet, the port still does get groundfish, and these are the consistent landings that allow our one remaining full service fish buying dock to keep employees working and pay the bills. The City is dedicated to supporting this remaining fish buying dock and is currently in the process of installing a new $700,000 ice making machine for commercial fishing use at this location.

Clearly the policy of subsidizing more and bigger trawlers in the 1970s was a disaster, but just as clearly the resource for 15 years now has been very lightly harvested compared to historic levels. Many of our local restaurants no longer can get local fresh fish and have turned, like most of the country, to frozen fish which is oftentimes harvested in environmentally damaging ways in unregulated countries. In the last two years we have seen some hope as groundfish prices have gone up a little, quotas increased slightly, (but typically not what was promised) due to the federal buy-back program and Class A permittees have started to see a reasonable economic return for fishing again. We are hopeful that some uncertainty can be relieved for these local businesses and for the City. In this context, we learned about the groundfish essential fish habitat draft environmental impact statement (EFH DEIS).

Many of the alternatives in the DEIS would appear to close fishing grounds to the extent that would eliminate consistent landings in Morro Bay and finally put an end to our commercial fishing harbor. We do not believe it is the intent of the National Marine Fisheries Service to eliminate fresh seafood landings in our area and decimate our City and we urge you to:

♦Work with the fishing industry on alternatives that will protect Essential Fish Habitat, especially those grounds with deep water corals and critical bottom habitat so that we can increase access to the abundant sustainable fishery resources in our area for our City and the seafood consumer.

♦Implement EFH designation for groundfish that have no strings attached or unforeseeable implications for low/no impact vertical gear or traps.

♦Extend the timelines for adoption of groundfish EFH so that the coastal communities/fishing industry can fully engage the discussion with NMFS and the environmental community.

♦Improve the outreach to community and fishing businesses by considering an ombudsman program, enhancing your sustainable fisheries outreach effort or some mechanism to empower local fishermen to give input and build trust with NMFS and the environmental community.

I would close by pointing out that virtually 100% of our commercial fishermen are owner operated small businesses. We don't have the corporate interests that can hire lobbyists that the large processors and factory producers of some other areas have or the money and influence of the environmental NGOs. It is tremendously difficult for a small business owner/operator or a small city for that matter to take the time to become informed on these issues, much less to attend the many meetings that are needed to have an impact. Thus our voices are often not heard or we find that decisions are made at meetings we are unable to attend. Even when we do comment (such as our support of the Federal Buyback Program, provided that the buy-back vessels would not become problems for harbors and the overall science based quotas would remain the same) we have come to have low expectations for results. Currently, two buy-back boats in this harbor are in arrears to the City approximately $4700 and the reallocation in groundfish quotas that were "bought back" has not happened as we felt was promised.

All of the above facts lead to a feeling of lack of empowerment and even distrust of the process that is not conducive to a positive collaborative process. Still, we remain convinced that almost all involved have the same goals of protecting our environment and maintaining sustainable fisheries; so we will continue to try to work with all parties for mutually beneficial solutions.

Please consider our recommendations and help us preserve the important economic and cultural values of allowing an environmentally sound and sustainable fishery to stay on the central coast of California.

Sincerely,

Janice Peters

Re: Comments on Pacific Coast Groundfish Fishery Management Plan Essential Fish Habitat Designation and Minimization of Adverse Impacts Draft Environmental Impact Statement

Dear Mr. Lohn:

The undersigned organizations submit these comments concerning the Draft Environmental Impact Statement for Pacific Coast groundfish ("DEIS") for consideration by the National Marine Fisheries Service.[1] While flawed, the analyses provided in the DEIS establish that current fishing practices and patterns cause significant long-term damage to essential fish habitat ("EFH"). Accordingly, the Fisheries Service and Pacific Fishery Management Council ("Council") are required to minimize these effects. Status quo measures are neither sufficient to meet the mandates of the Magnuson-Stevens Act nor responsive to the best available information.

These comments focus on some of the legal and analytical deficiencies of the DEIS. We believe that these deficiencies can be remedied between the draft and final Environmental Impact Statements, and most importantly that selection of a broad designation alternative and comprehensive minimization alternative is warranted by the facts, science, and the law.

The DEIS Does Not Satisfy the Requirements of the National Environmental Policy Act

I. The Statement of Purpose and Need is Impermissibly Narrow.

The Fisheries Service's statement of purpose and need in this DEIS is improperly narrow and vague. See City of Carmel-By-The-Sea v. U.S. Dep't. of Transp., 123 F.3d 1142, 1155 (9th Cir. 1997) (" . . an agency cannot define its objectives in unreasonably narrow terms."). The Fisheries Service states that the objectives for the Environmental Impact Statement ("EIS" or

[1] Some of the undersigned organizations have submitted additional independent comments, to be considered in conjunction with these comments.

"DEIS") are to consider alternatives for the designation of EFH and Habitat Areas of Particular Concern ("HAPCs"), to consider alternatives for the minimization of adverse effects of fishing on EFH, and to address gaps in the available data. DEIS at 1-4. The Magnuson-Stevens Fishery Conservation and Management Act ("MSA"), Fisheries Service's regulations, and the joint stipulation from AOC v. Daley require the Fisheries Service to do more than merely propose alternatives and identify gaps in the data. The Fisheries Service must implement all practicable measures to minimize adverse effects on EFH and must fully explore and evaluate those options in its EIS. Failure to include this fundamental objective within the purview of the DEIS violates NEPA, the MSA, and the agency's regulations and obligations under AOC v. Daley.

The MSA requires that the Fisheries Service minimize the adverse effects of fishing on EFH to the extent practicable. 16 U.S.C. § 1853(a)(7). The DEIS falls far short of analyzing the relative efficacy of the alternatives on minimizing adverse effects to EFH, not to mention recommending to the Council which measures the agency believes would be most practicable in achieving those goals. Instead, the reader is left with nothing more than a vague suggestion that the analysis contained within the DEIS might, someday, be incorporated into a decision that results in "on the water" EFH protections.

Additionally, the Joint Stipulation and Order from AOC v. Evans require that "NMFS will determine either that action is necessary or that action is not necessary to comply with the requirements of Section 303(a)(7) of the Magnuson-Stevens Act [16 U.S.C. § 1853(a)(7)]." AOC v. Daley, Joint Stipulation and Order at 5. This determination is one of the primary purposes of the DEIS and must be included in the statement of purpose and need, yet the DEIS is devoid of such a determination. The Fisheries Service must do more than merely consider and rate the alternatives under consideration and point out gaps in the available data; it must also decide which alternatives best satisfy its mandate to minimize adverse effects on EFH. The DEIS utterly fails to do so. The closest the agency gets to committing to whether it will take action (or require the Pacific Council to do so) is when it states that it will identify final preferred alternatives following the June 2005 Council meeting. DEIS at 2-1. By failing to include a determination of whether the findings contained within the DEIS merit action by the Pacific Council, NMFS has violated its obligations under AOC v. Daley to conduct full NEPA review of its efforts to minimize adverse effects to EFH. Joint Stipulation at 3-5. NMFS may not delay consideration of this decision until it issues its Record of Decision because the analysis that leads to the determination must be incorporated into the NEPA process. Failure to evaluate the environmental effects of the decision of whether or not NMFS will require action to be taken "would frustrate the fundamental purpose of NEPA, which is to ensure that federal agencies take a hard look at the environmental consequences of their actions early enough so that it can serve as an important contribution to the decision making process." California v. Norton, 311 F.3d 1162, 1175 (9th Cir. 2002) (internal citations and quotation marks omitted). We believe that conservation action is appropriate and required for the reasons stated below.

II. The Range and Quality of Alternatives Considered is Inadequate.

NEPA requires the Fisheries Service to consider "alternatives to the proposed action." 42 U.S.C. § 4332(2)(C)(iii). The alternatives analysis is the "heart" of the environmental review process. 40 C.F.R. § 1502.14. As such, agencies must "rigorously explore and objectively evaluate all reasonable alternatives." Id. As explained above, "an agency cannot define its objectives in unreasonably narrow terms," City of Carmel-By-The-Sea v. United States Dep't. of Transp., 123 F.3d 1142, 1155 (9th Cir. 1997), in order to limit the range of alternatives that it must consider. Alaska Wilderness Recreation & Tourism Ass'n v. Morrison, 67 F.3d 723, 729 (9th Cir. 1995) (quoting Idaho Conservation League v. Mumma, 956 F.2d 1508, 1520 (9th Cir. 1992)). The Fisheries Service is obligated to consider all reasonable alternatives that fit squarely within the scope of identifying and describing EFH and HAPC, as well as identifying and recommending which minimization measures the Pacific Council should implement and when they will be implemented. While the agency and Council clearly may consider alternatives refined in response to public comment, and refine or combine alternatives in response to public comments, the Fisheries Service may not consider or adopt any alternate proposals not included within the range of alternatives presented within the DEIS absent full NEPA review. Doing so would violate NEPA's express purpose of informed decision making and public participation. Robertson v. Methow Valley Citizens Council, 490 U.S. 332, 349 (1989); Metcalf v. Daley, 214 F.3d 1135, 1141 (9th Cir. 2000).

Before commenting on the issues raised by the EFH, HAPC, and minimization alternatives, we would like to voice a universal critique of the methodological approach taken by the Fisheries Service. By considering alternatives for EFH, HAPC, and minimization separately, the agency has greatly limited the number of alternatives available for consideration and adoption. This leads to arbitrary and illogical results. As the agency readily acknowledges in the section entitled "The Implications of the EFH Identification and Description Alternatives on HAPC and Affects Minimization," the choice of EFH alternative limits which HAPC and minimization alternatives remain available for implementation. DEIS at 4-11 – 4.12. Thus, the Fisheries Service could choose EFH, HAPC, and minimization alternatives that do not work together. As a result, the number and range of HAPC and minimization alternatives considered in this DEIS are far fewer and less broad than the agency would like the reader to believe. This approach violates NEPA's express requirement that the Fisheries Service consider a reasonable range of alternatives. To correct this methodological problem, the agency should either consider a range of HAPC and minimization alternatives within each EFH alternative so that the steps ultimately taken to minimize adverse impacts correspond to the EFH identified, or permit selection and implementation of any combination of alternatives.

A. The Fisheries Service Relies Too Heavily on HSP to Define EFH and Fails to Identify a Threshold for Determining Whether Habitat is Essential Under its HSP Alternatives.

The Fisheries Service relies exclusively on the Habitat Suitability Probability ("HSP") model in all but two of the alternatives considered for EFH identification and designation. DEIS at 2.3. As described further below, this raises great concerns about the adequacy of the range of EFH designation and identification alternatives. In addition, the HSP model does not include all relevant information, such as data layers concerning coral and sponge. The range of data used to select EFH also is truncated impermissibly by the overly-quantitative nature of the analysis and the focus on the abundance of managed species to the exclusion of other necessary components of EFH, such as prey species and their habitats. The Fisheries Service should include more information in its analysis in order to improve the precision of its EFH model.

Additionally, the agency explains that the HSP scores are used as a proxy for determining whether habitat is "essential," but fails to define the threshold level for making such a determination. DEIS at 2-3. Instead, the Fisheries Service asserts that "the higher the HSP, the more likely the habitat area should be identified as EFH." DEIS at 2-3. Applying this logic to the alternatives presented leaves the Council and the general public to guess whether essential habitat equates to 100% of the area with HSP above zero (Alternatives A.2 and A.3), the top 70% (Alternative A.5), or the top 30% (Alternative A.6), and whether distinctions should be made for overfished and precautionary zone species. The Fisheries Service's approach here is inadequate. See Morongo Band of Mission Indians v. F.A.A., 161 F.3d 569, 575 (9th Cir. 1998) ("The touchstone for our inquiry is whether an EIS's selection and discussion of alternatives fosters informed decision-making and informed public participation.") (citation and internal quotations omitted).

The very purpose of the DEIS – to provide a management tool for developing conservation efforts and stewardship of EFH – is rendered meaningless if the tool relied upon fails to identify the point at which habitat should be considered "essential" within the meaning of the law. The Fisheries Service must provide more reasoning in its analysis and guidance to the Council than it has chosen to provide in the DEIS. Additionally, the nearly exclusive reliance on HSP as a means of describing and identifying EFH greatly limits the quality and range of EFH alternatives considered.

B. Considering HAPC as a Subset of EFH Leads to Illogical and Arbitrary Results.

Designation of HAPC should identify areas based on one or more of the following criteria: (i) the importance of the habitat's ecological function provided by the habitat; (ii) the extent to which the habitat is sensitive to environmental degradation; and (iii) whether development activities are, or will be, stressing the habitat type. 60 C.F.R. § 600.815(a)(8). The Fisheries Service's decision to consider HAPC as a subset of EFH could lead to illogical and arbitrary results. The Council's designation of HAPC could be circumscribed by its contemporaneous designation of EFH if the HAPC alternative selected does not fit within the chosen EFH. Alternatively, the Council could choose to avoid this inconsistency by only considering HAPC alternatives that fit within certain EFH alternatives, or vice versa. Either way, the number of HAPC alternatives that can be considered fully is limited by the agency's insistence that HAPC be a subset of EFH.

III. The Fisheries Service's Environmental Effects Analysis is Inadequate.

NEPA requires that agencies discuss "the environmental impacts of the proposed action and alternatives." 40 C.F.R. § 1508.9(b). Environmental impacts are defined to include "both beneficial and detrimental effects, even if on balance the agency believes that the effect will be beneficial." 40 C.F.R. § 1508.8(b). The fundamental purpose of the DEIS is the detailed consideration of the environmental effects of implementing all practicable minimization measures. The DEIS fails to accomplish this. Indeed, the Fisheries Service admits that "[i]t is not possible to analyze the degree to which the function of habitat within the ecosystem or for groundfish will be affected by the alternatives." DEIS at 4-1. Although NEPA does not require agencies to "foresee the unforeseeable," it does require agencies to predict potential consequences of their actions before those consequences are fully known. Methow Valley

Citizens Council v. Regional Forester, 833 F.2d 810, 816-817 (9th Cir. 1987), rev'd on other grounds, Robertson v. Methow Valley Citizens Council, 490 U.S. 332 (1989) (quoting City of Davis v. Coleman, 521 F.2d 661, 676 (9th Cir. 1975). The Fisheries Service may not shirk its responsibilities to consider environmental effects merely due to limitations in the available data. "Reasonable forecasting and speculation is . . . implicit in NEPA, and we must reject any attempt by agencies to shirk their responsibilities under NEPA by labeling any and all discussion of future environmental effects as crystal ball inquiry." Kern v. U.S. Bureau of Land Management, 284 F.3d 1062, 1073 (9th Cir. 2002) (internal quotations and citations omitted).

NEPA also requires that the Fisheries Service fully consider the cumulative impacts of its decisions together with "other past, present and reasonably foreseeable future actions." 40 C.F.R. § 1508.7; see Klamath-Siskiyou Wildlands Center v. Bureau of Land Management, 387 F.3d 989, 993-94 (9th Cir. 2004) ("Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time."). Accordingly, the agency is required to analyze all past, present, and reasonably foreseeable fishing efforts in terms of their cumulative impact to EFH. The Fisheries Service does not appear to have done so, especially with regard to a cumulative analysis of all past fishing activities within EFH.

The DEIS Does Not Satisfy the Requirements of the Magnuson-Stevens Act

One of the primary purposes of the 1996 Sustainable Fisheries Act amendments to the Magnuson-Stevens Act is to protect habitat. Accordingly, Congress imposes on the Fisheries Service the duties to describe and identify Essential Fish Habitat, and to minimize the adverse effects of fishing on EFH to the extent practicable.

The statute makes clear that the duty to minimize adverse effects focuses on the effects of fishing on habitat. See 16 U.S.C. § 1853(a)(7) (duty to "minimize...adverse effects on such habitat caused by fishing). The regulations similarly make clear that the inquiry regarding whether there are adverse effects to EFH focuses on whether a fishing activity has any affect on the quality or quantity of EFH:

> Adverse effect means any impact that reduces quality and/or quantity of EFH. Adverse effects may include direct or indirect physical, chemical, or biological alterations of the waters or substrate and loss of, or injury to, benthic organisms, prey species and their habitat, and other ecosystem components, if such modifications reduce the quality and/or quantity of EFH. Adverse effects to EFH may result from actions occurring within EFH or outside of EFH and may include site-specific or habitat-wide impacts, including individual, cumulative, or synergistic consequences of actions.

50 C.F.R. § 600.810(a). Thus, in order to determine the universe of adverse effects that may require measures to minimize, the Fisheries Service must examine any and all impacts that reduce the quality or quantity of the habitat itself. These impacts include considerations of benthic organisms, prey species and their habitat, and other ecosystem components. In other words, the adverse effects inquiry is a broad one, focused on the effects of fishing on habitat and elements of the ecosystem, and not limited to the effects of fishing on fish stocks themselves.

In addition, the agency must perform a cumulative impacts analysis, which is to consider impacts on the environment. 50 C.F.R. § 600.815(a)(5).

Based on the adverse effects evaluation and the cumulative impacts analysis, the "Council must prevent, mitigate, or minimize any adverse effects from fishing, to the extent practicable, if there is evidence that a fishing activity adversely affects EFH in a manner that is more than minimal and not temporary in nature... ." 50 C.F.R. § 600.815(a)(2)(ii).

I. <u>NMFS Cannot Limit Its Analysis of Adverse Impacts to Managed Species Alone and Fails to Evaluate Properly MMNT.</u>

The MSA requires that the Fisheries Service and the Fishery Management Councils "minimize to the extent practicable adverse effects on [EFH] caused by fishing, and identify other actions to encourage the conservation and enhancement of such habitat." 16 U.S.C. § 1853(a)(7). The EFH rule requires that the Fisheries Service and the Councils "must act to prevent, mitigate, or minimize any adverse effects from fishing, to the extent practicable, if there is evidence that a fishing activity adversely affects EFH in a manner that is more than minimal and not temporary ["MMNT"]." 50 C.F.R. § 600.815(a)(2)(ii). The agency acknowledges that "[p]racticable Council action is triggered by adverse effects that are more than minimal and not temporary in nature." DEIS at 2-15. The agency goes to great lengths in both the DEIS and the appended Risk Assessment to create a sensitivity and recovery index ("SRI") to value the impact to habitat by gear type. While this helpful first step provides ample justification for implementing a minimization alternative, the SRI model itself does not consider all relevant factors.

First, the SRI that forms the basis of all but three of the minimization alternatives limits its consideration of habitat primarily to benthic habitat. The EFH rule requires consideration of a much broader definition of habitat when considering adverse effects. 50 C.F.R. § 600.810(a) ("Adverse effects may include direct or indirect physical, chemical, or biological alternations of the waters or substrate and loss of, or injury to, benthic organisms, prey species and their habitat, and other ecosystem components, if such modifications reduce the quality and/or quantity of EFH."). The agency must include qualitative analysis in addition to its SRI index that considers all of the best available science pertaining to prey species and their habitat and other important ecosystem components not captured by the SRI model.

Second, the DEIS provides no guidance to the public, the Council, or the decision maker about which adverse effects of fishing on EFH must be minimized. The Fisheries Service asserts that the Risk Assessment was intended to define when impacts from fishing exceed the MMNT threshold, but "due to data and time constraints it was not possible . . . to create an analytical tool capable of identifying areas of impacted habitat and demonstrating the effects of minimization alternatives." DEIS at 2-12 – 2-13. In other words, the main tool relied upon to create the minimization alternatives is incapable of accomplishing the very thing it was designed to do. Nevertheless, it is clear from the analyses currently described in the EIS that there are effects of fishing that reduce the quality and quantity of EFH in a manner that is both more than minimal and not temporary and therefore, that minimization is required.

In addition, the Fisheries Service regulations recognize three categories of tools to address adverse effects on fishing: fishing equipment; time/area closures; and harvest limits. 50 C.F.R. § 600.815(a)(2)(iii)(A)-(B). None of the alternatives considered in the DEIS even considers the use of reduced harvest limits as a way of minimizing adverse effects to EFH. The DEIS also fails to explain the basis of the decision to omit this tool from consideration under any of the alternatives. This decision not only contravenes the agency's regulations, but also ignores the conclusion of the National Research Council that "[e]ffort reduction is the cornerstone of managing the effects of fishing, including, but not limited to, the effects on habitat." NRC, 2002. In addition to being contrary to law, the decision violates NEPA for failing to consider a reasonable range of minimization alternatives and violates the APA for failing to articulate a reasoned basis for its decisions. Effort reduction is a reasonable management tool that NMFS must add to its suite of minimization measures under consideration.

II. The DEIS Fails to Consider the Best Scientific Information Available.

As described further below, the DEIS fails to consider the best scientific information available. This failure violates not only NEPA's mandates, but also the MSA and National Standard 2. 16 U.S.C. § 1851(a)(2); 50 C.F.R. § 600.315.

The DEIS Analysis is Deficient

In addition to the legal failures outlined above, the DEIS's analyses and conclusions are substantively and analytically flawed. While the DEIS contains valuable information that provides ample basis for a broad EFH designation and demonstrates clearly that minimization measures are necessary, the analyses should be improved to meet relevant legal and scientific standards.

I. EFH Identification: Description of the Alternatives

The rationale for Alternative A.1 should be revised to include more than simply a description of the status quo EFH identification alternative to describe fully why this alternative was chosen in the initial EFH identification decision. The discussion should pay special attention to depths greater than 3400 meters which are part of the status quo but not included in Alternatives A.2-A.6. Furthermore, as Alternative A.1 is the only alternative not based on the HSP model, it must be fully compared and contrasted with the HSP model-based alternatives, including the number of uncertainties in the HSP model output and how this alternative addresses these uncertainties.

Similarly, the description of Alternative A.2 should be enhanced to include a more explicit description of how this alternative provides better assurance that groundfish essential fish habitat is properly identified. The description of this alternative in its current form notes only that the addition of 100 meter depth provides a precautionary adjustment in case of non-observed species. This description should also clearly convey that the extra 100 meter depth helps buffer the uncertainties surrounding the HSP modeling effort and major prey species habitat requirements that are noted below.

A. The Shortcomings of the HSP Models Should be Clearly Stated in the Description of Alternatives and Environmental Analysis.

Only two of the six EFH identification alternatives are not solely based on the Habitat Suitability Probability (HSP) model. It is therefore imperative that the description of the alternatives and the environmental analysis provide the public with a clear understanding of the limitations and uncertainties involved in this modeling effort.[2] The following major uncertainties should be clearly defined in an accessible format to aid the decision maker and public in understanding the differences between alternatives:

1. The HSP modeling effort only includes depths out to 3000 meters. The discussion in Alternative A.2 and information from the groundfish life history appendix clearly illustrate that groundfish have been observed at depths up to 3400 meters;
2. Of the possible 328 maps of groundfish species and their life stages, only 160 HSP maps can be produced resulting in roughly half of the maps needed to adequately identify EFH by life stage for each of the eighty-two groundfish species.[3] The primary life stage where little information is available is larvae and eggs. This is particularly important for overfished species;
3. The trawl surveys utilized in the HSP model provide limited information concerning the function of habitat for a species for the following reasons. First, temporal aspects of the survey data may omit important habitats (for example, winter breeding grounds for lingcod using summer trawl surveys). Second, trawl surveys are of limited value for identifying EFH for juvenile stages (evident by a review of the HSP model outputs). Third, there is a strong bias towards habitats that can be trawled which can result in under representation of species that associate with untrawlable substrates for purposes of modeling the effects of depth and latitude[4]; and
4. The limited mapping of organisms that form biogenic habitats, which are particularly vulnerable to impacts and may have long recovery times, may result in these areas not being identified as EFH.

B. The Treatment of Groundfish Prey Species is Improperly Limited.

The EFH final rule states that:

> Loss of prey species may be an adverse effect on EFH and managed species because the presence of prey makes waters and substrate function as feeding habitat, and the definition of EFH includes waters and substrate necessary to fish for feeding. Therefore, actions that reduce the availability of major prey species, either through direct harm or capture, or through adverse impacts to the prey species' habitat that are known to cause a reduction in the population of the prey species, may be considered adverse effects on EFH if such actions reduce the quality of EFH. FMPs should list the major prey species for the species in the

---

2 We note that Appendix A, the Risk Assessment provides a fuller discussion of the HSP modeling process and applicable limitations and uncertainties. However, this information should be stated clearly in the main body of the EIS to help ensure the public and decision makers can make an informed decision.

3 50 CFR 600.815(a)(1)(iv).

4 Appendix A at 91.

fishery management unit and discuss the location of prey species' habitat. Adverse effects on prey species and their habitats may result from fishing and non-fishing activities.

50 C.F.R. 600.815 (a)(7). Accordingly, the groundfish FMP must include a list of major prey species for groundfish and discuss the location of prey species' habitat. The discussion of prey species in the main text of the EIS is currently limited to one section[5] describing primary prey species and a general statement that prey species utilize the same habitats as groundfish. The EIS currently includes only one alternative focused on protection of a prey species. The EIS should be revised to include a better discussion of the habitat requirements of major prey species to be included in the range of alternatives to aid the public in fully analyzing these alternatives. If information does not exist, this must be stated clearly in the EIS.

C. Habitat Areas of Particular Concern Should not be Limited to Essential Fish Habitat Alternatives.

The EIS should make clear that the identification of HAPCs for groundfish should not be limited by alternatives for identifying and describing EFH. If an area is identified as a HAPC but is located outside of an area included in a EFH identification alternative, this area can be identified as both EFH and a HAPC. For example, if the PFMC or public identifies an area that meets the requirements for designation of a HAPC but this area is located deeper than preliminary preferred Alternative A.2 (3400 meter depth designation for EFH), this area can still be designated as both a HAPC and EFH.

II. Effects of Fishing on Essential Fish Habitat: Description of Alternatives

The description of the development of alternatives to minimize adverse impacts of fishing on essential fish habitat gives the public a misguided understanding of the proper management standard of the MSA and EFH regulations.[6] While the EIS provides the definition of adverse impacts from the final rule, it then goes on to provide a different standard for assessing adverse effects centered around the link between EFH and groundfish production, resulting in a "precautionary" label being applied to development of the alternatives.

The EIS bases this on the following rationale. First, the EIS discusses the purpose of the impacts model and its inability to model the relationship between the intensity of fishing effort and effects on habitat due to a lack of data. Next it states that the current state of habitats effects research only makes it possible to construct alternatives that are targeted at physical alteration of habitat and changes in biodiversity from the impact. It therefore concludes that alternatives cannot be quantitatively constructed to increase production of groundfish or enhance ecosystem function, leading to a precautionary approach being taken by NMFS and the Council in developing the alternatives. The EIS further elaborates on this point by stating:

[5] EIS at 3-30.
[6] EIS at 2-15; this same rationale is also presented in a summarized form at 4-1.

> [A]lthough the alternatives cannot be specifically targeted to promote sustainable fisheries with predictable population level results, the alternatives were developed to reduce adverse impacts in terms of physical modification to habitat and biodiversity. The paucity of quantified, spatially explicit data on adverse impacts, and the extent which adverse impacts have reduced the ability of groundfish to sustain themselves, functioned as the problem statement around which the alternatives were constructed. The alternatives were deliberately developed to reflect the broad range of available data and present the full spectrum of precautionary choices for decision makers to meet the purpose and need of action to minimize the adverse effects of fishing.[7]

The MSA obligation to minimize the adverse impacts of fishing on EFH is not based on a production standard. Rather, it is based on the definition of adverse impact or effect:

> Adverse effects may include direct or indirect physical, chemical, or biological alterations of the waters or substrate and loss of, or injury to, benthic organisms, prey species and their habitat, and other ecosystem components, if such modifications reduce the quality and/or quantity of EFH. Adverse effects to EFH may result from actions occurring within EFH or outside of EFH and may include site-specific or habitat-wide impacts, including individual, cumulative, or synergistic consequences or actions.[8]

The EIS seems to put too much emphasis on the failure of the EFH impacts model to model the relationship between the intensity of fishing effort and effects on habitat. The model is not the only way (and not even the proper way considering available data) to assess adverse effects as defined by the MSA and EFH regulations. Studies analyzing the impacts of fishing gears on EFH can provide information to show an adverse effect necessary for developing a range of mitigation alternatives. Furthermore, the current state of the art habitat research, as defined by the EIS, provides the appropriate type of information to assess adverse effects. Quantitative studies linking gear impacts to production are not needed to meet MSA requirements.

Therefore, the proper standard and the one that guided development of these alternatives by the PFMC's EFH EIS Committee, is based on minimizing adverse impacts as defined in the EFH regulations using the best scientific information available. In this case, a review of the literature, the development of a sensitivity and recovery index (SRI) and guidance provided by the National Research Council ("NRC") are utilized to identify fishing operations that have adverse effects on habitat. Therefore, the description of the development of the alternatives should be revised to clearly state the definition of adverse impacts and that the tools necessary to identify and minimize the adverse effects of fishing gears on EFH are contained within the EIS as opposed to couching the alternatives as "precautionary" by using a groundfish production and quantifiable impacts standard.

The presentation of the sensitivity and recovery indices in the EIS discusses the decision to interpret global literature to help understand the effects of fishing on habitat. The EIS should cite the NRC report to support this choice and better inform the public on the basis of this

---

[7] Id.
[8] 50 C.F.R. 600.810.

recommendation.[9] To do this the EIS should include a general discussion on the NRC report, as well as the Auster and Langton paper and others, by incorporating the discussion in Appendix A to help better inform the decision maker as to how the adverse impacts were identified and a range of alternatives for minimizing them was developed.

The description of Alternative C.1 includes the potential mitigative effect of the rockfish conservation area ("RCA"). The description must also include the fact that the RCA is in place as a bycatch reduction management tool to help maximize fishing opportunities and that the RCA changes in size and shape frequently. This section of the EIS should make this clear by incorporating discussion of the use of the RCA contained in section 4[10] to help better inform the public about this alternative.

Finally, the EIS incorrectly states that Alternatives C.12-C.14 are mutually exclusive and that only one could be contained in a final preferred alternative.[11] This statement is misleading. While the areas identified in C.12, C.13, and C.14 are identical, the levels of protection afforded these areas could range from no bottom trawling to no fishing. Therefore, the mitigation strategies identified in the different alternatives can be mixed and matched for the specific areas contained in alternatives C.12-14.

III. Effects of Fishing on Essential Fish Habitat: Analysis of Adverse Impacts

The alternatives for minimizing the adverse impacts of fishing gear on EFH rely almost exclusively on a the SRI that displays in a numerical fashion the impact of a gear on a specific habitat in terms of how sensitive the habitat is to a particular gear type and the expected time needed for the habitat to recover from an impact. The main body of the EIS must include a discussion of the methodology utilized to develop this index in order to inform the public of key information that was not included. For example, it is our understanding that only literature that included quantifiable before and after differences of gear effects was included. There is ample literature on growth, age, biology, re-settlement and other relevant factors that should have been included. It is important that all available studies and sources of information are included in the EIS, regardless of whether or not they are considered useful for the SRI, to provide the public and the decision maker with the information necessary to make an informed choice.

The information presented in the SRI is treated as a range with standard errors based on the number of studies for each category. This methodology may result in certain values having a greater range of impact based on the number of applicable studies, not necessarily on the basis of the certainty provided in the original study. For example, only one study on the effects of bottom trawling on hard slope biogenic habitat showing major changes in bottom structure was considered. The sensitivity value for this category is given as 1.5-3 solely for the reason that it is one study as opposed to the impacts found.

---

[9] We recognize that the NRC report is cited in various places in the document and should also be cited here for the reasons discussed.

[10] EIS at 4-14.

[11] EIS at 2-12.

The sensitivity index provides a relative measure of the likely changes to habitat caused by interactions with various fishing gears and therefore provides little information on subsequent impacts.[12] This makes the cumulative impacts analysis (see below) critical in determining adverse impacts. Furthermore, the sensitivity values do not incorporate the relationship between fishing impacts and depth. The gear impacts analysis notes that benthic communities in deeper waters are probably less adapted to resisting and recovering from physical disturbances generally.[13] Considering that over the last few years fishing effort has been redirected into deeper waters, this factor is a significant one and must be stated clearly in the environmental analysis discussion to ensure the public makes an informed decision. Finally, the SRI does not consider the issue of fishing intensity or frequency of disturbance of the bottom by fishing gear.

IV. Effects of Fishing on Essential Fish Habitat: Prey Species

The EFH final rule states that:

> Loss of prey species may be an adverse effect on EFH and managed species because the presence of prey makes waters and substrate function as feeding habitat, and the definition of EFH includes waters and substrate necessary to fish for feeding. Therefore, actions that reduce the availability of major prey species, either through direct harm or capture, or through adverse impacts to the prey species' habitat that are known to cause a reduction in the population of the prey species, may be considered adverse effects on EFH if such actions reduce the quality of EFH. FMPs should list the major prey species for the species in the fishery management unit and discuss the location of prey species' habitat. Adverse effects on prey species and their habitats may result from fishing and non-fishing activities.

50 C.F.R. 600.815 (a)(7). While the EIS describes major prey species and identifies their habitat requirements generally, it provides no information on direct harm or capture with the exception of krill. The EIS should utilize information in the Bycatch EIS and groundfish observer data to identify direct removal of prey species by fishing and incorporate discussion of adverse impacts to prey species and their habitats into the description and environmental consequences of alternatives to minimize adverse impacts of fishing on EFH.

V. Effects of Fishing on Essential Fish Habitat: More than Minimal and Not Temporary Threshold

The EFH Rule states that:

> Councils must act to prevent, mitigate, or minimize any adverse effects from fishing, to the extent practicable, if there is evidence that a fishing activity adversely affects EFH in a manner that is more than minimal and not temporary in nature, based on the evaluation conducted pursuant to paragraph (a)(5) of this section.

---

[12] Appendix A Risk assessment at 124.
[13] Appendix A, Gear impacts analysis at 27.

50 CFR 600.815 (a)(2)(ii). In Section 2 of the EIS there is a discussion of the "minimal and temporary threshold" and how the risk assessment process sought to delineate where impacts exceeded this threshold.[14] At the conclusion of the discussion, the EIS does not define the "minimal and temporary threshold". Yet in Section 4 of the EIS a de facto "minimal and temporary threshold" is established for gear types with no rationale other than to "simplify the large amount of information for the analyses of individual alternatives".[15] These minimal and temporary thresholds are arbitrary. In the absence of evidence that can demonstrate that these values do in fact equate to minimal and temporary, the proper standard should be values of 0 for sensitivity and recovery in the SRI. In addition to being precautionary, an approach the EIS touts often to describe the range of alternatives to minimize adverse impacts of fishing on EFH, there is precedence for this approach in another region. In the EIS for EFH in the Gulf of Mexico NMFS and the Council utilized a similar metrics tool for assessing impacts of fishing gears on different habitat types based on a global literature search. In that EIS, anything above a value of 0 (no impacts) was considered to have crossed the minimal and temporary threshold unless proven otherwise. Furthermore, it is abundantly clear from the data presented in the EIS that by any rational measure, the more than minimal and not temporary threshold has been crossed, and that measures must be taken to minimize the adverse effects of fishing on essential fish habitat.

VII. Cumulative Effects Analysis

The EFH final rule states that:

> Cumulative impacts are impacts on the environment that result from the incremental impact of an action when added to other past, present, and reasonably foreseeable future actions, regardless of who undertakes such actions. Cumulative impacts can result from individually minor, but collectively significant actions taking place over a period of time. To the extent feasible and practicable, FMPs should analyze how the cumulative impacts of fishing and non-fishing activities influence the function of EFH on an ecosystem or watershed scale. An assessment of the cumulative and synergistic effects of multiple threats, including the effects of multiple threats, including the effects of natural stresses (such as storm damage or climate-based environmental shifts) and an assessment of the ecological risks resulting from the impact of those threats on EFH, also should be included.

50 CFR 600.815 (a)(5). To analyze cumulative impacts the EIS provides a brief discussion for each of the alternatives and a methodology to rank the cumulative impacts of the specific alternative. Section 3 of the EIS should provide an analysis of the past, present and reasonable foreseeable future actions on EFH and discuss the ecological risks posed by the cumulative impacts of these actions. Relevant discussions would include past, present and reasonably foreseeable future temporal and spatial patterns and trends of fishing in conjunction with the same considerations for spatial and temporal trends of non-fishing activities contained in the section 3.10. This analysis will better inform the decision maker as to the true status of groundfish EFH and the implications of impacts minimization alternatives in section 4.

---

[14] EIS at 2-13.
[15] EIS at 4-2.

VIII. Economic Analysis

Any viable economic analysis of minimization measures should include not only the short-term direct costs of management measures, but also the long-term costs of continued habitat damage, as well as the long-term benefits of habitat protection. In addition, the economic impact analysis of section 4 must be revised to include the expected future economic gains by groundfish trawl vessels due to the buyback program. This program was established based on the premise that by reducing the number of fishing vessels in the trawl fishery, the remaining vessels would become more profitable. The EIS should consult the appropriate analysis from the groundfish trawl vessel buyback program to include in the EIS.

Conclusion

Industrial fishing off the West Coast causes serious impacts to habitat. Adverse effects to habitat are occurring in West Coast waters that are long-term and substantial. The Fisheries Service is legally required to minimize these effects. A comprehensive regulatory system specifically designed to protect habitat is necessary for the agency to live up to its legal mandates and its responsibility as steward of our public resources.

RE: GROUNDFISH MANAGEMENT PLAN ESSENTIAL FISH HABITAT (EFH) DRAFT EIS

Dear. Mr. Lohn:

Our Association is composed of small trawl vessels in the 32 to 60 foot range, most being less than 45 feet long, who trawl for California halibut, ridgeback prawns and sea cucumbers, and formerly for spot prawns. We fish along the coastline from San Pedro, sometimes as far south as San Diego, up to Point Conception, from Point Arguello up to Pt. Buchon, and a few of our boats fish in Monterey Bay for halibut seasonally. Our boats are home-ported in Morro Bay, Port San Luis, Santa Barbara, Ventura, Channel Islands and San Pedro Harbors.

The purposes of this letter are 1) to fill in some serious information gaps in the DEIS regarding small-boat artisanal trawling that is done by our Association members in this region, and 2) comment on the various alternatives offered in the DEIS to mitigate impacts of fishing on EFH. Since most, if not all, of the information regarding trawling and its impacts in the DEIS relate to Groundfish Management Plan A-Permit trawl vessels, only one of which, home-ported in Morro Bay, is in our Association, we believe it is in the best interest of all for us to provide you with information about our fisheries.

In the Santa Barbara Channel area, particularly, there is no groundfish fishery to speak of, as described in the DEIS. This was not always the case: in the 1940s until about 1980 or so, groundfish were trawled in this region. Due to market and infrastructure changes, ***not*** stock decline problems, this fishery gradually moved out of the Southern California Bight (SCB). However, many, if not most, of the alternative proposals for management actions under the groundfish plan that address mitigation of impacts to EFH will certainly affect our small-boat artisanal fisheries for the remaining species we fish for, as well. So far, however, this is without including relevant information about our fisheries, to any appreciable extent, upon which the Pacific Fisheries Management Council (Council) can make an informed decision on EFH mitigation measures that accounts for our fisheries.

Habitat Mapping Discrepancies

The DEIS map scales are nearly useless for us to have any accuracy regarding exactly where EFH, HAPC or mitigation closure areas are. Larger scale maps need to be created in order for us to effectively understand and comment on the accuracy (or lack thereof) of habitat type information in the SCB.

Partly due to scale, partly due to very inappropriate assumptions on limited data, areas noted in DEIS maps as rocky or gravelly bottom are grossly inaccurate for the SCB. Our Association members have a combined, cumulative fishing experience history approaching a few hundred years of time on these seafloors, and pretty much know where the hard bottom habitat is. Unfortunately, we have not been consulted regarding these details of habitat type distribution. This information disconnect should be corrected prior to making decisions about closing areas of presumed habitat in the SCB based on mostly inaccurate habitat type geographic data.

As an example, and as far as we can determine given the small-scale of maps presented in the DEIS, Oceana's Alternative 12 mapping misses significant detail for water depths that we trawl, particularly with respect to mapping of bottom types (*see* DEIS Appendix C, Figure 42). It is clear that Alternative 12 wishes to place the entire Channel Islands National Marine Sanctuary in marine no-take reserve status, despite the extremely detailed habitat analysis undertaken by the CINMS Marine Reserve Working Group (MRWG) that resulted in the nearly-consensus array of no-take zones implemented by the California Fish and Game Commission. Much of the discussion in Alternative 12 lacks any of the habitat typing specificity that was readily available online from the CINMS web site, and makes erroneous assumptions about habitat types in those federally managed waters as a result.

What is unclear, however, is the status of the western Santa Barbara Channel. A green-blocked area is marked "open to bottom trawling" in the eastern half of the Channel, and a pink zone "Areas closed to bottom trawling" extends 6 miles around the Sanctuary, but the map is white (is that open?, closed? both?) in the western half of the southern part of the Channel, and western quarter of the coastal, northern part of the Channel. This area is currently open to trawling. This ambiguity must be resolved prior to making any meaningful comment on the proposal for the SCB, particularly the Channel.

Other conservation efforts have similarly mischaracterized large swaths of habitat type, and we are concerned that this misinformation made its way, by reference or by inappropriate use of this misinformation by the DEIS writing team: an area from Santa Barbara Point to Pitas Point from 1-2 miles offshore was mischaracterized as gravel bottom. This area is predominantly soft mud bottom, as any trawler would have been able describe. There is one reef structure, Carpinteria Reef, that everyone knows about and avoids, and there are a couple of hard bottom area outside of Carp Reef towards the oil platforms that we also know about and avoid to prevent damage to our nets. However, to characterize the entire area as gravel bottom is to ignore well-marked bottom type notations on the NOS charts, as well as failing to incorporate readily-available local fishing knowledge of the region.

Cumulative area closures in the SCB

This consideration of EFH is not happening in a vacuum, and should not be approached as if it were the only management measure that will reduce risk for groundfish EFH. A number of other actions have been taken by both State and Federal ocean regulatory agencies that bear directly on risk-averse, precautionary protection of groundfish EFH in the SCB. Some examples of these:

▪ State Waters Inside One Nautical Mile. This area is closed to trawling at all times throughout California. The bulk of nearshore rocky reefs occur in this zone, and this is some of the best essential fish habitat (EFH) along the coastline. It is completely protected from any impacts of trawl fishing.

▪ Channel Islands National Marine Sanctuary (CINMS) Marine Protected Areas (MPAs). This effort culminated in 2003 with a number of complete no-take marine protected areas (called marine reserves) around the northern Channel Islands. These areas were carefully selected to represent an array of habitat types, but the driving factor in discussions about these reserves was clearly the perceived status of groundfish stocks in the area. We say "perceived status" because at a time when conservation groups and state and federal marine resource regulators were saying that the SCB was devoid of bocaccio, our Association members were seeing startlingly large numbers of bocaccio in the region. Likewise with cowcod, hook and line fishermen repeatedly reported that there were many areas that were abundant in cowcod that were not being reported by scientists studying the area.

▪ Proposition 132 (Gillnet Ban) State Waters Marine no-take zones. Two of the four no-take zones in this regulation protect dozens of square miles of EFH in the SCB.

▪ CINMS Federal-waters MPAs. Currently, the Sanctuary Program (NMSP) is circulating a Sanctuary Designation Authority amendment document that proposes to give authority for the Sanctuaries Program to regulate commercial and sport fishing in ocean waters, traditionally the role of its sister agency, National Marine Fisheries Service (NMFS) or NOAA Fisheries. The purpose of this attempt to power-shift from NMFS to NMSP is to facilitate the implementation of "Phase 2" of the CINMS MPA plan in federal waters of the Sanctuary from 3 miles to 6 miles offshore of the four northern Channel Islands. Many of these areas are in places where our Association fishermen have traditionally fished for ridgeback or spot prawn, and this effort will, once again, further reduce the perceived risk to groundfish EFH in federal waters.

▪ Federal-State designated Cowcod Conservation Area. This area, some 5,200 square miles of ocean area is designated to, again, reduce risk to groundfish stocks (cowcod) and to protect EFH under the groundfish management plan (and California management consistency therewith) is closed to all trawling, and most other types of fishing as well.

▪ Federally-designated Rockfish Conservation Area (RCA) (Shelf Closure). In the SCB, the area has been somewhat of a "moving target," but currently is believed to be closed to fishing of all types for groundfish between shore and 150 fathoms, but changes seasonally to 60 or 75 fathoms and outward.

▪ California Halibut Trawl Bill. Enacted in 2004, these new regulations and management measures provide yet another risk-averse layer of gear, permitting and area closures that further protects groundfish EFH of concern to the Council. Some of the additionally precautionary measures include observers for California Halibut Trawl Grounds (CHTG) bycatch and habitat issues, excision of potential coral and sponge habitat from CHTG (all deepwater canyons in the CHTG), a permit system that declines or defers transferability until capacity goals/fleet reduction issues are considered, and a complete closure of the CHTG during the halibut spawning period (mid-March to mid-June, which no other halibut gear type observes), and others.

This accumulated suite of risk-averse, precautionary management actions taken together serve as a suitable array of areas that provide more-than-adequate protection for rebuilding groundfish stocks and the EFH upon which they depend. It should be considered as an offset for both the small-boat trawl fishery in the SCB, and as sufficient buffer for protection from impacts of fishing on groundfish EFH.

1. This array (See Figures 1 and 2) is hereby formally proposed as another alternative to be comprehensively and cumulatively analyzed in the EFH DEIS for the SCB region to protect groundfish EFH.

Monterey Bay

At a recent meeting in Morro Bay to discuss various alternatives, we learned that the Oceana Alternative 12 and the Nature Conservancy Alternative both have the entire Monterey Bay closed to trawling to protect hard bottom habitat, especially corals and sponges. However, this ignores the fact that in certain areas (see Attachment A), our Association members fish in highly storm-disturbed sandy bottom area (Terrace Point to the Pajaro River) for California halibut seasonally, and no deepwater coral or sponge habitat exists in the relatively shallow 25 to 60 fathom halibut flats used by our members. In order to achieve the stated goal of maximizing protection of EFH while minimizing socioeconomic impacts to fishing, further information sharing and a finer-scale closure proposal should be examined in the Monterey Bay. The areas currently used by halibut trawlers in our Association do not impact biogenic organisms or hard bottom substrate in Monterey Bay. Those areas should not be closed to trawling. The approximate bounds of this very small portion of the Monterey bay are as follows: outside the 3-mile line to the 60 fathom contour, from a point where these two lines intersect off Terrace Point (approximately 36° 53.61' x 122° 4.13') to a point where these two lines intersect again off the Pajaro River (approximately 36° 50.26' x 122° 52.37').

2. We respectfully request that this area be kept open to trawl fishing, as currently regulated, in any final proposal to protect groundfish EFH.

Avila Beach Area

Attachment A describes an area From Point Buchon to Point Arguello outside the 3-mile state waters limit line out to 60 fathoms. This area is historically fished for California halibut in muddy seafloor bottom habitat as the fish and weather allow.

3. We respectfully request that this area be kept open to trawl fishing, as currently regulated, in any final proposal to protect groundfish EFH.

Cumulative Socioeconomic Impacts

With the array of closures already implemented along the California coastline, a significant concern relates to the cumulative impacts of these closures on the essential infrastructure required to sustain viable commercial "working" fishing ports and harbors along the 1,100 mile coastline of California. At what point do we see the regulation that becomes "the straw that broke the camel's back?" That is, which additional layer of no-fishing regulation will cross the threshold of cutbacks to the number of boats required to harvest a sustainable yield from California's ocean resources, the number of buying stations still left in Morro Bay, San Pedro or Santa Barbara Harbors, the number of fish processors and/or retailers that can keep their doors open in order to serve the remaining few fishing boats that still go out? The cultural value of working ports and harbors is measured in both cultural heritage and tourism value: it is common knowledge that what attracts tourist dollars to the Morro Bay or Santa Barbara Harbor is "the quaint fishing boats" that still number in the tens, at least, in each Harbor (actually, there are only 5 A-permit boats left in the combined ports of Morro Bay and Port San Luis, we learned at the May 1 meeting in Morro Bay). At some point, an additional regulation will be the last one necessary to remove the infrastructure, more or less permanently (due to the failure of the commercial fishing industry to recruit young people among its numbers), that supports this cultural heritage in California ports and harbors. It behooves the Council to carefully consider whether or not further draconian measures are actually required to effectively protect groundfish EFH, or whether these further measures are, in fact, "the last straw" for fisheries culture and infrastructure in these ports and harbors. Another way to phrase this question is to turn it on its head: "how much fishing area, how many fishing boats, are necessary to maintain the year-round sustainable infrastructure of buying stations, ice houses, hoists, fish processing plants, wholesalers and retailers, that can provide fresh California seafood to seafood consumers?"

Fishing Grounds for Southern California Trawlers Association members

Attachment A lists the areas that our Association members use to harvest California halibut, ridgeback prawns, sea cucumbers and (formerly) spot prawns in the disjunct fishing grounds from Monterey Bay to San Diego. Figures 1 and 2 chart the areas closed to trawling due to a wide variety of management and regulatory actions. As you will see, due to recently implemented regulations, these areas are vanishingly small compared to "the Pacific Ocean," a common yardstick for conservationists to conclude "but we're only closing 1-4% of the ocean to trawling." They are vanishingly small compared to any EFH Alternative proposal currently in the DEIS. That 1-4% referenced, depending on how it overlaps with our trawl areas, might actually represent an additional erasure of 20, 30, 40, or even 50% of our remaining trawl grounds. Which percentage will be the final straw?

To conclude, we offer another alternative for the Southern California Bight that we respectfully request be analyzed concurrently with the other alternatives in the DEIS prior to the Council making a final decision regarding further protection for EFH from the impacts of trawling. We offer assistance to any proponent of any alternative in the form of consultation on detailed information regarding habitat types in our region. Please contact Mike McCorkle (805) 566-1400 to arrange such information sharing. Thank you for considering our request for analysis of our alternative to protect EFH while minimizing socioeconomic impacts to our Association members.

Sincerely,

Mike McCorkle

Attachment A

Southern California Trawlers Association:
Southern California Trawl Grounds

The Southern California Trawlers Association is a group of small-boat artisanal trawl fishing vessels that use a small footrope (8" or less) to trawl sustainably for mainly fresh, local markets and buyer/processors. Our Association is composed of relatively few boats (variable from 13 to 20), but the age composition of our captains makes attrition a problem today that is accelerating (we held funeral services for Association Member, Captain Tony West, F/V Steel Fin II, in late April, 2005). Few younger fishermen are entering the trawl fishery due to the incessant clamor of some conservation organizations that "all trawling is bad," and due to the draconian measures taken by both State and Federal regulatory agencies in the last few years to rebuild several groundfish stocks. Due to horsepower and gear limitations, our boats do not fish on rocky substrate or in extremely deep water. Net damage from reefs has taught us the wisdom of avoiding these areas of rocks.

Our boats provide local live halibut, ridgeback prawns (and, formerly, spot prawns) and some sole to local markets. We also trawl for sea cucumbers, for human consumption, mostly in Asian ethnic markets in the San Francisco, Oakland, Los Angeles areas, and some dried sea cucumber is exported.

Areas our Association Members Fish

San Diego

From the 3 mile line out to about the 45 fathom depth. The seafloor from Pt. Loma down to the Mexican border is mostly relatively low gradient sand flats. We catch mainly halibut and sea cucumber in this area, but ridgeback shrimp are in the Navy dumping area but it is so full of debris we can't fish there.

Newport Beach

From the western edge of the Newport Canyon up to Pt. Fermin, off San Pedro, from the 3 mile line outward as far as (for ridgeback prawn) 100 fathom depth. We catch sea cucumbers, halibut and ridgeback prawns over mud seafloor in this area, but the halibut are mainly closer to the 3-mile state waters limit line.

Santa Monica Bank and Bay

Along the eastern edge of the Santa Monica Bank we fish for halibut, ridgeback prawn and sea cucumber, all on soft mud bottom from the Santa Monica Bay fishing closure line and/or the 3-mile state waters limit out to 100 fathoms for ridgebacks. Along the western edge of the Santa Monica Bank up to Malibu we fish along the closure line & outside 3 miles also. We do not fish any part of Redondo Canyon.

Pt. Mugu to Arguello

Along the mainland side of the Santa Barbara Channel from Point Mugu to Point Arguello. During the California Halibut Trawl season (June 16 to March 15) we fish from 1 mile offshore to 3 miles out and beyond. During the closed (for spawning) season in this area, we fish outside of state waters 3-mile limit line. As a result of discussions with conservation groups regarding the recently enacted California Halibut Trawl Permit legislation, we agreed not to fish in areas that may contain deepwater corals and/or sponges or other biogenic organisms such as sea fans. For this area specifically, we now do not fish in Mugu Canyon, Hueneme Canyon, or in the canyons off Point Arguello and Point Conception. We fish out to 150 fathoms from mainly Conception to Santa Barbara, and in the Ventura Flats from Hueneme Canyon west. We fish these areas for sea cucumbers, ridgeback prawn, and California halibut. We used to fish for spot prawns, but due to concerns over bycatch of bocaccio (principally in the area north of Point Arguello), we no longer are able to fish for spot prawns at this time. The bottom types we fish in this area are mostly mud and some sandy mud. There are a few well-known rock reef areas we all avoid so as not to damage our small trawl nets. Historically we also fished for ridgeback and spot prawns in China Bay, Santa Cruz Island, and in the Channel inside of the gap between Anacapa and Santa Cruz Islands, also over mud bottom. In 100-130 fathoms we also historically fished for Dover and English sole on soft bottom in that area, and along "the Finger" (100-fathom west-pointing bathymetric feature in mid-Channel) for rockfish. Sole were also caught along the lower (northeastern) edge of the Finger as it merges with the Ventura Flats (the "Dunes" area where Platform Gail is now located).

Avila Beach

From Point Buchon to Point Arguello outside the 3-mile state waters limit line. We catch principally California halibut in this sand and mud bottom area, but also catch some sole in quantities allowed by the Groundfish Management Plan.

Monterey

Outside the 3-mile line to the 60 fathom contour, from a point where these two lines intersect off Terrace Point (approximately 36° 53.61' x 122° 4.13') to a point where these two lines intersect again off the Pajaro River (approximately 36° 50.26' x 122° 52.37'). We catch halibut and sole, and the bottom is mostly sandy. Association members do not fish in the Monterey Canyon.

Portland, OR 97220-1384

RECEIVED
MAY 16 2005
PFMC

Dear Chairman Hansen:

The following comments are on behalf of the members of the Fishing Vessel Owners' Association regarding the various alternatives for the fishing gear impact Minimization Alternatives that address Essential Fish Habitat and Habitat of Particular Concern. The Association represents 34 fixed-gear permit holders that operate off the Washington, Oregon, and California coast.

Alternative C.2 Depth based gear specific restrictions

This alternative has three options, C.2.1, C.2.2, and C.2.3, which close waters at specific depth contours to trawl and fixed gear. Options C.2.1 and C.2.2 propose to close fixed gear shoreward of 100 fathoms north of 40°10' N latitude and 150 fm south of 40°10' N latitude. Option C.2.3 proposes to close fixed gear shoreward of 60 fm.

The members oppose options C.2.1 and C.2.2 from a longline and pot gear perspective. These options mirror the current bi-annual restrictions on fixed gear operations. These restrictions were put into place largely due to the overfished status of yellow-eye rockfish and canary rockfish in the north and bocaccio in the south. The deeper restrictions in the south being an attempt for fixed gear to avoid bocaccio. These restrictions were based and continue to be justified with the information that is generated from the observer program. These proposed options, based on habitat protection and the resulting restrictions on fixed gear are not justified in the current analysis.

The only attempt to justify a restriction on fixed gear under this option is found on page 2-18. It states:

> **"Although the impacts of deploying fixed gear, such as longlines and traps, are considered less severe than that resulting from bottom trawling, these gear types can access the rocky habitat currently inaccessible to small footrope trawl gear. Therefore, this alternative closes shoreward areas to fixed gear."**

This statement suggests that, because one gear can access rocky habitat and the other cannot, they should both be banned. Tables 3 and 4 (Appendix 10, pages 14-19) show the sensitivity levels and recovery times for different habitat relative to the different gear types. These tables suggest that hook and line gear is shown to be 4 to 6 times less impacting than dredges or bottom trawls. Additionally, the analysis states relative to these tables, "moving across in the two tables, note that the ranges reflect the relative rankings of impact of gear in the following order: dredges > trawls > pots and traps > hook and line." Hook and line gear is listed as the least impacting type of gear yet this option treats fixed gear types equally with those gear-types that have greater impacts.

There is absolutely nothing in the analysis to justify including fixed gear in options C.2.1 and C.2.2.

Option C.2.3 Some form of this could be accommodated by hook and line and pot fishermen. We would repeat that the analysis indicates fixed gear has the least impact on habitat. Our permit holders traditionally fished sablefish off the North Coast into 75 fathoms off of Washington. Should yellow eye and canary rockfish be rebuilt, our permit holders would like to move back into 75 fathoms. Our CPUE levels for sablefish have dropped off in the late summer and fall due to the current rockfish 100 fm. conservation restriction for fixed gear. There are a few vessels that have fished for dog fish inside of 75 fm. We could support a 75 fm restriction for directed sablefish activities for future habitat protection. This restriction would affect 80 to 90% of the current fixed gear activity off of Washington and Oregon. We would support some limited activity on a case by case basis such as for dog fish inside of 80 fm.

C.4 Prohibit the Geographic Expansion of Fishing

This alternative has two options.

Option C.4.1 Trawl fishing would be prohibited from fishing in areas that were untrawled during 2000, 2002. No Comment.

Option C.4.2 – Apply the expansion limit to all bottom tending gear types. Closes area west of 2000 m. (deeper than 1094 fm). Our only comment is that our longline vessels have not operated seaward of this depth contour. The restrictions would have no affect on our fishing operations.

Alternative C.5 Prohibit a Krill fishery

Krill are an important prey for many fish species. They are important for juvenile species in particular and could be critical in the recovery of different salmon and rockfish species. Our members support this action; however, we are unsure which of the four implementation options is best for the Council.

C.6 Close hotspots.

This alternative prohibits trawling in habitat that has high probability of being EFH for a large number of groundfish. No Comment.

C.7 Close Areas of Interest.

This option is two complicated and subjective relative to areas of potential closure. There needs to be more detail on the impacts to the different user groups. The members of FVOA do not support this option.

C.8 Zoning Fishing Activities.

This option would potentially establish gear-specific closed zones. Though this option seems to recognize a difference between the impacts of fixed gear versus trawl and dredges, there is not enough description on what areas will ultimately be closed. It is therefore difficult to support or comment on.

Alternative C-9.

The Association will comment on options C.9.3 and C.9.4

C.9.3 **Limit the length of a single longline groundline to 3 NM**. Our vessel owners that hold coastal permits typically set close to 3-mile sets of hook and line gear. We could make this option work. However, the Council should be aware longline fishing is significantly a numbers game from the perspective of the vessel owner and crew in that it is CPUE driven. The lower the CPUE, the more times you throw the gear back into the water, which means more potential impacts on the sea floor. If the length of a set of gear is shortened, from what the current industry practice is, it means a vessel would set the same amount of hooks in more sets in order to catch a days worth of fish. With each new set of gear will be two more anchors and mid-gear weights creating impacts on the habitat.

Fishing Vessel Owners' Association can support the current proposal, but requests the Council be mindful that to require shorter sets may have the opposite impacts on the habitat than what is intended.

Alternative C.9.4. Employ Habitat-Friendly anchoring systems. FVOA members would support this option. Currently, our vessels use traditional 50 pound anchors on the end of our sets of gear. The anchor has a chain attached to the bottom of the fluke of the anchor and a gangion tied at the top of the anchor to the chain. If the anchor gets caught up, the gangion will break shifting the torque to the fluke and the lift is then from a different angle. We would like to help in any regulation of this type. A regulation that would adopt this safeguard, would be beneficial, lessening habitat impacts.

C.10 Central California No Trawl Zones

No Comment.

C.11 Relax Gear Endorsement Requirements.

Thee members of the Association could support this, however, it is unclear how this would work based on the analysis. There needs to be more detail provided. The following should be incorporated into the alternative.

(1) There needs to be a declaration prior to the fishing season on how a permit would be utilized, either with fixed gear or trawl.

(2) There should be a discussion on the duration of the declaration (i.e. bimonthly or yearly).

(3) Should fixed gear be used with a trawl permit, fixed gear should be able to take advantage of any gain due to having lesser bycatch mortality. As an example, if a trawl permit was used by an operation using fixed gear to target sablefish, the fixed gear operation should be able to have the addition of 30% more round pounds to target. This is currently the assessed discard mortality against trawl activity on sablefish. In this way there would be an economic incentive to use the gear that has the least discard and also has the least impact on the habitat. This consideration would convert current trawl discard mortality into landed mortality. If there are other species fixed gear could target with a trawl permit similar conversions would need to be provided for. The conversion rates are currently upgraded each year with the observer program so this should not be an undue complication

C-12 Close Ecologically Important Areas to Bottom Trawl.

No Comment.

C-13 Close Ecologically Important Areas to Bottom-Contacting Gear.

The Association opposes this option as proposed. The Association references the analysis tables 4 and 5 which suggest there is no rationale to treat all gear types similarly. These tables suggest fixed gear and hook and line in particular, is 4 to 6 times less impacting than trawls. To apply similar restrictions is unjustified.

Alternative D-2 Expanded Log Book Program

Option D.2.1 The Association supports this option for the longline sablefish fleet, particularly the tiered program. We also request that should this alternative be chosen, that the Pacific Council consider using the current longline log book used by NMFS for waters off of Alaska. This would minimize confusion and create a consistent information flow between the two Council jurisdictions.

Sincerely,

Robert D. Alverson
Manager

RDA:cb

Enclosures: support data

SE=0.0, n=3" for sensitivity and recovery. Although these means are based on three studies, they probably do not represent the situation for estuarine macrophytes generally. The three studies were all done on turtle grass (*Thalassia testudinum)* using a relatively light-weight (75 kg) trawl with the footrope rigged with rollers designed for catching shrimp in seagrasses. Turtle grass has leaves that range from several centimeters to a meter or so long and they are quite flexible, capable of lying nearly flush against the substrate in tidal currents. Hence, it may be expected that this type of gear could move above the turtle grass with minimal impact. The authors of these studies noted that certain gear specifications are needed to minimize damage to seagrasses. Hence, these studies should not be interpreted to represent the range of macrophyte and gear type combinations that may occur on the west coast.

The second gear by habitat combination that warrants comment is dredges in estuarine shellfish habitats, where sensitivity and recovery values were also quite low. All studies to date have been done on previously harvested oyster reefs where the natural vertical structure probably had already been greatly reduced. Oyster reefs that have not been harvested can have vertical relief ranging from < 1 m to several meters. Mechanical harvesting gears (whether hand-held or towed under power) typically used to harvest oysters are capable of greatly reducing this vertical structure because their effect is to destroy the natural aggregated nature of the reef, typically resulting in a reef that largely consists of individual oysters lying flat on the bottom. The studies summarized in Table 3 indicate that once the vertical structure of a reef is destroyed, further dredging apparently has only minimal impact on reef characteristics, including productivity. This is an important finding, but as in the case of the three trawl studies on one kind of seagrass, must not be pressed too far.

In conclusion, it should be emphasized that we only have a preliminary understanding of how fishing gear impacts biogenic habitats. Some trends are emerging, but further consideration of the two gear/habitat combinations that departed from general trends should be a warning that the relationships involved can be quite complex.

Table 3. Summary of mean sensitivity levels and recovery times for all combinations of five major gear types and bottom habitat types (i.e. three megahabitats, two induration types [hard and soft] and biogenic) for which empirical data were available.

Sensitivity Levels (range: 0 to 3)

Megahabitat, Induration, Meso/macrohabitat	**Habitat Code**	**Dredges**	**Bottom Trawls**	**Nets**	**Pots & Traps**	**Hook & Line**
Estuarine, Biogenic/Macrophytes		**2.9 (SE=0.07 , n=4)**	**0.0 (SE=0.00, n=3)**	(nd)	(nd)	(nd)
Estuarine, Biogenic/Shellfish		**0.9 (SE=0.93, n=3)**	(nd)	(nd)	(nd)	(nd)

Estuarine, Soft		1.3 (SE=0.34, n=9)	0.7 (SE=0.25, n=7)	(nd)	(nd)	(nd)
Shelf, Biogenic/Macrophytes		2.8 (SE= , n=1)	2.0 (SE= , n=1)	(nd)	(nd)	(nd)
Shelf, Biogenic/Shellfish		1.0 (SE= , n=1)	1.0 (SE= , n=1)	(nd)	0.8 (SE= , n=1)	(nd)
Shelf, Biogenic/Sponges		(nd)	2.2 (SE=0.15 , n=2)	(nd)	(nd)	(nd)
Shelf, Biogenic/Corals		(nd)	1.0 (SE= , n=1)	(nd)	(nd)	(nd)
Shelf, Hard, Exposure	She	1.7 (SE=0.40, n=3)	2.5 (SE=0.50, n=2)	(nd)	0.3 (SE=0.30, n=2)	(nd)
Shelf, Soft	Ss_u	1.0 (SE=0.10, n=22)	1.2 (SE=0.14, n=29)	(nd)	(nd)	(nd)
Slope, Biogenic, Sponges		(nd)	3.0 (SE=0.00 , n=2)	(nd)	(nd)	(nd)
Slope, Biogenic, Corals		(nd)	3.0 (SE=0.00 , n=2)	(nd)	(nd)	(nd)
Slope, Soft	Fs_u	(nd)	1.0 (SE= , n=1)	(nd)	(nd)	(nd)

Recovery Time (years)

Megahabitat, Induration, Meso/macrohabitat	Habitat Code	Dredges	Bottom Trawls	Nets	Pots & Traps	Hook & Line
Estuarine, Biogenic/Macrophytes		3.8 (SE=1.17, n=3)	0.0 (SE=0.00, n=3)	(nd)	(nd)	(nd)

Estuarine, Biogenic/Shellfish		**0.0 (SE=0.00, n=2)**	(nd)	(nd)	(nd)	(nd)
Estuarine, Soft		**0.4 (SE=0.17, n=8)**	**0.2 (SE=0.07, n=6)**	(nd)	(nd)	(nd)
Shelf, Biogenic/Macrophytes		**4.0+ (SE= , n=1)**	**3.0 (SE= , n=1)**	(nd)	(nd)	(nd)
Shelf, Biogenic/Shellfish		(nd)	(nd)	(nd)	**0.1 (SE= , n=1)**	(nd)
Shelf, Biogenic/Sponges		(nd)	**1.3 (SE=0.25 , n=2)**	(nd)	(nd)	(nd)
Shelf, Biogenic/Corals		(nd)	**1.0 (SE= , n=1)**	(nd)	(nd)	(nd)
Shelf, Hard, Exposure	She	(nd)	(nd)	(nd)	**0.0 (SE= , n=1)**	(nd)
Shelf, Soft	Ss_u	**0.5 (SE=0.17, n=9)**	**0.4 (SE=0.18, n=8)**	(nd)	(nd)	(nd)
Slope, Biogenic, Sponges		(nd)	(nd)	(nd)	(nd)	(nd)
Slope, Biogenic, Corals		(nd)	**7.0+ (SE= , n=1)**	(nd)	(nd)	(nd)
Slope, Soft	Fs_u	(nd)	(nd)	(nd)	(nd)	(nd)

Table 4 below is a first-draft "sensitivity matrix" and Table 5 is a first draft "recovery matrix." Each impact level is expressed as a range, which represents plus or minus one standard error around the mean for the values based on empirical data and plus or minus 50% of the mean for the derived values. The following 4-step protocol was used to derive the levels in both tables.

Table 4. Sensitivity level ranges for five major gear categories for all mapped habitat types. Sensitivity levels range from 0 to 3 (see Table 2 for descriptions). Values in green shaded cells are ranges from the literature, showing + or - one SE around the calculated means in Table 5. Others are derived values (see text for details).

Pacific Marine Conservation Council

May 10, 2005

Mr. D. Robert Lohn, Regional Administrator
National Marine Fisheries Service
c/o Maryann Nickerson
7600 Sand Point Way, NE
Bin C15700
Seattle, WA 98115-007

Re: Comment on 2005 Pacific Coast Groundfish DEIS for Essential Fish Habitat

Dear Mr. Lohn,

Pacific Marine Conservation Council (PMCC) is pleased to take this opportunity to offer comments on the Draft Environmental Impact Statement (DEIS) on Essential Fish Habitat for Pacific Coast Groundfish. PMCC is a west coast regional non-profit organization that works with commercial and sport fishermen, marine scientists, environmentalists and others. We operate with a mission dedicated to sustaining healthy and diverse marine ecosystems and fishing communities. It is from this perspective that we offer these comments.

The Northwest Region of NOAA Fisheries and the Pacific Fishery Management Council (Council) are to be congratulated for the work that has been accomplished on the DEIS, given the limited resources available. While we will offer constructive criticism of aspects of this document and associated processes, we do so with accompanying respect for the efforts of your staff.

PMCC has long engaged in habitat issues regarding Pacific groundfish, including several years' service by Science Director Jennifer Bloeser on the Council's Habitat Advisory Committee. We have carefully monitored the development of the DEIS, and Senior Policy Director Peter Huhtala helped development draft alternatives on the Council's EIS Oversight Committee.

During this comment period PMCC has conducted extensive outreach to attempt to engage more members of the fishing industry and residents of coastal communities in this important process. We will describe some of this outreach in this comment letter, partly because we feel compelled to let you know that we believe that the limited outreach conducted by the federal government was inadequate. The decisions that will emerge from this DEIS will likely have significant short and long-term impacts on fisheries and coastal communities, and extraordinary efforts should have been

PO Box 59 • Astoria, Oregon 97103

made to communicate with this portion of the public as well as with all citizens interested in the future of marine habitat.

PMCC also facilitated the work of an Independent Scientific Review Panel. This group conducted their own examination of the DEIS and their conclusions and recommendations are submitted separately from these comments. Neither PMCC staff nor board members participated in the Panel's deliberations. PMCC was solely interested in bringing the additional, independent insight of well-respected scientists to this process.

PMCC Outreach: Essential Fish Habitat Draft Environmental Impact Statement

On February 23, 2005, PMCC distributed a letter stating the need for public comment on the DEIS to Pacific groundfish permit holders, fishing groups and associations, and others who we identified as being involved or interested in the fishery. We also contacted senior personnel with natural resource agencies, including Sea Grant, in Washington, Oregon and California; and all members of the Pacific Fishery Management Council and groundfish-related advisory bodies.

The response was significant. We received inquiries almost daily in the following weeks, and during March and April met with more than 40 sport and commercial fishermen in 24 Washington, Oregon and California coastal communities. Over 100 copies of the DEIS on CD, provided to PMCC by NOAA Fisheries, were handed out with written background materials on the DEIS process and how to comment. We also distributed these materials to interested National Marine Sanctuary managers and staff, and instructors and graduate students at the University of Washington and Oregon State University.

Many fishermen with whom we spoke did not know about or understand the DEIS nor know how to comment. Several raised concern over whether regulations that affect nearshore fishing efforts, particularly sport fisheries for salmon, rockfish and halibut, will result. PMCC's outreach efforts in Washington and California fueled those in Oregon, where town meetings were held by OSU Sea Grant Extension and the Oregon Department of Fish and Wildlife.

PMCC believes that NOAA Fisheries' outreach in coastal communities with regard to the DEIS should have been more extensive. Additional constructive input from people who make their living on and near the water would have resulted in a more comprehensive EFH EIS, and in superior protection of sensitive marine habitats with minimal impact on fishing communities.

PMCC Recommendations on the DEIS Alternatives:

EFH Designation

PMCC recommends adopting *Alternative A.3, Depths less than 3,500 m* as Essential Fish Habitat (EFH) for Pacific groundfish. This alternative encompasses all of the known Habitat Suitability Probability (HSP) information and adds a precautionary spatial extent by depth. This allows for species for which HSP is not known for all life stages and provides a buffer for uncertainty. A reasonably broad designation of EFH, but short of the entire EEZ, reduces potential conflicts with HAPC designation as well as defining an adequate area where actions by other federal agencies should be subject to EFH consultation with NOAA Fisheries.

PO Box 59 • Astoria, Oregon 97103
Tel: (503) 325-8188 • (800) 343-5487 • Fax (503) 325-9681 • www.pmcc.org

HAPC Designation

PMCC encourages the Council and NOAA Fisheries to designate Habitat Areas of Particular Concern (HAPC). The designation would, we believe, add a layer of focus that may inspire more attention to be paid to Conservation Recommendations made to other federal agencies during EFH consultation. This could have a positive impact on fisheries and coastal communities.

We understand the challenges in defining specific areas as HAPCs, but attention should be paid to the Areas of Interest in *Alternative B.7*. One challenge we foresee in geographically-defined HAPC designation based on "ecological function" is the lack of robust data regarding specific functions throughout the areas. This might be overcome by defining a process to modify the boundaries of the HAPCs as new data becomes available. PMCC supports *Alternative B.9 Process for New HAPC Designations*, and we suggest that procedures for modifying or removing HAPC designation might be implemented within a refined version of this alternative.

The Council's preliminary preferred alternatives, *B.2: Estuaries*, *B.3: Canopy Kelp*, *B.4: Seagrass*, and, *B.6: Rocky Reefs* all describe habitat types observed to serve important ecological functions. PMCC supports final adoption of these alternatives.

Minimize Adverse Fishing Impacts to EFH

This is the most challenging and controversial of the suites of alternatives. It is also where decisions can be made that result in real protection of the most sensitive or slow to recover marine habitats within EFH.

In general, PMCC supports use of fishing gear and techniques that are appropriate to the environment being fished. Incentives should be offered to encourage use of gear that least damages habitat. Considerable investment should be made in cooperative research that offers opportunity for fishermen to design and participate in studies to demonstrate the effective use of gear that minimizes damage to sensitive habitat.

PMCC acknowledges the limited amount of research that has been conducted on the West Coast to demonstrate specific impacts of a variety of gear on habitat. In addition, reliable fishing effort information relative to location is minimal, except in the case of the groundfish trawl fishery.

There has been a great deal of research conducted worldwide that documents the negative habitat impacts of mobile, bottom-contact gear. *Alternative C.12: Close Ecologically Important Areas to Bottom Trawl* focuses on this gear. PMCC generally supports the approach used in this alternative. The concept of using multiple data sources to define sensitive and slow to recover habitat in a precautionary manner, and then to close these areas to bottom trawling, while minimizing the economic impact makes a lot of sense. This should be the starting point in crafting a comprehensive alternative that works for both the marine environment and the fishery.

Alternative C.12 freezes the trawl footprint based on areas trawled 2000-2003, providing a reasonable basis for protecting potentially pristine habitat without affecting economic activity. *Alternative C.4: Prohibit the Geographic Expansion of Fishing* utilizes a similar approach with 2000-2002 as the qualifying years. This provides a measure of precaution but is not adequate in itself for minimizing adverse impacts of fishing gear on habitat.

PO Box 59 • Astoria, Oregon 97103
Tel: (503) 325-8188 • (800) 343-5487 • Fax (503) 325-9681 • www.pmcc.org

Alternative C.12 also identifies areas where trawling has occurred in recent years that would be off limits to the gears. The basis for closing these areas to trawling needs to be based on the best scientific information available, with a reasonable measure of precaution. In defining these areas, including buffers around the most sensitive habitat, consideration should be given to where any displaced fishing effort may move. Increased effort in nearby areas that remain open may have unintended consequences.

While the intent of *Alternative C.12* is to minimize gear impacts to the extent *practicable*, this requires some ground-truthing. PMCC has consistently testified to the Council that we believe that it is important to assess whether disparate adverse economic impacts may accrue to individual communities if important opportunities are lost due to restricted access. NOAA Fisheries can determine this to some degree using economic and spatial effort data regarding the trawl fishery, but it remains essential to engage fishermen in this process.

It is encouraging to hear that members of the trawl fishery have been working with *Alternative C.12* to reconfigure some of the closed areas so that the impact on the industry would be minimal even as important habitat is protected. There will probably be some give and take, but if NOAA Fisheries and the Council work closely with the fishermen and states to verify to the extent possible both biological and economic data, the outcome seems promising. Using trawl track data, logbooks and landings reports should help to refine the maps in order to minimize displacement of effort while still achieving significant habitat protection.

PMCC is supportive of *Alternative C.9: Gear Restrictions*, but only including those restrictions that very likely will protect habitat, such as *C.9.5: Prohibit dredge gear* and *C.9.6: Prohibit beam-trawl gear*. *C.9.1: Prohibit roller gear larger than 15 inches on bottom trawls* might be considered if, in the total package of alternatives, roller gear larger than 8 inches is only prohibited on the shelf.

PMCC is also supportive of a modification of *Alternative C.11: Relax Gear Endorsement Requirements,* if trawl-endorsed permit holders are allowed to switch to longline or pot gear, but not vice versa.

Research and Monitoring

PMCC strongly recommends that the final Research and Monitoring EFH EIS Alternative combine elements of *Alternatives D.2, D.3, and D.4*. The management tools outlined in the Alternatives are complimentary to each other and would provide information critical to improving our understanding on the location and impacts on EFH. Selected individually, none of the proposed Alternatives is extensive enough to gather the information needed for adequate protection of EFH. An Alternative developed from elements of all of the proposed Alternatives would provide the balance of fishery dependent and fishery independent information sources we require in other areas of fishery management.

We recommend that the Council and NOAA Fisheries develop a research plan specific to the EFH research needs identified through the process of developing this EIS. While we recognize the need for improved information around groundfish habitat and strongly support the development of a research plan for this purpose, inaction (Alternative D.1) is not an acceptable response to lack of information. We recommend that the Council move forward with the identification and designation of sensitive habitat areas for protection and research purposes using the best available science.

PO Box 59 • Astoria, Oregon 97103
Tel: (503) 325-8188 • (800) 343-5487 • Fax (503) 325-9681 • www.pmcc.org

The National Research Council report on Improving the Use of the "Best Scientific Information Available" Standard in Fisheries Management makes the following recommendation in terms of developing plans to improve available science.

> *"NOAA Fisheries should develop and implement a plan to systematically improve the quality of the "best scientific information available" that includes regular assessments of the outcomes of management actions and evaluation of the predictive quality of the scientific information supporting those actions."*

To accomplish this we strongly recommend and support the development of a research program that uses local area knowledge and collaborative research with members of the fishing industry as information gathering mechanisms.

Our specific recommendations on the proposed Alternatives are outlined below.

Alternative D.2: Expanded Logbook Program
PMCC strongly supports the use of an expanded logbook program designed to gather information on habitat.   In recognition of the cost of such a program we would support Option D.2.2, where a random sample of fishing vessels is required to maintain logbooks as long as there is explicit buy-in at the onset of the program for adequate design, allowing for extrapolation of the information to the nonparticipating portion of the fleet.

Alternative D.3: Expanded Vessel Monitoring Program
PMCC supports the use of vessel monitoring programs for the purposes of increased safety and application of spatial management that allows for continued fishing opportunities while rebuilding overfished stocks. We encourage and support the use of technology in VMS systems that allows for the distinction between a vessel fishing and a vessel transiting. This would allow vessels to transit through closed areas for safety purposes. To the extent possible the cost of VMS units and associated transmission costs should be paid by the federal government.

Alternative D.4: Research Reserve System
PMCC strongly supports an Alternative that includes the development and use of a research reserve system. The EFH DEIS explicitly acknowledges the constraint placed on our knowledge of the effects of fishing on habitat resulting from the lack of unaffected control sites. The information gathered from control sites is a critical piece of the information puzzle and will not be accomplished through Alternatives D.2 or D.3. We recommend a collaborative process be developed with the fishing industry for the purposes of identification and design of this system.

Thank you for this opportunity to comment on the DEIS. We will be happy to discuss our recommendations

Sincerely

Jennifer Bloeser	Peter Huhtala

Re: Comment on 2005 Pacific Coast Groundfish EFH DEIS

Dear Administrator Lohn:

This letter submits comments of the Natural Resources Defense Council and The Ocean Conservancy on the above referenced topic, supplementing the comments we sent jointly with Oceana under separate cover analyzing the legal and technical adequacy of the Essential Fish Habitat Draft Environmental Impact Statement (DEIS). The purpose of this letter is to express the support of our organizations and our more than 2 million members, volunteers and activists for specific alternatives analyzed in the DEIS. In summary, we support EFH Identification Alternative A.2 (depths less than 3,500m) plus seamounts and Impact Miminization Alternatives C.5 (prohibit a krill fishery) and C.12, revised version (close ecologically important areas to bottom trawl), combined with closures to bottom-contacting gear, per Alternative C. 13, at Cordell and Daisy Banks and seamounts. We also support Research and Monitoring Alternatives D.2.1, D.3 and D.4, combined with a systematic research and monitoring program aimed at providing relevant information on habitat quality and impacts to decision makers and the public, and fostering adaptive management of habitat measures (an alternative omitted from the DEIS). We urge you to remedy the deficiencies in the document, described in our joint comments with Oceana, and to take action as quickly as possible to implement the alternatives described herein.

Background and Principles

Fishery managers and scientists have called habitat damage the most significant long term threat to the health of fisheries. Extensive research, including a National Academy of Sciences (NAS) report,[1] documents the adverse impacts of bottom trawling on a variety of habitats. A number of studies identify bottom trawling as one of the most disruptive disturbances to seabed communities, decreasing habitat complexity and

[1] National Research Council, 2002. Effects of Trawling and Dredging on Seafloor Habitat, National Academy of Sciences.

potentially altering productivity. The NAS study emphasizes that lack of area-specific studies on trawling effects does not justify postponing action to address fishing effects on seafloor habitat.

Over the last two years, two national blue ribbon ocean commissions have made recommendations for improving fishery management and the health of the oceans. Those reports embrace a number of principles that are consistent with the NAS approach and that we believe should underlie the National Marine Fisheries Service's (NMFS's) decisions regarding protection of groundfish essential fish habitat (EFH). They include the precautionary approach, which errs on the side of conservation in the face of uncertainty and limited information; ecosystem-based management, which reflects the relationships between ecosystem components, including humans; adaptive management, in which management measures are designed to continually provide new information and improve the basis for future management decisions. The alternatives we support incorporate these principles. They take important steps to reduce the adverse effects of fishing on Pacific groundfish habitat, provide protection to diverse and vulnerable habitats, and proactively prevent new potential impacts in the future.

Rationale

Alternative A2: Depths less than 3,500 meters plus seamounts. Alternative A.2, selected by the Pacific Fishery Management Council (PFMC) as a preliminary preferred alternative, is the only EFH-identification alternative that utilizes both the habitat suitability probability (HSP) modeling outputs and other data sources, yet is not so broad as to be meaningless. This alternative addresses the uncertainties involved with the HSP modeling outputs by including other data sources plus a 100 meter-depth buffer. Alternatives A.3 through A.6 rely exclusively on the HSP model outputs and therefore fail in several ways to utilize the best scientific information available. First, the HSP modeling outputs are limited to depths less than 3000 meters. That limitation results in identification of EFH out to a maximum of 3000 meters despite information that groundfish occur at depths of 3400 meters. Second, the HSP modeling effort only produced EFH requirements for about half of the species by life stage. Thus, that modeling effort did not identify EFH for a number of life stages for key groundfish species. Alternative A.2 takes these uncertainties into account by incorporating other data sources and adding a 100-meter buffer to acknowledge our information is likely to be incomplete. Finally, the HSP modeling process excluded major prey species. Considering that the EFH rule requires that councils interpret information for designating EFH in a "risk averse fashion to ensure adequate areas are identified as EFH for managed species," Alternative A.2 is also the best choice because it provides a greater degree of certainty that the habitat needs of prey species are incorporated into EFH designation.

We support inclusion of seamounts for the following reasons. First, though seamounts may rise to a depth level above 3500 meters, the EFH identification methodology in the EIS utilizes the 3500-meter depth line on the continental slope to exclude areas beyond that line, including seamounts occurring outside it. Second, given what is known about the potential biological productivity, degree of endemism, occurrence of fragile habitats including coral and sponge, and other ecological functions of seamounts, the most prudent course of action would be to include seamounts in Alternative A.2 for EFH designation.

Alternative C.5: Prohibit a Krill Fishery. We support Alternative C.5 as a proactive measure to protect a crucial part of groundfish habitat: an abundant prey species at the base of the food web, nourishing groundfish directly and indirectly as food for other prey species. Food availability is a critical prerequisite for groundfish growth and recruitment. Protecting krill, currently an unfished species, as habitat is consistent with the EFH rule[2] and provides a zero-cost way to ensure that a major prey species remains available. Adopting Alternative C.5 is a smart step in a complex multi-species fishery with many uncertainties about how fishing is currently altering food-web relationships, productivity and rebuilding potential.

Revised Alternative C.12: Close Ecologically Important Areas to Bottom Trawl, combined with specified features of C. 13. The Council adopted the suite of C.12 through C.14 as preliminary preferred alternatives, and we support a combination of these options that provides higher levels of protection for habitats that are unique, particularly vulnerable, and/or important sources of productivity. Specifically we propose C.12 plus the greater protection level provided by C.13 (Close Bottom-Contacting Gear) for at least Cordell Bank, Daisy Bank (based on a proposal for a habitat area of particular concern submitted by Dr. Mark Hixon for consideration of the Pacific Fishery Management Council's EFH EIS Committee) and to all seamounts, as unique habitats with a high degree of endemism and vulnerability. We believe greater protection is warranted for these habitats because they are rich in fragile structure-forming invertebrates and likely to be slow to recover.

C.12 combines closure of identified areas to bottom trawling, freezing the trawl footprint, restricting catch, restricting gear, monitoring via observer data and expanded use of VMS, and benthic research and mapping. It thus incorporates the key measures recommended by the National Academy of Sciences to address the long-term adverse impacts of bottom trawling on fish habitat. The selection of these areas is based on the overlap of three or more habitat-related data sets, including the results of the risk assessment conducted by NMFS consultants to evaluate the sensitivity and recovery time of various habitats. This use of multiple data sets makes it the spatial alternative that most systematically uses available scientific information. As noted by the PFMC's Scientific and Statistical Committee, it is the only set of alternatives that deals explicitly with protection of habitat-forming invertebrates such as deep-water corals and sponges, in addition to encompassing a broad range of other groundfish habitat types.

Alternative C.12 has been revised recently, based on trawl track data, to reduce its potential economic displacement and increase protection in areas where displacement is unlikely to be a factor. The SSC found economic assessment methodology used by its proponents likely to be more accurate than that used in the DEIS.[3]

---

[2] 50 C.F.R. 600.815 (a)(7).
[3] SSC Notes Nov. 1, 2, 2004

Alternatives D.2.1: Expanded Logbook; D.3: Expanded Vessel Monitoring System; and D.4: Research Reserve System. The DEIS identified a number of data needs that, if satisfied, can improve our knowledge about gear impacts (particularly those of the non-trawl groundfish fleet), assess habitat quality, minimize adverse impacts on groundfish habitat, mitigate economic displacement, and adaptively manage this fishery. We therefore support collection of data through expanded logbooks and VMS, the creation of research reserves that will facilitate studies of habitat impacts and better protection for essential groundfish habitat, and a research and monitoring program that utilizes this data to inform decision makers and the public and improve management.

Trawl logbook information has repeatedly proved useful for management purposes, from its supporting role in developing the first depth-based bycatch model to its use in revising the C.12-C.14 suite of alternatives to reduce economic displacement while maintaining protection for habitat. It makes sense to expand logbooks to other vessels in the groundfish fleet. Likewise, the kind of spatially specific information VMS provides is vital to improving habitat protection over time, managing adaptively, and mitigating economic impacts of management measures to fishing communities. Finally, we support creation of a research reserve system designed to improve our understanding of the impacts of fishing gear and for other management purposes. The DEIS finds that such a system may increase knowledge relating habitat to living marine resources, thereby resulting in improved stock status, higher fishery yields and improved education resources. To minimize economic displacement of such a system, we expect it could be designed within a subset of the areas identified in Alternatives C.12-C.14.

Summary

We believe NMFS and the Pacific Council have a historic opportunity to take a more ecosystem-based approach to managing the groundfish fishery by moving forward with a combination of Alternative C.12 and C.13, alternatives already designated as preliminary preferred by the Council. We appreciate the opportunity to comment, and urge you to take action now to address the flaws in the DEIS and provide the long-term habitat protection needed to sustain Pacific groundfish.

Sincerely,

Karen B Garrison

Subject: Comments on the "Pacific Coast Groundfish Fishery Management Plan - Essential Fish Habitat Designation and Minimization of Adverse Impacts" Draft EIS Support of Modified Alternatives of Collaborative Efforts between Environmental Non-Governmental Organizations and Fishermen and Protection and Consideration of Impacts to Coastal Communities

Dear Mr. Robert Lohn:

We appreciate this opportunity to comment on the "Groundfish Essential Fish Habitat Designation and Minimization of Adverse Impacts Draft Environmental Impact Statement (DEIS)." We support the Pacific Fisheries Management Council and National Marine Fisheries Service's efforts to assess the environmental and socioeconomic effects of the alternatives presented in the Draft EIS. Our review of the Draft EIS document and discussions we have had with NMFS staff, including Dr. Rebecca Lent and Mr. Steve Copps, provided us with a good understanding of the intent and variables of the Essential Fish Habitat program. Our comments are broad with respect to the fisheries issues but are focused on the effects of the Essential Fish Habitat program on local coastal communities and fishing dependent harbors.

The Magnuson-Stevens Act and a 2000 court order require the preparation of this DEIS. The purpose of this DEIS is to evaluate the effects of fishing on essential fish habitat and to identify measures that will minimize those impacts to the extent practical. The project will also designate "Habitat Areas of Particular Concern" and identify other actions that encourage the conservation and enhancement of Essential Fish Habitat (source: DEIS). The Pacific Coast Groundfish Management Plan (FMP) will ultimately be amended to incorporate the alternatives selected by the Pacific Fisheries Management Council (PFMC) and as may be approved by the National Marine Fisheries Service (NMFS).

Subject: Comments on the "2005 Pacific Coast Groundfish Fishery Management Plan - Essential Fish Habitat Designation and Minimization of Adverse Impacts" DEIS - Support of Modified Alternatives of Collaborative Efforts between Environmental Non-Governmental Organizations and Fishermen and Protection and Consideration of Impacts to Coastal Communities

Dear Mr. Lohn:

Thank you for this opportunity to comment on the "Groundfish Essential Fish Habitat Designation and Minimization of Adverse Impacts Draft Environmental Impact Statement (DEIS)." We support the Pacific Fisheries Management Council (PFMC) and National Marine Fisheries Service (NMFS) efforts to assist the environmental and socioeconomic effects of the alternatives presented in the Draft EIS. Our comments are broad in scope on the fisheries issues but are focused on the effects of the Essential Fish Habitat program on local coastal communities and fishing dependent harbors.

The Magnuson-Stevens Act and a 2000 court order require the preparation of this DEIS. The purpose of this DEIS is to evaluate the effects of fishing on essential fish habitat and to identify measures that will minimize those impacts to the extent practical. The project will also designate "Habitat Areas of Particular Concern" and identify other actions that encourage the conservation and enhancement of Essential Fish Habitat (source: DEIS). The Pacific Coast Groundfish Management Plan (FMP) will ultimately be amended to incorporate the alternatives selected by the PFMC and as may be approved by the NMFS.

Current Joint Efforts

There are an estimated 23 permit holders that we believe regularly trawl in central California region, some of whom offload at the Moss Landing Harbor. We support the efforts of the environmental non-governmental organizations (NGO's) and these 23 commercial fishermen (and their associated representatives) to see if they can agree on designated zones in the study area (such as Alternatives C.10 and C.12 as may be modified) as no-bottom trawl zones. Of course, other areas would remain available for trawling and other types of fishing, for both sport and commercial take. It is my understanding that the NGO's, individuals and Fishing Associations (local Fishermen's Associations, FMA, PCFFA and others) are working to identify areas they think should be kept open to bottom trawl fishing and those remaining areas to be closed to bottom trawlers. We strongly support these efforts and recommend that whichever alternatives are eventually submitted to the PFMC be taken seriously and adopted by NMFS and the Commerce Department. We believe that the collaborative efforts of the NGO's and the Fishermen will ultimately result in the best alternative for the central California coast area for designation of the Essential Fish Habitat, meeting the requirements of the court order and the Magnuson-Stevens Act, et seq.

We request both the PFMC and NMFS allow the NGO's to continue working with the trawl fishermen (who will be most impacted) in order to prepare recommendations on open trawl areas and trawl closed zones within the central California coast study region. We expect these groups to provide a preliminary zoning plan for at the PFMC meeting in June 2005. We support any alternative submitted by a collaborative group effort of NGO's and commercial fishermen.

We respectfully request that both the PFMC and the NMFS accept and support any Alternative submitted by any joint effort of these groups as one of the preferred alternatives in the EFH EIS, and allow the fishermen and NGO's to continue their collaborative work with the commercial fishermen, that is, to identify essential fish habitat, to designate habitat areas of particular concern, to minimize, to the extent practical, the adverse effects of fishing on the essential fish habitat, and to identify other actions that will encourage the conservation and enhancement of the essential fish habitats within any modified Alternative for this region.

Potential Impacts on Ports, Harbors and Coastal Communities

There are many small ports and harbors that have mutually beneficial relationships with fisheries industries, both sport and commercial, within the study region. These small craft harbors rely on the fisheries to provide steady jobs and act as an economic engine to keep the community vibrant. In the case of central California harbors, the past few years of increased regulatory actions have had a drastic negative affect on the ability of the fishing fleets to continue making a profit, which has a direct effect on the coastal host community (harbors and marinas). The implementation of yet another regulatory action (closure) will have a great economically adverse effect on these local communities. Therefore, we ask that both the PFMC and the NMFS carefully consider the socioeconomic effects of any designation of essential fish habitat in the central California region.

We understand that it is very difficult to quantify the social and economic effects of such a project or plan and cannot offer specific verifiable evidence of those effects, other than our past experience and day-to-day observation of the fishing industry and the benefits it has on our communities. There is a synergy that occurs which is un-measurable in terms of cash value that needs to be considered in the development of fishing regulations, including the designation of essential fish habitats on the west coast. The public comes to the ports and harbors and enjoys getting their fresh seafood while watching the boats offload their catch. Without that, these small craft harbors become stagnant and turn into yacht harbors for the rich. The little guys are forced out and the working harbors cease to exist. We have seen this in southern California harbors and hope that that does not happen here. Please be careful in the implementation of the EFH and take these comments into consideration when doing so.

Again, we thank the Council and Fisheries Service for your consideration of this alternative. We are available for future discussions on this issue. Should you require additional information please contact me by email at mcintyre@mosslandingharbor.dst.ca.us or by telephone at (831) 633.5417.

Sincerely,
Moss Landing Harbor District

Manchester, CA 95459
(707) 895-2584

May 9, 2005

Mr. D. Robert Lohn, Regional Administrator
National Marine Fisheries Service
7600 Sand Point Way NE, BIN C15700
Seattle, WA 98115-007

Dear Mr. Lohn,

I am writing on behalf of the Mendonoma Marine Life Conservancy to express our support for the effort to identify, restore, and protect ocean habitats that are essential to Pacific Coast groundfish.

We are a private group of sixteen educators, fishermen, environmentalists, divers, Native Americans, kelp harvesters, and other stakeholders focused on mapping offshore geography, ecology, fisheries, and recreational uses in California State waters from the Humboldt-Mendocino county line to the outflow of the Russian Gulch Watershed south of Fort Ross. MMLC's mailing list includes over 100 individuals and organizations, and our By-Laws authorize advocacy as an "interested party" as referenced in Section 2861(a) of the California Fish & Game Code.

Groundfish share a vulnerability to overfishing with open water, schooling fish. But because many groundfish species live in and around the same rocky reefs and other bottom features for most of their adult life, they are also vulnerable to destruction of their homes, feeding areas, and breeding grounds from certain kinds of fishing activity. These homes, feeding areas, and breeding grounds often include living seafloor animals as well as geologic terrain and vegetation.

MMLC supports efforts to (1) identify and protect habitat areas of concern essential to groundfish, and (2) protect some areas from further damage by prohibiting the use of fishing gear known to damage groundfish habitat and seafloor animals. We believe that the elimination of habitat-damaging fishing gear should be done in such a way as to minimize economic hardships on fishermen, as they are simply applying techniques and tools created before mankind realized their potential for damage.

MMLC would also like to point out that Figure 2-7 [B.2 HAPC Estuaries] omits the longest undeveloped estuary in California: Big River Estuary, where the upper extent of salt water intrusion can exceed eight miles. Bocaccio is among the species that were documented in the Big River Estuary and lower subbasin by Warrick & Wilcox in 1981, and several other groundfish species have been identified in the Estuary at some stage in their development. We feel Big River Estuary offers an excellent venue for estuarine research in general and studies of potential interaction between juvenile salmonids and juvenile rockfish in particular. Please include Big River Estuary in Alternative B.2.

Lastly, we would caution that precautionary management principles be used in all cases where information needed for decision making is unavailable. In the history of U.S. and Canadian management of North Atlantic fishing grounds many decisions placed socioeconomic interest over precautionary management principles, and eleven years after the fishery was finally closed Atlantic cod population levels were still among the lowest ever recorded.

We understand that application of precautionary management principles will skew decision making in favor of protecting essential habitat in those cases where definitive data is unavailable or inconclusive. Because of the degree of uncertainty surrounding much current data, precautionary management principles will need to be employed often early-on; thus we feel it is important that the final EIS include a definition of "precautionary management principles" in Chapter 9.

Thank you for the opportunity to comment.

Sincerely,

Rob Cozens

Re: Comment on 2005 Pacific Coast Groundfish DEIS for Essential Fish Habitat
Independent Scientific Review Panel

Dear Mr. Lohn,

Pacific Marine Conservation Council (PMCC) has facilitated the work of an Independent Scientific Review Panel (Panel) to review the Pacific Coast Groundfish DEIS for Essential Fish Habitat during the public comment period. We are pleased to provide you the report from this Panel.

It is PMCC’s belief that the thorough, scientific assessment of the DEIS "Purpose and Need" and proposed alternatives is a valuable contribution to this important process, and we encourage you to give the report careful consideration. We want to be clear that these comments are independent from PMCC, and wholly separate from the comments submitted by PMCC staff.

No staff or board members of PMCC served on the Panel. The Panel members were not offered or provided financial compensation.

Sincerely,

Peter Huhtala

Dr. Don Gunderson

Dr. Ralph Larson

Dr. Les Watling

Consensus Statement

The Draft Environmental Impact Statement (DEIS) on Essential Fish Habitat (EFH) for the U.S. West Coast represents an important opportunity for the Pacific Fisheries Management Council (PFMC) to take a major step toward ecosystem-based management. The document has a number of shortcomings, principally, a) lack of data on habitat impacts of various gear types, b) lack of ground-truthing for the GIS-based model that forms the foundation of several of the recommended management actions, c) lack of data to determine the functional relationship between habitat condition and fish population or community response, and d) repeated failure to identify appropriate response variables to assess the likely success or failure of a proposed action. Nevertheless, the DEIS does a reasonable job of acknowledging these shortcomings (many of which will require years of research to rectify) and providing alternatives with a wide range of precaution. The authors of the DEIS are to be congratulated on production of a comprehensive document in a very short time frame that provides paths for habitat definition and protection, while highlighting the paucity of information available on fish habitat off the west coast of the United States.

This review Panel's preferred alternatives for each DEIS objective reflect a general consensus of precaution, based on our understanding of the alternatives presented, data gaps (particularly on the distribution and intensity of non-trawl fisheries) and the our collective experience in marine ecology and fishery impacts. Because data on gear impacts, habitat sensitivity and recovery are not available for the West Coast, the data layers used to generate EFH and mitigation alternatives are not functionally connected. This is a major drawback, although the GIS-based model is an excellent tool for visualizing and evaluating the spatial extent of each alternative. We urge the PFMC to utilize this tool carefully and to acknowledge the uncertainty that accumulates with each data layer by avoiding decisions that require a high level of precision.

The impact of fishing on habitat can be reduced through one or more of the following actions:

a) gear modification,
b) gear restrictions in space – permanent (including closure to all gear types),
c) gear restrictions in space – rotating, and
d) effort reduction.

We anticipate that the PFMC will settle on a “package” of EFH protection that utilizes most or all of these actions. However, as marine ecologists, we are not well-qualified to judge the likely effectiveness of gear modifications and effort reduction. We also cannot evaluate the potential socioeconomic impacts of the alternatives, but support additional research to choose alternatives that minimize hardship while assuring adequate habitat protection. Progressive alternatives that include relief for fishermen, such as the Central California license buy-out, may be a viable solution for some areas. However, we have concerns about the potential redistribution of fishing effort if closures are enacted, and we urge the PFMC and its Habitat Committee to consider this possibility carefully for any management scenarios that involve closures.

We strongly recommend that the EIS be reviewed 5 years after implementation, to update the models with new information, ground-truthing, and assessment of the effects of the chosen alternatives. The research and monitoring necessary to improve the EIS will require a substantial commitment of funds from NMFS and state agencies. In order to estimate recovery times for damaged habitats, controlled experiments must be carried out over extensive time periods (decades in many cases). This research will be money well spent, however, if it is targeted at the major uncertainties of the model and effects of the mitigation actions. We anticipate that well-planned, cooperative research will decrease the amount of area designated as “essential” or “critical,” and permit a much more focused conservation effort that has less impact on fisheries and greater benefits to fish populations.

Preferred Alternatives – Summary

A. EFH designation

Alternative A.3, with some support for A.4.

B. HAPC designation

Alternative B.7 was strongly supported, along with designation for estuaries (B.2), kelp canopy (B.3), seagrass beds (B.4) and rocky shelf areas (B.6) that serve as juvenile rearing habitat.

Alternative B.5 is supported as a goal but some Panel members felt that Core Area designation is premature given the limited data available.

Alternative B.9 is supported with an emphasis on external review.

C. Alternatives to Minimize Impacts to EFH

Alternatives 3 or 12/13.

General goal: Reduce effort of most damaging gear on most sensitive habitat.

There is additional support for Alternatives 7 and 10.

D. Research recommendations

Alternatives D.2 and D.4 .

Preferred Alternatives – Justification and Discussion

EFH designation

All life stages and life processes require habitat, and these are not the same within a species. Identification of habitat necessary for growth, reproduction, and other life processes for all 80+ groundfish species and their life stages is an enormous undertaking, as evidenced by the large appendix listing these factors. It is not surprising that when presence/absence is used as a response variable to assess EFH, the entire EEZ becomes designated. No amount of probabilistic modeling is likely to change that conclusion, but placing EFH designation into a probability framework (Habitat Suitability Probability, or HSP) is a step in the right direction because it at least acknowledges uncertainty.

Able (1999, American Fisheries Society Symposium 22, *Fish Habitat: Essential Fish Habitat and Rehabilitation*) described a hierarchical scheme for EFH designation that could be integrated into PFMC's research and management goals:

- Tier 1: Presence/absence. This approach requires comprehensive sampling of all potential habitat with multiple gears, not just NMFS trawl survey data.
- Tier 2: Relative abundance. Better quality habitats should be able to sustain larger population sizes than lower quality habitats. This approach requires a repeated measures sampling scheme because population sizes fluctuate from year to year.
- Tier 3: Vital rates. Growth, frequency of reproduction, and other demographic rates should be greater in high quality habitat. This approach requires physiological sampling of multiple individuals from a variety of sites over time.
- Tier 4: Productivity. "Source" habitats contain healthy populations that consistently provide a net export of individuals through recruitment and spillover. The identification of "sources" is difficult and requires detailed sampling of many sites over long time periods.

The advantage of this hierarchical approach is that is can help us hone our designations substantially, from the entire EEZ to areas that truly are "essential" because they provide the food and shelter required to sustain healthy fish populations.

We are particularly concerned about the paucity of information on juvenile groundfish habitat because it is precisely those individuals that are most likely to be strongly tied to structure that may be damaged by fishing gear. Only the designation of estuaries, seagrass beds, kelp canopy areas and some "Areas of Interest" specifically address juvenile habitat. We believe that the PFMC should be most precautionary about potential impacts to juvenile habitat and be extremely wary of habitat status assessment that is based solely on the catch of adults.

Alternatives A.3 and A.4

Alternative A.1 (No action) keeps many options open, with less potential conflict when combined with HAPC designation and mitigation actions. It also identifies categories of habitat, although these should be expanded. However, designating the entire EEZ as EFH does not focus attention on any particular habitats, and shifts the entire direction of the exercise to designation of HAPC.

Alternative A.3 (100% HSP area) received the most support within the Panel, with additional consideration of alternatives that designate unknown deep water areas. However, this alternative is primarily based on HSP calculations from trawl survey records, which are insufficient measures of habitat use by all life stages. This option also makes everything "essential," hence nothing is essential, and makes actions targeted to conserve particular species difficult or impossible to implement using the EFH boundaries

We like the flexibility and added precaution of EFH based on management status (Alternative A.4), and 2 Panel members supported this option as preferred. Designation is weighted by management status of the exploited populations and protects “essential” habitats based on frequency-dependent distributions (Tier 2, above). Further, this alternative designates seamounts as EFH in a precautionary manner appropriate for the management regime and sensitivity of such habitats. However, this alternative is problematic because a) a population at low abundance may not occur regularly in areas that could be “essential”, and b) habitat needs of individuals do not change just because their management status changes.

The alternatives with lower HSP thresholds lack data to support the assumption that such designations truly contain essential habitats of managed species and that other areas do not have habitats that play an important role in mediating demographic processes.

Recommendations:

1) Retain the seven composite areas identified in the 1998 EFH designation, but consider other habitat designations based on structure, function and impacts. For example, splitting nearshore rocky shelf habitat (<100m depth) into a separate category is supported because of the importance of these shallow reef areas as juvenile fish habitat and increased impacts of recreational fishing gear.
2) Final designation of EFH should be based on maps that include the most recent information from multiple sampling sources. A research plan for ground-truthing those maps should be a top priority for the first 5 years. Refinements to the HSP model using a tiered assessment approach are encouraged.

HAPC designation

We strongly support the effort to designate Habitat Areas of Particular Concern, and the list of considerations is a good start. The use of habitat-specific knowledge regarding sensitivity to impacts and recovery times to designate specific sites as HAPCs allows implementation of precautionary approaches to mitigate the effects of fisheries activities in the context of ecosystem-based management. Unfortunately, the first consideration for HAPC designation, “the importance of the ecological function provided by the habitat”, is far too broad and vague, and “ecological function” has not really been measured for any of the habitats listed. Nevertheless, the areas listed in Alternatives B.2 – B.7 are based on ecological principles and observations of fishes and particular life stages in those habitats. Core areas for managed species as well as areas of interest, with area-specific knowledge of function or sensitivity, should be included in HAPC designation.

The Areas of Interest listed for Alternative B.7 include various canyons and banks that have unique combinations of structure and oceanographic characteristics that seem to correspond with high productivity, biodiversity, or both. Many of these areas also include biogenic structure, likely because of particular combinations of depth and current. The danger of a somewhat vague "Areas of Interest" HAPC designation is that decisions to include or not include an area will be highly subjective, at least until further study can identify features that make these areas unique or areas of high groundfish productivity. There may be more specific combinations of structure, depth, and currents that would be better to use for HAPC designation and identification of Areas of Interest.

Three Panel members strongly support designation of Core Areas (B.5). Use of core areas based on frequency-dependent distributions are supported by theoretical and empirical studies of demersal fishes. Core Habitat designation is a good goal, but may be premature without more "higher level" data (Tiers 2-3) than are currently available.

Specific HAPCs for areas known to serve important ecological functions are supported. Alternatives B.2 (Estuaries), B.3 (Kelp canopy), and B.4 (Sea grass) make sense, although the potential effects of non-fishing human activities on these habitats may exceed the effects of fishing activities, and there seems to be little power to limit these activities (such as development and filling of estuarine areas, or dredging and disposition of spoils). The kelp canopy designated for California (based on 1989) probably underestimates potential kelp coverage, although the map of kelp canopy in California looks reasonably complete at the scale shown. The area of kelp canopy habitat that does not coincide with area designated as essential under EFH alternative A.3 (Habitat Table 4-4) must be on sand bottom. If the inconsistency of the EFH alternative A.3 and the HAPC alternative B.3 is a problem, HAPC alternative B.6 would cover most of the important habitat included in alternative B.3.

Alternative B.6 (Rocky reefs) makes sense to the Panel, as the physical structure of the reef is essential for a number of species of fish, and can be subject to modification by some fishing activities. This alternative would include most kelp forests, so if alternative B.3 was not chosen, most of the same habitat would still be recognized as HAPC.

The Panel generally did not support the designation of oil platforms as HAPCs (Alternative B.8), despite the fact that they do serve as habitat.

All of these designations lack specific consideration of biogenic habitat other then kelp and sea grass, and all soft-bottom habitat. Much of biogenic habitat associated with hard substrates would be covered under Alternative B.6, and some in B.7, but none associated with soft bottom habitat would be included. Hard-substrate habitats are probably more sensitive to some effects of fishing, but focus on these areas may be at the expense of soft-bottom habitat.

The process for designating new HAPC areas (Alternative B.9) is supported, as it allows flexibility and response to new findings. Recommendations from the PFMC Habitat Committee should be reviewed by experts on benthic habitats, fish ecology and fish distribution. There should also be a mechanism for "delisting" HAPCs, as new information may actually reduce the perceived importance of specific areas.

Recommendations:

1) Combine Alternatives B.7, 2, 3, 4, and 6, with effort to identify quantifiable

characteristics for designation.

2) Strongly consider Alternative B.5, Core Area designation, if species-specific relative abundance data are available.
3) Support Alternative B.9, with emphasis on external review.

Alternatives to Minimize Impacts to EFH

General goal: reduce effort of most damaging gear on most sensitive habitat

We would encourage the use of more habitat-friendly gear, and the participation of the fishing community in the development of effective fisheries management systems. Therefore, to the extent that it is possible, we would like to see the use of the most destructive gear in the most sensitive habitats be restricted the most, and other gears restricted less (or encouraged). Given a wealth of experimental and observation data on the negative impacts of mobile, bottom-contacting gear in multiple habitats, we favor restrictions on dredging and trawling (especially on hard bottom). Restrictions on fixed gear are more problematic, because the effects of pots, nets and lines on habitat are poorly documented and probably less than mobile gear. Thus, precautionary restrictions on these gear types, in addition to trawl restrictions, may stifle a move toward more sustainable fishing practices. At present, we can only guess at habitat sensitivity to different gears, and it may be a long time before this lack of knowledge changes. Certainly, gear design and fishing tactics can minimize damage, so that this problem will be a constantly moving target.

Alternatives 3 and 12/13

The Panel favors impact reduction through protection of sensitive habitat. We favor options within Alternatives C.3 and C.12/13, although both of these approaches have flaws. These options provide a choice between a subjective set of "Ecologically Important Areas" identified by Oceana (C.12 and C.13) or, or an alternative set of areas chosen more objectively by the National Ocean Service (C.3) but using crude data inputs (trawl survey data) and admittedly questionable analytical techniques. Only option C.13 addresses invertebrate megafauna explicitly. Neither option seems to identify what will happen to the HAPC areas identified in Alternatives B.1 to B.8. Redistribution of fishing activities must be carefully considered, as "unsensitive habitat" may become heavily impacted, and more explicit justification for restricting the designation based on trawl effort is needed under Option C.3. However, either alternative offers a place to start, providing the areas involved can be added to or deleted as further information on HSP or sensitivity becomes available. Present information is crude at best, making it imperative that some flexibility be built into the selected alternative.

The amount of area closed to fishing under alternatives C.3.1 and C.3.3 is extensive, and would certainly play a role in limiting the effects of fishing on habitat. C.3.2 and C.3.4 apply more limited restrictions, focusing on the most highly-rated sensitive habitats, and might be more palatable from a socioeconomic perspective. The PFMC should consider the addition of Alternative C.7 (close Areas of Interest) if this alternative is adopted. Alternatives under C.3 may be particularly useful on an experimental basis as part of an adaptive management plan that includes intensive monitoring.

Alternatives C.12-14 are specific to habitat and the footprint of fishing and are most tightly linked to the distribution of managed species based on habitat selection theory, where areas of highest density, at particular life history stages, are generally an organism's preferred habitat. The description of these Alternatives is comprehensive and rather complex, requiring a) identification of ecologically important areas and b) an assumption that bottom trawling is the major impact on those areas. The latter is likely, but impact from other fisheries should not be ignored. The former requires a complex assessment and a number of assumptions, given the lack of data on relative abundance for many species and life stages. The Panel liked these alternatives from a biological standpoint, but data are lacking to provide a strong *empirical* justification for the large areas affected. From a precautionary standpoint, restriction of gear that is known to damage structure forming invertebrates in areas where those invertebrates are likely to occur is reasonable, but should be verified. This Alternative is strongly driven by protection of deep sea corals, which are poorly mapped on the west coast slope and may or may not provide critical habitat for groundfish.

Specific regulations that result from the adoption of this Alternative will require much discussion, compromise, and assessment monitoring. Efforts to "appease" fisheries by allowances for certain important fishing areas may be a successful compromising measure. Redistribution of effort must be modeled, at least qualitatively, and may be anticipated through analysis of logbook data following trawl footrope restrictions that occurred in 2000.

Alternatives C.13 and C.14 are more restrictive variations on C.12, and were generally viewed by Panel members as overly precautious. The exception to this is a recommendation for restriction of fixed gear in deepwater areas that are likely to house structure-forming invertebrates. There is a great advantage to having some areas closed to all fishing activities, but the large areas covered by these alternatives are likely excessive. Selective closures of Areas of Interest may be more palatable and avoid massive effort redistribution. One Panel member argued that the provision on footropes (none greater than eight inches in diameter) allowed in the open area should be removed from C.13 if this Alternative is adopted.

Alternative C.1 was deemed unacceptable because current regulations and closures are not based on habitat, which is the mandate of this EIS.

Alternative C.2, depth-based gear restrictions, could serve as a default option in light of poor information on impacts and recovery, but may be overly cautious. Restrictions on large-footrope trawl gear would seem to have positive effects, constraining trawling largely to non-rocky areas without having to specifically identify the rocky areas. Information on habitat recovery in areas currently closed or no longer trawled would be helpful to determine recovery times and relative impact functions. Without field data, it was difficult for the Panel to evaluate which depth zones would be best for this under the alternatives in C.2. However, we do not favor the restrictions on fixed gear in shallow water. Two important and well-managed fisheries, the Dungeness crab and California spiny lobster fisheries, would be particularly affected by the restrictions posed here, and it seems excessively punitive to destroy these fisheries after the members have helped to create reasonable systems of management.

Alternative C.4, prohibit geographic expansion of fishing, has some serious methodological flaws. Why would anyone assume that areas not fished between 2000 and 2002 are “potentially pristine”, given the long history of fishing on our coast? Nevertheless, the Panel agrees that preserving the current fingerprint of fishing seems like a good idea with few economic impacts right now. Alternative C.4.2 (all gear) would be preferable, as a way to encourage gear with smaller impacts (as covered under C.11). Fixed gear has a limited but measurable impact footprint, especially in deep waters during deployment and recovery. On hard substrates, gillnets and other fixed gear have been shown to impact emergent fauna like corals as well as fragile geologic structures. However, we note that these alternatives are not consistent with most of the EFH designation alternatives.

Alternative C.5. prohibit a krill fishery, is an interesting idea from an ecosystem-based management standpoint. It may also “set the stage” for setting limits to the expansion of fisheries for other low-trophic level species, such as northern anchovy, shortbelly rockfish, sardine and squid. However, this alternative seems outside of the scope of EFH, and it does not make sense from an ecological standpoint to equate prey availability with habitat.

Alternative C.6, close hotspots. This alternative focuses on biodiversity and needs further development. Hotspots do not directly address the sensitivity of habitats. For fisheries enhancement or biodiversity protection, hotspots can be stratified by depth, latitude and habitat type. They should also be based on data collected over a number of years. Identification and protection of hotspots of productivity or juvenile recruitment may meet sustainable fisheries goals more than biodiversity criteria.

Alternative C.7, close Areas of Interest. This may be a reasonable, precautionary alternative until data show “minimal impact” of each gear type on the Area of Interest identified in the HAPC Alternative B.7. However, as with Alternative C.3, redistribution of effort will be important to consider, and closing these areas is probably insufficient for EFH protection. This alternative could be added to Alternative C 3, and overlaps with areas identified in our current preferred alternative, C12.

Alternative C.8. Ocean zoning is a hotly debated option that we feel is politically unfeasible at this time. While the idea of zoning fishing activities and doing further research on ways to fish while reducing impact on the habitat may be useful, these concepts are better addressed in other alternatives. Also, zoning quickly turns the scientifically-based issue of habitat protection into a pure allocation issue.

Alternative C.9 covers a series of gear restrictions. Alternatives that involve the development of less harmful gear types, rather than fishing restrictions, are an effective management approach when there are data available to show that the gear modifications actually work (i.e., maintain catch and substantially reduce impact). This approach leads to cooperative research, which further enhances the relationship between fishermen, researchers and managers. Also, this alternative codifies many current practices. Gear restrictions are likely to be useful in some areas but are not precautionary by themselves. Some on the Panel felt that we should avoid support for gear-specific options, given our mandate and expertise. The measures described in this option are aimed only at a subset of the bottom-tending gears and are thus more allocative than biologically based, and may be more difficult to enforce than some other Alternatives.

Alternative C.10, no-trawl zones plus license buy-out in Central California, is the most progressive alternative and is likely to be useful in some areas, but may not be feasible where multiple gear impacts are common. It would also be important to know what the trawlers will do in response to the buy-out. C10 requires actions of private organizations after passage and is outside the purview of the Council and NMFS to require implementation of all of the provisions. In general, the Panel felt it was beyond our abilities to evaluate the socioeconomic trade-offs of acceptance or rejection of this alternative.

Alternative C.11 relaxes gear endorsement requirements. Adding flexibility to fishing strategies can ease the negative effects that area closures or gear restrictions may have on fishermen, promotes the use of more habitat-friendly gear, and may also help spread effort of individual fishermen across space, time and species. However, the biological impacts of this Alternative are unclear.

Recommendations:

1) Alternatives that consider the spatial distribution of habitat, impacts on habitat (fishing effort) and its sensitivity to those impacts should be adopted. Of the alternatives provided, C.3.4 and C.13 best meet those goals, and could be modified to reduce socioeconomic impacts.
2) Impacts of all gear types should be included in the assessment, and ground-truthing is needed.
3) Areas of Interest identified in the HAPC designation should also be protected (Alternative C.7).
4) Solutions that reduce economic hardship and encourage partnerships between conservation groups and industry should be supported (Alternative C.10).
5) Gear modifications to reduce impacts on habitat should be encouraged but require field testing (Alternative C.9).
6) Adoption of any Alternatives that include area closures should include an assessment of likely effort redistribution.

Research Recommendations

The Panel developed and ranked a series of general research needs that included our own judgments as well as specific alternatives from the DEIS:

1) Ground-truthing habitat suitability probability
2) Habitat recovery monitoring
3) Research reserves
4) Expanded logbook to include data from other fisheries
5) Gear impact experiments
6) Vessel Monitoring System effort distribution analysis
7) Alternative sampling methodologies

Recommendations 5, 6, and 7 received equivalent mean ranks from Panel members. Note that all of these research needs are important, but restricted funding will likely require some prioritization. We strongly recommend intensive pre- and post-closure monitoring of any closed areas that may result from adoption of the alternatives outlined in this DEIS.

Research reserves that are closed to all fishing activities are highly controversial, but provide the only tool to separate fisheries impacts from changes in habitats or fish abundance that are due to environmental change. Research reserves could also serve as locations for habitat sensitivity and recovery assessment. Two Panel members ranked establishment of reserves as their top research priority. We support cooperative efforts by coastal communities and scientists to design these reserves, as recommended by Oregon’s Ocean Policy Advisory Council.

We also make the following general recommendations for improvements to the HSP designations:

1) Trawl survey data needs to be supplemented with ROV or submersible observations.

2) The correct spatial scale (based on home range) for habitat analysis needs to be determined for each life stage of each species.

3) The analysis of habitat suitability currently should incorporate additional parameters and interactions of those parameters with the current ones (depth, latitude, and “substrate”).

4) Relative abundance (Tier 2 response) should be used instead of presence/absence whenever possible.

5) More habitat categories should be considered. Ten is overly crude, and misses important detail on features such as rugosity, biogenic cover, etc.

Comments on the DEIS process and document

The idea of "Essential Fish Habitat," as outlined in the SFA in 1996, was flawed at the outset, in that no guidance was provided to distinguish mere "habitat" from "essential habitat." The idea of habitat bottlenecks (habitats of limited size through which the population passes at some time in its life cycle, which are also vulnerable to the effects of fishing gear and other factors) is ecologically sound. However, the language of the law makes it difficult to account for the effects of density-dependent habitat selection (and therefore to distinguish the core areas of habitat that are most suitable for a population), the rarity of a habitat that might be used by a particular life stage, and the vulnerability of that habitat to human and natural disturbances. Thus, NMFS was probably correct in its first assessment, designating everything within the EEZ as "Essential Fish Habitat," even though that designation in the end meant nothing because it failed to allow focus on any particular portion of the habitat. As a result, the HAPC designation became the means of identifying "really, really Essential Fish Habitat."

Use of the HSP models for identifying habitat is a reasonable approach, but subject to limitations of the data used in the analysis. Because of the inherent problems in identifying "essential fish habitat" as it has been defined, perhaps the highest purpose of this section (EFH designation) should be to recognize the diversity of species and the habitats utilized, and allow for the broadest context for the identification of really, really essential (and vulnerable) habitat in the designation of HAPC and of measures to minimize adverse impacts to EFH.

It is critical, for the logic of this EIS, that any HAPC and actions for remediation are areas that have been designated as EFH. All of the alternatives to reduce impacts must interact with the designation of EFH that is ultimately chosen, and with the alternatives for HAPC. Ideally, mitigation efforts should be nested within EFH and HAPC designations to drive the alternatives to limit impacts, with explicit language linking mitigation issues to the attributes of concern. We recommend that the PFMC Habitat Committee develop a comprehensive framework for action that more logically follows the hierarchy necessary for non-conflicting action: a fairly broad EFH designation based on ground-truthed information on relative abundance of all life stages (which may not need to be species specific), HAPC designation for areas with unique functions, such as nursery grounds, areas with high biogenic habitat, high productivity, and/or high biodiversity, and impact reduction actions that target critical areas within these designations. The alternatives presented in the DEIS are disjoint, requiring an overwhelming appendix of tables and maps to show conflicts that will arise. This approach is inefficient and makes it extremely difficult to do more than simply choose a preferred action (or combination of actions) for each of the 3 sets of alternatives, based on ecological principles, conservation concerns, socioeconomic concerns, etc.

The apparent conflicts between EFH and HAPC designation shown in Appendix 4 are of particular concern and difficult to understand. For example, Habitat Table 4-4 shows that only EFH alternative A.6 would not include the areas identified in HAPC alternative B.6, but Figure 4-3 shows some areas (which seem mostly like deep-water areas) included in HAPC alternative B.6 are excluded in several of the EFH alternatives. Likewise, some of the areas included in HAPC alternative B.7 (Areas of Interest) are not included in some of the EFH alternatives because of a disconnect between methods to identify HSP (catch records) and in-water observations of these areas that identify them as Areas of Interest.

The “Purpose and Need” section does a good job describing the management framework for west coast groundfish but does a poor job linking the management framework to EFH designations, thus making it impossible to evaluate EFH alternatives against a set of explicit goals (e.g., minimally capture the top 50% of the population distribution of each managed species, capture 80% of spawning habitat, etc.). While there are targets set within alternatives (e.g., 70% HSP), these are thresholds for specific alternatives and not an overall goal for which various alternatives were proposed and can be compared. The four goals stated in section 1.4 are strawmen and the existing preferred alternatives discussed in chapter 2 clearly “consider” these in aggregate. Without explicit threshold values for particular metrics (e.g., what are thresholds for “practicable” alternatives?), it is impossible to develop a review criteria that does not explicitly include personal viewpoints related to balancing industry needs with conservation goals. This is not an unusual situation (in fact, a similar process and framework were recently evaluated for groundfish EFH in the New England Region) and is why reviews of the EFH and HAPC alternatives from other Councils preclude rigorous scientific review. While the underlying theory and methods used to develop alternatives is certainly open to scientific debate, the value-laden alternatives are really not. Thus, we believe that the approach used by the PFMC is generally robust and defensible, but science-driven vs. value-driven decisions should be distinguished whenever possible.

The Purpose and Need section is supposed to “set the stage” for what the EIS is and why it is important. Overall, the description of the EIS process is reasonable, but there are a few elements missing, such as the definition of EFH and habitat-related mandates of the Sustainable Fisheries Act. Some Panel members also found it confusing to have the EIS presented as a document describing “the effects of conservation actions [on habitat]” when the mandate is to determine the effects of fishing on habitat. This may be more than a simple semantics issue, as the “burden of proof” may rely on proper definition of the problem. Because the “action” in this case is implementation of conservation measures, rather than introduction of a new stressor, this apparent switch of focus may be intentional and necessary – but it should be better explained.

This section of the DEIS also includes a description of the current management framework for west coast groundfish, but does not really provide information about how habitat management would fit into that framework. Most importantly, state vs. federal regulations and their interactions should be addressed. Also, there is no description of the current regulations that are designed to reduce impacts on overfished stocks (these closures are described in the Alternatives chapter).

The current methods for determining HSP and habitat sensitivity are not up to the task at hand, primarily due to a lack of data. The Risk Assessment group developed a model that relies on a complex matrix of these interacting factors, which in turn is based on published studies that are mostly from other areas. The functional relationship between habitat sensitivity and impact is based on a sound premise, but one without any empirical support. There are no data on effort and local impacts of non-trawl fisheries. There is also a problem of spatial scale that was noted by the SSC - fishing effort blocks (large scale) vs. habitat patch (EFH polygons – small scale). The SSC’s conclusion was that fishing impacts model is inadequate and should not be used in its present form for risk assessment. Some Panel members were less certain of this conclusion, as long as the results of the model are used in a qualitative, rather than quantitative way. The level of apparent precision given by the models can be misleading, but only if you let it be. The DEIS authors acknowledge the uncertainty in the model and argue that the array of alternatives provides a range from extremely precautionary to risk-prone approaches. As a result of current uncertainty in key parameters, the PMCC Independent Scientific Review Panel believes that an adaptive approach is required whereby the EFH process allows for both closing and re-opening areas to fishing activity.

Pacific Marine Conservation Council
Independent Scientific Review Panel

DR. SELINA HEPPELL is an Assistant Professor in the Department of Fisheries and Wildlife at Oregon State University (OSU). She is also Adjunct Faculty in the OSU Marine Resource Management Program at the College of Oceanic and Atmospheric Science, as well as the Nicholas School of the Environment at Duke University. Selina is a member of the IUCN Marine Turtle Specialist Group (sea turtle conservation), the Willamette-Lower Columbia Technical Recovery Team (listed salmonid recovery planning), and the Environmental Quality Committee of the American Society of Ichthyologists and Herpetologists (fish conservation). Her expertise is population ecology, marine fisheries ecology, conservation biology, and life history evolution, and her research generally focuses on how populations respond to perturbations. Some current research projects include: comparative life-history analysis of Oregon groundfish, changes in habitat structure and fish communities in de facto marine reserves off the Oregon coast, grouper population dynamics and marine protected area design in Florida, maternal effects on offspring quality and changes in recruitment variability with age of maternal stock, and sea turtle population dynamics in response to management and longline bycatch.

DR. RALPH J. LARSON was born in 1946, and from the age of 4 grew up in southern California. He attended Occidental College, where he met Dr. John S. Stephens, Jr., and was introduced to marine ecology and the biology of fishes. He graduated with departmental honors in 1968. He then attended graduate school at the University of California, Santa Barbara, under the tutelage of Dr. Alfred W. Ebeling, earning his M.A. degree in Biology in 1972, and his Ph.D. degree in 1977. At UCSB, he studied the ecology of kelp-forest fishes, and interspecific competition between two species of kelp-forest rockfishes. He then taught for a year in the Department of Zoology, U. C. Berkeley, was a research Biologist for a year at the New York Ocean Sciences Laboratory, studying larval fish ecology, and then spent a year assessing the effects of the San Onofre nuclear power plant on fishes. He was appointed an Assistant Professor of Biology at San Francisco State University in 1980, and has spent the remainder of his career at that institution. He has taught courses in ecology, biology of fishes, fisheries biology, biological oceanography, biogeography, general zoology, and general biology, and has supervised the Master's thesis research of nearly 40 students. He also spent 2 ½ years working on leave with the National Marine Fisheries Service, studying the ecology of pelagic juvenile rockfishes. He and his students have studied life history of rockfishes, the ecology of juvenile rockfishes and other species, the genetics of the larval and juvenile stage of fishes, and the effects of climate change on fish communities. He is a Fellow of the California Academy of Sciences, was Chair of the Board of Governors for the Moss Landing Marine Laboratories, was a member of the Master Plan Team for the Marine Life Protection Act in California, and is the President-elect for the Western Society of Naturalists.

DR. LES WATLING received his Ph.D. in Marine Science from the University of Delaware in 1974. He is currently Professor of Oceanography at the University of Maine. He served on the U.S. National Research Council's Committee on Marine Biodiversity and he is a Past President of the Crustacean Society. He also serves on the International Council for the Exploration of the

Sea's Working Group on Benthic Ecology. His research interests have spanned two disparate topics, crustacean taxonomy and phylogeny on the one hand and benthic oceanography on the other. Watling's benthic interests are focused on impacts of humans on benthic environments, with an emphasis on organic enrichment and habitat disruption. Topics investigated in the last few years include the impact of salmon net-pen aquaculture on benthic environments, and the effects of fishing activities on benthic habitats and its consequences for benthic community structure. Most recently he has been the co-sponsor of two symposia dealing with impacts of mobile fishing gear on benthic communities and his research projects have focused on the potential loss of marine biodiversity associated with fishing activities. Much of the current work has been conducted using research submersibles as well as samples taken from surface ships.

DR. DONALD R. GUNDERSON is a Professor in the School of Aquatic and Fishery Science, University of Washington. His research has focused on the biology, population dynamics, and management of groundfish, with nearly 40 years of experience at the University of Washington, the Washington Dept. of Fish and Wildlife, and the National Marine Fisheries Service. Most of his current research is on spatial processes in population dynamics, and habitat utilization by groundfish.

DR. PETER J. AUSTER is the Science Director for the National Undersea Research Center and an Assistant Professor-in-Residence in the Department of Marine Sciences at the University of Connecticut. His research focuses on the ecology and conservation of fishes. He has participated as scientist or chief-scientist on 40 major research cruises and countless day trips in the northwest Atlantic, Gulf of Alaska, Bering Sea, Caribbean Sea, South China Sea, and equatorial Pacific. He also participated in research expeditions to Lake Baikal in Russia and Lakes Victoria and Malawi in the Rift Lake Valley of East Africa.

For the past 20 years, he has conducted studies to define how seafloor landscapes effect the distribution and abundance of fishes, understand the linkages between habitat level processes and population-community dynamics, and develop methods for monitoring habitat integrity. From an applied science perspective, he has focused his attention on the impacts of fishing gear on the environment and developing the scientific basis for using marine protected areas as a conservation tool in outer continental shelf regions.

His basic approach to fieldwork has been to use the same types of techniques underwater that wildlife biologists use on land. That is, making direct underwater observations to study how individual animals react to variations in nature. He has conducted over 1,400 scuba dives, 59 submersible dives (using the Johnson Sea-Link I and II, Delta, Mermaid IV, NR-l, Alvin, and Deepworker 2000), and 360 remotely operated vehicle dives (using Minirover, SeaRover, MaxRover, Phantom, Recon, and Ventana ROVs).

Peter serves on a number of panels and committees that are focused on marine resource management and conservation. He is involved in several outreach initiatives that are targeted at informing the public about marine conservation issues. Most recently, he was awarded a Pew Marine Conservation Fellowship in 1999, the NOAA Environmental Hero Award in 2000, and was named an Ocean Hero by the American Oceans Campaign in 2001.

RE: Comments on Pacific Coast Essential Fish Habitat Draft EIS

Dear Mr. Lohn,

Our Association represents a small boat fleet of trap fishermen in the California Bight that fish for Spiny Lobster, Crab, Spot Prawn and Nearshore Rock fish with traps. The area of the Santa Barbara Channel and Channel Islands are the focus of my comments.

California Bight Shellfish trap fisheries.
There are several factors that characterize our fisheries in general as being conducted with no detectable impact to the seabed.

1. We fish the perimeters of essential fishery habitat due too the crustaceans we targets foraging behavior we are fishing in sand gravel or mud bottom.
2. Our fisheries have limited entry programs and are conducted seasonally or in very discreet areas they are temporal or spatially limited
3. The traps themselves have evolved to be highly selective by design and placement. The majority of the trapping takes place within state waters with minimum bycatch. A high percentage of that incidental bycatch is released alive. It is composed of nearshore rockfish.
4. The exception is Spot prawn trapping which does take place in federal waters and has had an observer program for the last three years.
5. Our fish-trapping fishery has been restricted by the state based on a data low stock assessment to the point that it is not an economically viable fishery any more.
6. In the Northern Channel Islands where we have the highest diversity of groundfish. This is due to the transition of California and Oregonian biological provinces and the extensive reef systems. In this area we have an extensive MPA system designed as a precautionary buffer that covers well over 30% of the high quality reef inside 25 fathoms. This is really a small-scale EFH no-take MPA system complemented by the existing federal stock rebuilding programs.
7. In reality the extreme weather combined with the extreme and rapid harvest controls have made a large portion of the traditional groundfish fisheries economically unviable for the dominant sport charter fleet and small scale fixed gear rockfish fleet.

8. There has been a natural oceanographic regime shift that has triggered a trend in overall kelp canopy regrowth and successful rockfish recruitment as this is documented by our MPA monitoring program. These favorable conditions for recruitment are now supported by very strict harvest control in both catch limits and spatial management that restricts gear and harvest by area.

General Comments on Draft EIS.

We believe that the document needs to provide a better framework for regional assessment of fishery habitats in connection to the fishing ports as economic units that are characterized by diversity of fishing enterprise. The most significant omission is that there does not seem to be a human dimension to what is essential fishery habitat.
That would be the area that is essential to maintaining harvest and the working fishing port as a Cultural Resource for the Coastal Communities. There should be a defined alternative for insuring the fishing heritage of each port by adaptively managing the fisheries with experimental zonal harvest policies conducted with no-take representative habitat heritage reserves as monitoring control sites.

The key elements of this would be

1. Creating a policy for expanding the federal observer programs into fishing for data programs that develop a scientific protocol for incorporating research into traditional fishing practice.
2. Developing regional GIS support by expanding the NMFS port liaison program to directed fishery and habitat mapping
3. Regional development of joint fishery and scientists survey design forum supported by NOAA fisheries labs and the above geo-referenced mapping project.
4. Social and economic profiles of the ports and the spatial documentation of harvest control as baseline for EFH assessment.
5. A variety of monitoring programs by scale and region to calibrate monitoring of stock rebuilding objectives by area. Focusing the development of a representative sample of habitat and fishing as a bio-economic model for the various bioregions habitat types.
6. Achievable monitoring that has realistic goals so we will not be subject to more lawsuits.
7. Modeling of EFH experimental harvest policies with real stock data to quantify scenarios that would mitigate mandatory stock rebuilding timelines with an exponential level of precaution Harvest and habitat control.

Comments on California Bight Spatial Management.

As a commercial fisherman fishing in the California Bight we have witnessed the ad-hoc nature of spatial closures initiated in the California Bight. We recommend building adaptive management of the California Bight as a management unit for planning habitat quality based MPA systems. Restricting harvest by habitat is essentially creating a MPA.

We recommend an alternative reconfiguring the CINMS reserves taking into account the cumulative harvest control and fleet reduction in our region. That creates a monitoring reserve as a federal addition to CINMS through the council process adding slope fisheries.

This would be followed by adjusting the Existing Cow Cod Closure to open area for slope fisheries and creating a more scientifically based MPA network spatially designed by habitats that are high quality diversity areas.

This process would form the analytic basis for coordinating the federal and state MPA design to provide as a framework for adaptive harvest policy based in regulatory flexibility spatially utilizing the California Bight as an experimental regional management unit on a scale for habitat based community based spatial management systems.

We still do not have a definitive spatial baseline of cumulative spatial harvest control to address a monitoring plan design. The DEIS alternatives for monitoring cannot be adequately analyzed with out the definition of a baseline in habitat protection.

We provide attachments design examples in GIS image files.

1. Joint Scientist Fishery Straw-man designs for CINMS reconfiguration
2. Industry supported reconfigurations with state zoning changes for specific reserves from no-take to MPA status.
3. Ground fish Habitat maps and value distribution surveys from CINMS process

Habitats of particular concern.

The DEIS supports an alternative of Surf Grass habitat as essential fishery habitat. This habitat is protected by the California State Water Quality Control board under the Coastal management act. The primary threat to this habitat is from sedimentation of nearshore low relief reefs associated with dredging and the developing reliance of coastal property owners on opportunistic beech replenishment programs. We support the need for comprehensive mapping of surf grass habitats in regions where beech replenishment programs are being initiated by coastal city governments. It is critical to be able to assess cumulative impacts from coastal beech replenishment permits and a monitoring program to insure minimum impacts of these programs to surf grass.

Our organization is very willing to work with NMFS in the development of proposals to assist in funding habitat analysis and the development of infrastructure for a collaborative process with NMFS and the Pacific Fisheries Management Council. We recommend initiating a pilot regional strategic plan for habitat mapping in the California bight under a partnership with NMFS and Sea Grant Fisheries extension. This should be conducted in collaboration with support from local academic institutions such as the Bren School of Ecology and Management at UCSB Santa Barbara, the Channel Islands State College at Camarillo and the NOAA fisheries labs.

We request that the Northwest region designate a point person to serve as liaison to our organization and the NMFS Southwest region to insure we have the best level of communication possible on developing the EFH analysis for our area over the next year. We would like to maximize our ability to assist in this process

Sincerely

Chris Miller VP CLTFA

RE: ERROR CORRECTION, COMMENT LETTER ON EFH DEIS

To whom it may concern:

On May 4, 2005, our Association sent a letter to Dr. Robert Lohn regarding our comments on the Draft EIS on Essential Fish Habitat currently under review. Unfortunately, due to the large volume of information we had to review in a very short time frame, we inaccurately described one of the alternatives to minimize fishing impacts on EFH.

Alternative C.10, described in Chapter 2 of the DEIS, involves the Nature Conservancy's alternative to work with fishermen to come up with areas closed to trawling in the central coast. Figure 2-27 illustrates an area from above Monterey Bay to Pt. Conception and out to at least 200 meter depth. The figure was captioned "no-trawl zones" and the text was not specific in detail other than to say that the Conservancy would work with fishermen to come up with no-trawl zones.

We erroneously concluded that the entire area, including all of Monterey Bay, was proposed to be closed to trawling, due to our reading of the text and figure. We understand now that that is not the stated intent of the Nature Conservancy proposal represented by Alternative C.10.

Please strike the words "...and the Nature Conservancy Alternative both..." from line 2 of the paragraph on page 4 of our letter that is headed "Monterey Bay." Thank you for making this correction to our comments on the EFH DEIS.

Sincerely,

Mike McCorkle

Re: Comments on 2005 Draft EIS for Pacific Coast Groundfish Essential Fish Habitat

Dear Mr. Lohn:

Thank you for the opportunity to comment on the Draft Environmental Impact Statement (DEIS) for Essential Fish Habitat Designation for the Pacific Coast Groundfish Fishery Management Plan. This letter contains comments on the DEIS from the California Artificial Reef Enhancement Program (CARE). CARE is a nonprofit organization which, through public education and scientific research, promotes awareness and understanding of the potential value to be derived from artificial reef ecosystems in offshore California, and supports the preservation and enhancement of artificial reefs when recognized as beneficial to the marine environment.

As stated in our comments submitted on October 5, 2004, CARE supports the designation of the oil and gas platforms offshore of southern California as “Habitat Areas of Particular Concern” (HAPC) under the Magnuson-Stevens Fishery Conservation and Management Act. For the reasons stated in our previous comments and in these comments, we believe that Alternative B.8 in the DEIS, which would designate the oil and gas platforms off of the California coast as Habitat Areas of Particular Concern (HAPC), should be adopted as part of the comprehensive strategy to conserve and enhance essential fish habitat for fish species managed under the Pacific Coast Groundfish Fishery Management Plan. With these comments, we are providing additional scientific information that should be included and evaluated in the Final EIS for the purpose of selecting the final preferred alternative. Please contact me at (805) 320-8456 if you have any questions or would like any further information that CARE may be able to provide.

Sincerely,

George Steinbach

George Steinbach
Executive Director

May 11, 2005

Comments of CARE on the February 2005
Draft EIS for Pacific Coast Groundfish EFH

General Comments:

General Comment 1:

CARE supports Alternative B.8 in the Draft Environmental Impact Statement ("DEIS"), the designation of oil and gas platforms offshore of southern California as "Habitat Areas of Particular Concern" ("HAPC") under the Magnuson-Stevens Fishery Conservation and Management Act ("Magnuson-Stevens Act"). The information submitted with these comments and with our comments dated October 5, 2004 strongly supports this designation.

General Comment 2:

In these comments, we use the term "platform reefs" to refer to the valuable groundfish habitat that oil and gas platforms provide. This term is meant to emphasize that scientific research demonstrates that the underwater portions of oil and gas platforms serve as de facto reef habitat. In addition, the term emphasizes that only the underwater portion of the platform is relevant to the discussion of groundfish Essential Fish Habitat ("EFH") and HAPC. We use "platform reefs" to emphasize the need for decision-makers to consider the habitat value of the underwater portion of the platform structure, and that both future groundfish fishery management and platform decommissioning decisions should consider their potential impact on the habitat that the platform reefs provide.

General Comment 3:

As the DEIS notes (p. 4-12), designation of HAPC "may result in indirect effects greater than those associated with EFH because resource managers and regulators are likely to place a high priority on protecting areas that have been designated as HAPCs." With respect to Alternative B.8, the DEIS (p. 4-13) acknowledges that: "Designation of the areas surrounding oil platforms would enhance NMFS' opportunity to fully consider their potential contribution to rebuilding overfished species before they are removed" on decommissioning. For these reasons, a careful, thorough and balanced analysis of potential positive and negative consequences associated with this alternative is essential to enable decision-makers to make informed decisions among the alternatives. However, the DEIS does not contain such an analysis. The Final EIS should acknowledge and evaluate the environmental consequences of the decision whether or not to adopt Alternative B.8 based on the information discussed in these comments.

General Comment 4:

The discussion of environmental consequences for the proposed preferred alternative and other alternatives addresses the protection of habitat for groundfish species and includes conservative assumptions that habitat used by groundfish has positive value.[1] By contrast, the analysis of Alternative B.8 on p. 4-13 states only that: "One view holds that scientific research indicating an abundance of fish species located near oil rig platforms is a benefit to the ecosystem." No citations are given and the unidentified "scientific research" is not described at all beyond that single summary sentence. The remainder of the discussion consists of arguments against the designation of platform reefs as HAPC, based on one outdated citation and unsupported speculation cited as "personal communications" (as discussed in specific comments below). We are very disappointed with the lack of attention in the "Environmental Consequences" analysis to the scientific evidence supporting the important ecological role of platform reefs and the need for their protection. This one-sided presentation does not provide decision-makers or the public with the information necessary to make an informed comparison among alternatives. The Final EIS must be revised to take into account the information presented in our prior comments and in these comments in order to present an unbiased basis for decision-making.

General Comment 5:

Some information on groundfish populations at platform reefs is described under the heading of "Alternatives" (DEIS, p. 2-10) and "Affected Environment" (DEIS, pp. 3-8 – 3-10). However, this information is disregarded — and is not even cross-referenced — in the "Environmental Consequences" analysis (DEIS, p. 4-13). With all respect to those who read this large document and attempt to digest and utilize the massive amount of information it contains, inclusion of this material in the "Alternatives" and "Affected Environment" sections is not an adequate substitute for full and fair consideration of this information in the evaluation of environmental consequences as required by the National Environmental Policy Act ("NEPA").

General Comment 6:

EFH decisions must be based on "the best available scientific information" (50 CFR § 600.815(a)(1)(ii)), and this information must be interpreted "in a risk-averse fashion" (*id.* at § 600.815(a)(1)(iv)). On that point, it is critical to note that ***the designation of platform reefs as HAPC will not have any adverse environmental consequences***. Rather, as the DEIS itself acknowledges, this designation would "enhance NMFS' opportunity to fully consider their potential contribution to rebuilding overfished species before they are removed." (DEIS, p. 4-13) Whatever scientific uncertainties may yet remain can be considered when NMFS consults regarding decommissioning plans for particular platforms. CARE believes that the increasing accumulation of evidence clearly supports the benefits of platform reefs. Nevertheless, should substantive scientific evidence be presented to document the speculative suggestions raised in the DEIS (*id.*), that evidence can be taken into account in the EFH consultation process. The HAPC designation itself would not prevent NMFS from conducting a thorough evaluation of each decommissioning proposal in order to minimize any adverse consequences. On the other hand, once the structures are removed, NMFS will have no opportunity for further evaluation because the platform reef habitat and thriving ecological communities will be destroyed. Moreover, since the removal of oil and gas platforms is typically

[1] For example, see DEIS pp 4-3 ("Each alternative is analyzed for the extent to which it protects habitat for individual species/life stages of groundfish") and 4-4 ("in the absence of definitive research, the analysis concludes that it is beneficial to protect some portion of each habitat type. . .") .

carried out by using explosives to sever the jacket, removing the platform reefs will kill the marine animals and fishes in the vicinity when the explosives are detonated. (Gitschlag et al., 2000.) As a result, large numbers of juvenile and adult individuals from slow-growing, slow-reproducing and long-lived species will be killed. This is a serious adverse consequence for the program of rebuilding these overfished stocks, especially since some of the highest observed populations of some rockfish species are associated with platform reefs. (Love 2003.) Yet the DEIS entirely ignores this issue. The cursory analysis presented of environmental consequences on p. 4-13 is wholly inadequate in failing to take into account the "one-way" nature of those consequences: If HAPC designation indirectly leads to any adverse consequences from the presence of the platform reefs, those consequences can be addressed in future decisions. If lack of HAPC designation indirectly leads to adverse consequences from elimination of the platform reefs, they and their existing groundfish populations cannot be restored.

General Comment 7:

In addition, the information submitted with our prior comments and these comments supports the decision not to select Alternative A.6, the most geographically restricted EFH designation, as the final preferred alternative. Were Alternative A.6 to be adopted, some platform reefs would be excluded from the area designated as EFH. In that event, the substantial existing groundfish populations at those platform reefs would be deprived of the benefits of the overall EFH conservation strategy, as well as the protection of the EFH consultation process in future decisions regarding the decommissioning of the platforms. In addition, such exclusion would necessarily preclude designating excluded platform reefs as HAPC. The Final EIS should acknowledge and evaluate these environmental consequences of Alternative A.6. Should the Council wish to narrow the designation of EFH as proposed in this alternative, it should be modified to retain EFH status for platform reefs that are outside the current range of Alternative A.6.

Specific Comments

1. DEIS, pp. i, 1-3

The DEIS states that: "*The purpose of the proposed action* is: first, to provide the Council and NMFS with the information they need to better account for the function of Pacific Coast groundfish EFH when making fishery management decisions; …" In order to fulfill this purpose, the DEIS must provide the Pacific Fisheries Management Council ("Council") and National Marine Fisheries Service ("NMFS") with all of the available scientific information regarding the habitat value of platform reefs. The duty to consider all available scientific information is enshrined in NEPA and in the Magnuson-Stevens Act. An EIS must "provide full and fair discussion of significant environmental impacts and shall inform decisionmakers and the public of the reasonable alternatives which would avoid or minimize adverse impacts or enhance the quality of the human environment." 40 CFR § 1502.1. Fishery Management Plans ("FMPs") must demonstrate that "the best available scientific information was used in the description and identification of EFH." 50 CFR § 600.815(a)(1)(ii). In addition, Fishery Management Councils are directed to "interpret this information in a risk-averse fashion to ensure adequate areas are identified as EFH for managed species." *Id.* at § 600.815(a)(1)(iv). The one-sided discussion on DEIS p. 4-13 fails to achieve this purpose.

2. DEIS, pp. i to ii, 1-3

The DEIS states that "the Council and NMFS have not had the tools to consider habitat and ecosystem function, and their relation to other biological and socioeconomic conditions affecting the groundfish fishery, in management decisionmaking. . . . *An overriding problem has been the challenge of managing fisheries with limited scientific data.* This increases the risk that decisions exacerbate the kinds of fishery- and stock-related problems just identified" (emphasis added). Thus, the DEIS recognizes the risk inherent in managing the Pacific groundfish fishery with limited data, and relies on conservative assumptions throughout the document to address this uncertainty. This approach is consistent with the requirement that identification of EFH must be based on "the best available scientific information" (50 CFR § 600.815(a)(1)(ii)), and that this information must be interpreted "in a risk-averse fashion" (*id.* at § 600.815(a)(1)(iv)). The document fails to take this approach in only one case – the analysis of alternative B.8. In that case alone, the "lack of conclusive research" is cited as an objection to HAPC designation (DEIS, p. 4-13). On the contrary, under the risk-averse analytical approach used in the rest of the document and required by EFH regulations, any scientific uncertainties should be a basis for conservative assumptions in favor of protecting platform reefs that provide existing habitat utilized by groundfish species.

3. DEIS, p. 2-1

The DEIS states that:

> In order to satisfy this requirement [to identify a preferred alternative or alternatives] in a way that fosters public input and informed decisionmaking, the Council chose preliminary preferred alternatives for EFH identification and description, HAPCs, and fishing impact minimization measures at their November 2004 meeting. They explicitly construed this choice as preliminary—they intend to revisit their decision at the June 2005 meeting, after the public comment on the DEIS has been received, to further refine their choice of a comprehensive preferred alternative. After the June 2005 Council meeting, NMFS will publish a final EIS (FEIS), which will identify these final preferred alternatives.

The DEIS does not explain why certain alternatives were designated as preferred. The Final EIS must describe the criteria used to identify preferred alternatives and must explain how the final preferred alternatives meet the criteria, as well as why rejected alternatives are rejected As noted above, one criterion that should be used to identify preferred alternatives is to interpret the best scientific available information "in a risk-averse fashion to ensure adequate areas are identified as EFH for managed species." 50 CFR § 600.815(a)(1)(iv).

4. DEIS, p. 2-1

During the November 2004 Council meeting, Council members raised some concerns which appeared to bear on the decision whether to designate Alternative B.8 as a preferred alternative. To the extent that those concerns may be considered in evaluating the alternative, they should be disclosed to the public readers of the EIS and addressed in its analysis. First, a concern was raised by one Council member about the "questionable motives" of those who advocate designating platform reefs as HAPC. It is unclear what motives the Council member was referring to. As a general matter, however, the Magnuson-Stevens Act balances a variety of interests, including commercial, recreational and environmental interests, in the management of U.S. fisheries. Commenters are entitled to present their views in order to inform fisheries management decisions and the analysis of environmental consequences. Moreover, under NEPA, the "motives" of any commenter on an EIS are irrelevant. The only relevant issue is whether a suggested course of action conserves and enhances EFH and assists in the recovery of fish populations.

5. DEIS, p. 2-1

Second, concerns were raised during the Council meeting that designating platform reefs as HAPC would set a precedent that would allow discarded articles, such as furniture, oil cans and sunken boats to be left in the ocean as artificial reefs. This is not the case. In the past, some artificial reef projects may have been used to justify solid waste disposal with harmful environmental consequences. However, such actions would not be permissible today under the extensive laws and regulations that govern the construction, siting and placement of artificial reefs. Congress passed the National Fishing Enhancement Act ("NFEA") (33 U.S.C. §§ 2101 *et seq.*) in 1984. The NFEA established national standards for artificial reef development, one of which is to "minimize environmental risks and risks to personal health and property." *Id.* at § 2102(4). The NFEA directed NOAA to create a National Artificial Reef Plan ("NARP") (*id.* at § 2103) and authorized the U.S. Army Corps of Engineers ("Corps") to issue permits for artificial reefs (*id*. at § 2104; *see also* 33 CFR § 322.5(b)). The NARP and the Corps' regulations establish guidelines for siting, materials, design, construction, management and liability, among others. In particular, the NARP provides that materials proposed for artificial reefs must be of proven stable design. Furthermore, the proposed revision of the NARP (Feb. 2002) states that secondary use materials that have generally been found to be unsuitable artificial reef materials include light vehicle bodies, fiberglass boats and boat molds and light gauge metal items such as refrigerators, washing machines, and clothes dryers. Both of these guidelines would prohibit designating discarded junk as artificial reefs. Moreover, state and federal natural resource agencies, the Council, NMFS, and the public all participate in the artificial reef permitting process, which ensures that only appropriate materials will be utilized. Finally, artificial reef permits issued by the Corps are subject to environmental review under NEPA, which further ensures that the concerns about the suitability of a particular material will be addressed.[2]

---

[2] California also has an artificial reef program. Cal. Fish & Game Code §§ 6420-6425. Under California's program, the Department of Fish and Game has authority over the design, placement and monitoring of artificial reefs within state waters. Approximately 34 artificial reefs have been constructed along the California coast under

6. DEIS, p. 2-1

A third concern raised during the Council's consideration of Alternative B.8 was whether "man-made" habitat should be preferred over "natural" habitat in EFH and HAPC designations. The EFH regulations do not draw this distinction. EFH is defined as "those waters and substrate necessary to fish for spawning, breeding, feeding or growth to maturity." 50 CFR § 600.10. Substrate "includes sediment, hard bottom, **structures underlying the waters**, and associated biological communities." *Id.* (emphasis added). "Structures underlying the waters" means artificial (i.e., man-made) structures. NMFS added artificial structures to the definition of substrate in 1997. *See* Magnuson-Stevens Act Provisions: Essential Fish Habitat (EFH), 62 Fed. Reg. 66531 (Dec. 19, 1997) (interim final rule). In response to commenters that objected to the inclusion of artificial structures in the definition of substrate, NMFS stated that it:

> included "structures underlying the waters" in its interpretation of substrate to clarify that structures such as artificial reefs, jetties and shipwrecks may be considered EFH if they provide essential habitat for a managed species.

Id. at 66534. In 2002, when NMFS revised the EFH regulations, similar objections regarding the inclusion of artificial structures in the definition of EFH were raised, to which NMFS responded that it was "not modifying the interpretation of 'substrate' to exclude human made structures, because in some cases such structures can provide valuable habitat for managed species." Magnuson-Stevens Act Provisions: Essential Fish Habitat (EFH), 67 Fed. Reg. 2343, 2347 (Jan. 17, 2002) (preamble to final rule). Accordingly, NMFS has made it clear that artificial structures qualify as EFH. Nothing in the definition of HAPC is to the contrary. To the extent that the habitat characteristics of platform reefs qualify them as HAPC, the fact that they are artificial in origin must be considered irrelevant. Conversely, to reject platform reefs as HAPC for the reason that they are artificial would be inconsistent with the EFH regulations and the purposes of the Magnuson-Stevens Act. If the Council finds it necessary to prioritize, it should place the highest priority on those alternatives with the highest probability of achieving the fisheries management goals of the Act.

7. DEIS, p. iv, 2-6

It appears, based on Figure 2-6, that Alternative A.6, which would identify EFH as the upper 30 percent of the area where the Habitat Suitability Probability ("HSP") is greater than zero for all species, would exclude some of the 27 platform reefs off the California coast from the EFH area. However, there is not enough information in the text of the DEIS or in Figure 2-6 to determine whether or which platform reefs may be excluded from the area identified as EFH under Alternative A.6. In order to fully inform the decisionmakers and the public of the alternatives being considered, the DEIS should clearly state which platform reefs would be included in and excluded from the area identified as EFH under Alternative A.6. If the result of Alternative A.6 would be to eliminate some platform reefs from the EFH category – some of which support dense populations of groundfish as even the DEIS acknowledges (pp. 2-10, 3-8 to 3-10) – this

---

the state program. Some of these artificial reefs were built before the NARP was adopted, however the recently constructed artificial reefs were built in accordance with NARP guidelines.

consequence should be recognized in the DEIS analysis as an adverse environmental consequence of Alternative A.6.

For this reason, as noted above, CARE urges that Alternative A.6 should not be adopted in its present form. Should the Council wish to narrow the designation of EFH as proposed in this alternative, it should be modified to retain platform reefs as EFH that are outside the current range of Alternative A.6.

8. DEIS, p. 2-10.

In the description of Alternative B.8, the DEIS notes that: “High concentrations of groundfish have been observed in association with many of the platforms off the California coast, including overfished species such as bocaccio and cowcod.” For this reason, and as discussed below, identifying platform reefs as EFH and designating them as HAPC should be part of the comprehensive strategy to conserve and enhance EFH.

9. DEIS, p. 2-10

In the description of Alternative B.8, the DEIS states that: “In addition to providing suitable habitat, most of these structures are not fished and act as de facto reserves.” The scientific literature cited in Chapter 3 of the DEIS that supports this statement has been confirmed by more recent research. Love et al. (2003) (Exhibit 1) found that fishing pressure around most platforms has been minimal, in part due to U.S. Coast Guard regulations that restrict access of large fishing boats to the waters near platforms. The same fact is documented by the U.S. Environmental Protection Agency (“USEPA”) Essential Fish Habitat Assessment for NPDES Permit No. CA 2800000 (2000, pp. 5-2 to 5-3) (Exhibit 2). Further, the physical structure of oil platforms significantly restricts the use of both commercial and recreational gear to fish the resident fish populations.

10. DEIS, p. 2-10

In the description of Alternative B.8, the DEIS briefly acknowledges that: “The platforms rise steeply from the bottom and provide unique high relief habitat.” The “uniqueness” of the platform reef habitat should be emphasized, given that “rarity of the habitat type” is one of the factors to be considered in designating HAPC. 50 CFR § 600.815(a)(8)(iv). As the DEIS acknowledges, the latticework of footers and crossbars that comprise the underwater features of platform reefs provide unique high relief habitat. Pinnacle reefs are the only natural formations that provide a similar type of high relief habitat. However, natural pinnacle reefs are very rare off of the California coast, with only one such reef located in the Santa Barbara Channel (Love, personal communication). The DEIS (p. 3-9) also notes that pinnacles are only found on the outer continental shelf, well away from the mainland. Consequently, the majority of this rare type of habitat is provided by platform reefs. In addition, as discussed in these comments, platform reefs provide hard bottom habitat that is rare in the areas in which the platform reefs are located. These facts must be considered in evaluating the environmental consequences of designating platform reefs as HAPC and provide support for the environmental benefits of Alternative B.8.

11. DEIS, p. 2-10

The DEIS states that Alternative B.8 was developed to be consistent with 50 CFR § 600.815(a)(8)(i), but does not explain the reasoning behind this statement. Section 600.815(a)(8)(i) provides that one criterion for designating HAPC is the importance of the ecological function provided by the habitat. The DEIS correctly notes on page 2-10 that high concentrations of groundfish species, including overfished bocaccio and cowcod, have been observed associated with many platform reefs. However, this brief statement fails to adequately address and inform the reader of the variety and importance of the ecological functions that platform reefs provide. As discussed in section 3.2.2.2.4 of the DEIS (pp. 3-8 to 3-10) and in the additional scientific information discussed and cited in these comments:

- (i) platform reefs provide habitat for different life stages of rockfish (i.e., larvae, juveniles, adults) (Love 2000) (Exhibit 3), (Love 2001) (Exhibit 4), (Love 2003), (Love 2005) (Exhibit 5);
- (ii) different life stages of the same species inhabit different depths along the platform reef (i.e., adults inhabit the deep waters and juveniles inhabit the midwaters), thereby reducing predation by adults on juveniles (Love 2003);
- (iii) platform reefs create hard bottom habitat (via the lattice-work of legs and cross members) in areas that are primarily soft bottom habitat (Love 2003);
- (iv) each platform reef creates a variety of habitat (again, via the lattice-work of legs and cross members) (Love 2003);
- (v) because platform reefs have more adults in higher densities than natural reefs, they produce a disproportionate share of larvae in the region (Love 2003; Love 2005);
- (vi) platform reefs recruit larval fish, which grow into juveniles that live in the midwaters and are found in greater densities than at natural reefs (Love 2003; Love 2005);
- (vii) platform reefs recruit larval fish that would otherwise have perished in the absence of the platform reef (Love 2005);
- (viii) juveniles living at platform reefs may grow to adulthood and remain there throughout their lives (Love 2003); and
- (ix) a survey of six platform reefs revealed that approximately 20 percent of all bocaccio young-of-the-year in the Pacific Coast Groundfish fishery are found there (Love 2005).

Clearly, the platform reefs provide important ecological functions that must be addressed in the environmental consequences analysis of the Final EIS, and provide support for the environmental benefits of Alternative B.8.

12. DEIS, p. 2-10.

The DEIS states that Alternative B.8 was developed to be consistent with 50 CFR § 600.815(a)(8)(iii), but does not explain the reasoning behind this statement. Section 600.815(a)(8)(iii) provides that another criterion for designating HAPC is whether and to what extent development activities are, or will be, stressing the habitat type. The brief discussion on page 2-10 of the DEIS does not mention the fact that the current platform decommissioning regulations require complete removal of the platforms. However, as the DEIS correctly notes in section 4.3.3 (p. 4-13), "Oil platforms are subject to removal from the ocean as they are decommissioned." In fact, Gebauer et al. (2004) (Exhibit 6) estimates that removal of the oil platforms located in federal waters along the California coast will begin in 2010 and be completed by 2025. Complete removal of the oil and gas platforms will eliminate the groundfish habitat that the underwater platform reef portions provide. The Final EIS should consider the environmental consequences of this fact, which provides support for the environmental benefits of Alternative B.8, consistent with the HAPC criteria in section 600.815(a)(8)(iii).

13. DEIS, p. 2-10

The Final EIS should also explain that Alternative B.8 is consistent with the HAPC criterion in 50 CFR § 600.815(a)(8)(ii) ("The extent to which the habitat is sensitive to human-induced environmental degradation"). The habitat created by the platform reefs off of the coast of California is dependent on the platforms' presence and subject to elimination if they are removed under platform decommissioning regulations. As such, the platform reefs are sensitive to human-induced environmental degradation by removal of the structures. The Final EIS should consider the environmental consequences of this fact, which provides support for the environmental benefits of Alternative B.8, consistent with the HAPC criteria in section 600.815(a)(8)(ii).

14. DEIS, p. 3-8

The DEIS states that: "Managed species known to use offshore artificial structures include black rockfish, black-and-yellow rockfish, blue rockfish, bocaccio, brown rockfish, cabezon, calico rockfish, California scorpionfish, canary rockfish, copper rockfish, cowcod, darkblotched rockfish, flag rockfish, gopher rockfish, grass rockfish, greenblotched rockfish, greenspotted rockfish, greenstriped rockfish, kelp rockfish, leopard shark, Mexican rockfish, olive rockfish, quillback rockfish, rosy rockfish, sharpchin rockfish, starry rockfish, stripetail rockfish, treefish, vermilion rockfish, yelloweye rockfish, and yellowtail rockfish."

This list of 31 managed species understates the number of rockfish that use platform reefs as habitat. Based on annual surveys dating back to 1995, 42 species of rockfish have been identified as living around platform reefs. (Love et al. 2003; M. Love, personal communication.) The DEIS's understatement of the number of managed species that utilize platform reefs as habitat reflects the failure to rely on the best available scientific information on the habitat value of platform reefs.

15. DEIS, p. 3-8

The DEIS's discussion of the habitat value of platform reefs is based exclusively on *The Ecological Role of Natural Reefs and Oil and Gas Production Platforms on Rocky Reef Fishes in Southern California* (OCS Study MMS 99-0015) ("1999 MMS Report").[3] Several important scientific studies of the habitat value provided by platform reefs located off of California have

[3] The 1999 MMS Report is not listed as a reference in Chapter 10, "Literature Cited." It should be added.

been published since the 1999 MMS Report, including: Love et al. (1999) (Exhibit 7); Love et al. (2000); Love et al. (2001); Love et al. (2003). In addition, Love (2005) summarizes several articles that are based on his latest research, which have been submitted for publication in scientific journals.

In particular, in September 2004, Love (2005) surveyed the largest number of platform reefs since 1999. Love conducted complete surveys of platforms Irene, Hidalgo, Harvest, Hermosa, Hondo (first time), Heritage (first time), Holly, Gail, Grace, and Gilda. In addition, Love conducted midwater surveys at platforms C, B, A, Hillhouse, Henry, and Habitat (complete surveys were hindered due to poor water visibility). Love also surveyed a number of natural reefs (some first mapped in spring 2004) in the Santa Barbara Channel and around the northern Channel Islands. Love's research confirms that many platform reefs harbor higher densities of both juvenile and adult fishes than do most natural reefs. Moreover, new seafloor maps produced in 2004 by the U.S. Geological Survey demonstrate that the seafloor of much of the Santa Barbara Channel is composed of mud and sand. These studies corroborate the 1999 MMS Study and provide important additional evidence that platform reefs provide EFH for rockfish, and that platform reefs should be designated as HAPC. Love's research continues to demonstrate the importance of the Santa Barbara Channel platform reefs as providers of habitat for reef fishes. The DEIS again fails to present the best available scientific information on pp. 3-8 to 3-10, and disregards the breadth and depth of this research in concluding that there is a "lack of conclusive research regarding these issues specifically for the West Coast. . ." (p. 4-13).

16. DEIS, p. 4-13

The DEIS states that:

> One view holds that scientific research indicating an abundance of fish species located at oil rig platforms is a benefit to the ecosystem. Others refer to Holbrook et al. (2000) to stress that this research is inconclusive with regard to whether the observed fish abundance and densities indicate increased fish productivity or attraction of fish populations away from natural reef systems (Chabot, personal communication: Charter, personal communications).

The citation of Holbrook et al. (2000) is out of date. More recent research has addressed a number of the uncertainties that existed at the time that the Holbrook paper was written. The Final EIS must present a more up-to-date and accurate picture of the available scientific evidence. Moreover, the manner in which the DEIS frames the issue — i.e., platform reefs either increase fish productivity **<u>or</u>** attract fish populations away from natural reef systems — misleads the public and decisionmakers. Current research (summarized in the following comment) demonstrates that platform reefs have both effects — i.e., that platform reefs are important habitat for rockfish and function just as natural reefs do, in that they both produce and attract fish depending on species, site, season and ocean conditions. The DEIS, relying on the outdated reference to Holbrook et al., wholly fails to take into account these crucial findings in discussing the environmental consequences of Alternative B.8.

17. DEIS, p. 4-13

The Final EIS must consider the following current research results:

17(a). Love et al. (2003) found young-of-the-year rockfishes around platform reefs and around natural outcrops. His research indicated that the recruitment of juvenile fishes to platform reefs that are far from shore or in deep waters, such as Platforms Gail and Grace, is from maternal sources rather than attraction from natural outcrops. Platform reefs located nearer to shore or in shallow waters may attract juveniles from natural habitats because these platform reefs are located in areas in which it is relatively easier for juveniles to move between habitats. However, the converse is also true: juveniles may be attracted from platform reefs to natural habitats. One important difference, however, is the higher densities of young-of-the-year rockfishes found at platform reefs. Love et al. (2003) concluded that platform reefs provide a more optimal habitat than found on natural outcrops, making platform reefs functionally more important as nurseries.

17(b). Love et al. (2003) also found adult rockfishes around platform reefs and around natural outcrops. As with juveniles, adult rockfish found at platform reefs located far offshore or in deep waters likely arrived through recruitment rather than attraction. This research suggests that rockfishes may live their entire benthic lives around a single platform reef. Thus, the adult rockfishes at platform reefs result from maturation of resident fish rather than through the attraction of adults from natural outcrops. One important difference, however, is the higher densities of adult rockfishes found at platform reefs. The difference is so pronounced that, in some locations, platform reefs provide much or all of the adult fishes of some heavily fished species and thus contribute disproportionately to those species' larval production. (Love et al., 2003).

17(c). More recent research on the growth rate of young blue rockfish living around platform reefs demonstrates that they grow faster than fishes living around natural reefs in the same area (Love, 2005). Related research by Love (2005) indicates that platform reefs are more important producers of bocaccio and cowcod larva than natural habitat. Love's research demonstrates that mean densities for both species are higher at platform reefs than at natural reefs, and in some cases, the adult fishes at platform reefs are larger than those found at natural reefs. In particular, Platform Gail had the highest densities of mature bocaccio and cowcod of any natural or man-made habitat surveyed. Thus, the potential larval production at Platform Gail was much higher than any other site surveyed. Love estimated that for bocaccio one hectare of sea floor at that platform reef was equivalent to 68 hectares at an average natural reef, and for cowcod one platform reef hectare was equivalent to 26 hectares at an average natural reef.

17(d). Love (2005) also found that the number of juvenile bocaccio found around six platforms in the Santa Barbara Channel constituted 20 percent of the average number of juvenile bocaccio that survive in a year for the species' entire range. He determined that, when adults, these bocaccio will contribute about one percent of the additional amount of fish needed to rebuild the Pacific Coast population. His research demonstrates that, although platform reefs provide a relatively small amount of habitat area, this habitat can be crucial for rebuilding an overfished species.

17(e). Furthermore, recent research by Love (2005) indicates that platform reefs recruit larva that would not have survived were the platform reefs not there. By simulating surface currents in 1999 and 2002 originating at Platform Irene to model juvenile bocaccio distribution patterns, Love estimated the proportion of fish recruited to a platform reef that would have arrived at natural juvenile fish habitat in the absence of the platform. Love's results indicated that that seven percent and 23 percent, respectively, of young bocaccio would have survived to reach natural nursery habitat. In other words, the vast majority of young bocaccio would not have survived if they had been unable to settle on the platform reef during the recruitment season.

17(f). The research discussed above demonstrates that platform reefs perform much like natural outcrops, in that both produce and attract rockfishes. However, there is a difference in scale favoring platform reefs, which indicates that some platform reefs are important to regional rockfish production. (Love et al., 2003; Love, 2005.) This ecological role is of significant value especially to the recovery of the many overfished rockfish species that populate the platform reefs, such as bocaccio and cowcod.

17(g) Removal of oil and gas platforms is typically carried out by using explosives to sever the jacket, removing the platform reefs will kill the marine animals and fishes in the vicinity when the explosives are detonated. (Gitschlag et al., 2000) (Exhibit 8). As a result, large numbers of juvenile and adult individuals from slow-growing, slow-reproducing and long-lived species will be killed. This is a serious adverse consequence for the program of rebuilding these overfished stocks, especially since some of the highest observed populations of some rockfish species are associated with platform reefs. (Love 2003; Love 2005.)

In sum, the uncertainty as to the habitat value of platform reefs discussed in Holbrook (2000) has been rebutted by more recent research. Given the directive by the EFH regulations to interpret the best available scientific information in a risk-averse manner (50 CFR § 600.815(a)(1)(i) & (iv)), the Final EIS should rely on the most up-to-date research in order to evaluate environmental consequences, and should consider each of the above findings.

18. DEIS, p. 4-13

The DEIS states that: "Others refer to Holbrook et al. (2000) to stress that this research is inconclusive with regard to whether the observed fish abundance and densities indicate increased fish productivity or attraction of fish populations away from natural reef systems (Chabot, personal communication: Charter, personal communications)." The sources of these personal communications are identified in the "Literature Cited" section (DEIS p. 10-3) as Warner Chabot, affiliated with the Ocean Conservancy, and Richard Charter, affiliated with Environmental Defense. It appears that these personal communications relied solely on Holbrook (2000) which, as explained above, is out of date, to support their assertions. To the extent that the Final EIS relies on these personal communications, it should explain the qualifications of the persons cited and identify any supporting evidence for their statements.

19. DEIS, p. 4-13

The DEIS states that: "Other noted drawbacks to oil platforms HAPC designation include avoidance of returning the area under and around the platform to natural habitat that provide hiding places for rockfish, the potential for these sites to attract increased effort by fishermen and increased predators resulting in increased net mortality, and the potential for the oil platforms to be a hazard to navigation (Charter 2004, personal communication). No scientific evidence is cited as a basis for these assertions, which appear to be unsupported speculations. To the extent that the Final EIS relies on his assertions, it should explain Mr. Charter's qualifications and any supporting evidence for his statement.

20. DEIS, p. 4-13

The speculation that HAPC designation would prevent the restoration of soft-bottom hiding places for rockfish is contradicted by the best available scientific evidence. The soft-bottom habitat under and around the platform reefs is virtually devoid of hiding places. (Love 2005.) The only hiding places that exist are provided by the latticework of beams and cross members that make up the platform reef structure. Moreover, returning the area under and around platform reefs to soft-bottom habitat will require the destruction of existing hiding places and thriving habitat and kill large numbers of the resident fish. (Gitschlag et al., 2000.) The alternative that would enhance hiding places for rockfish is designating platform reefs as HAPC.

21. DEIS, p. 4-13

Regarding the claim that platform reefs could "attract increased effort by fishermen. . . resulting in increased net mortality (DEIS, p. 4-13): As the DEIS acknowledges, and as corroborated by Love (2003) and USEPA (2000), platform reefs are not currently heavily fished and, in fact, act as de facto marine refuges. This is due in part to U.S. Coast Guard regulations that restrict access of large fishing boats to the waters near platforms. In addition, the physical structure significantly restricts the use of both commercial and recreational fishing gear to fish the resident species. Designation of platform reefs as HAPC will not change the Coast Guard's regulation of navigation near the platform reefs nor will the designation alter the physical structure of platform reefs (i.e., large fishing boats will still find it difficult to navigate near them). Accordingly, designation of platform reefs as HAPC will not result in increased effort by fishermen.

22. DEIS, p. 4-13

Regarding the claim that platform reefs could attract "increased predators resulting in increased net mortality" (DEIS, p. 4-13), available scientific evidence suggests that the predation of young fishes on platform reefs is probably lower than that on natural outcrops. This is due to the fact that platform reefs occupy the entire water column and that the fish assemblages are distributed differently than on most natural outcrops. Natural outcrops in the area of platform reefs are typically 5 to 15 feet in height, putting all fish, both young and adults in close proximity. Adults prey on young fish. On platform reefs, the adult fishes are found near the bottom while young fishes occupy the midwaters. This separation implies lower mortality rates for young fishes residing at platform reefs. (Love 2003.) Further, other natural predators, such as pinnipeds, do not appear to be attracted to platform reefs. (Love 2005, personal communication.) The DEIS identifies no evidence to the contradict these observations.

23. DEIS, p. 4-13

Finally, regarding the claim that platform reefs have "the potential to be a hazard to navigation" (DEIS, p. 4-13), the U.S. Coast Guard is responsible for maritime safety in the navigable waters of the U.S. where the platform reefs are located. It has established requirements for all oil and gas platforms regarding the operation and maintenance of aids to navigation and other measures to insure marine safety. No vessel operator has lodged a formal complaint that any oil and gas platforms off of California created a navigation hazard (Boyes, personal communication). Similarly, no hazard complaints have been lodged by vessel operators regarding oil and gas platforms or artificial reefs in the Gulf of Mexico, where many platforms have been turned into artificial reefs. (Kasprzak 2005, personal communication; Boyes 2005, personal communication.) Mr. Kasprzak (Artificial Reef Coordinator, Louisiana Department of Fish and Wildlife, Baton Rouge, Louisiana) and Mr. Boyes (Waterways Management Officer, U.S. Coast Guard, District Eleven) are well-qualified to attest to these facts. The U.S. Coast Guard's regulatory oversight will not be affected by the designation of these platform reefs as HAPC. Thus, there is no basis to the claim that HAPC designation will cause the platform reefs to become a hazard to navigation or adversely affect marine safety.

24. DEIS, p. 4-13

The DEIS states that:

> Another potential drawback that has been of particular concern in the Gulf of Mexico is the relatively high levels of mercury contamination around oil platforms. The disposal of drilling fluids containing mercury from operational oil rigs has resulted in concerns that mercury levels in fish caught near oil platforms, even years after the oil rig is no longer operational, are substantially higher than those caught elsewhere and could be a hazard to humans (Charter 2004, personal communication).

No scientific evidence is cited as a basis for these assertions. To the extent that the Final EIS relies on his assertions, it should explain Mr. Charter's qualifications and any supporting evidence for his statement. The Department of the Interior, Minerals Management Service ("MMS"), has studied the issue of mercury contamination from drilling muds in the Gulf of Mexico and reached the opposite conclusion. As the MMS states on its website: "While the issue of mercury in seafood in the Gulf of Mexico is the subject of an increasing amount of research particularly because of global and regional inputs, the results of research to date generally supports the conclusion that oil and gas platforms do not play a significant role in elevating levels of mercury in fish and other seafood." (See:

http://www.gomr.mms.gov/homepg/regulate/environ/mercury.html). The MMS bases its conclusion, in part, on the following studies:

> 24(a). In 1995, a study of three OCS oil and gas platforms included the analyses of over 700 sediment samples and over 800 tissue samples from shrimp, crabs, marine worms, clams, fish livers, and fish stomach contents. Results of the analyses documented that total mercury is not concentrated to any greater extent in organisms living near the oil and gas platforms (less than 100 meters away) when compared to those living far away from the oil and gas platforms (over 3000 meters). From these results the scientists concluded that oil and gas platforms do not contribute to higher mercury levels in marine organisms. (Kennicutt, 1996) (Exhibit 9).
>
> 24(b). In 2002, a total of 196 sediment samples were taken from six drilling sites in the Gulf of Mexico and analyzed to determine if methyl mercury (MeHg) was being produced in the sediment around drilling platforms. The results showed that concentrations of MeHg in sediments around drilling platforms do not vary significantly with concentrations found at sites that were far from drilling. The report concluded that elevated levels of MeHg around oil and gas platforms are not a widespread phenomenon in the Gulf of Mexico. (Trefry, 2002) (Exhibit 10).
>
> 24(c). The MMS Subcommittee on Mercury in the Gulf of Mexico ("MMS Subcommittee") corroborated these findings. (Creselius et al., 2002) (Exhibit 11). The MMS Subcommittee was established to independently evaluate existing scientific literature on whether OCS oil and gas activities were causing mercury pollution in the Gulf, and provide guidance as to what actions MMS should take. The MMS Subcommittee determined that high levels of total mercury around oil and gas drilling sites was directly correlated with the drilling mud weighting agent barite. However, the increase in sediment concentrations of MeHg at or adjacent to OCS oil and gas drilling sites is not directly attributable to mercury introduced with barite. Further, the MMS Subcommittee determined that the discharges at OCS oil and gas drilling sites do not create conditions that enhance the conversion of mercury to MeHg.
>
> 24(d). An additional study is currently being conducted by the Battelle Marine Sciences Laboratory to determine if barite (the source of mercury in drilling muds) is soluble in the stomach of marine animals and if trace metals are released. Preliminary results indicate that barite is only minimally soluble and that mercury is not bioavailable to marine animals. (Cimato 2005, personal communication.)

Accordingly, the available scientific evidence does not support a high level of concern regarding mercury levels. In order to provide complete and accurate information to the public and decision-makers, each of these studies should be considered in the discussion of mercury issue in the Final EIS.

Trawl Industry Proposal
For
Groundfish Bottom Trawl Closures
To
Protect Essential Fish Habitat in the Pacific Region

May 24, 2005

Process

In November of 2004, the PFMC selected preliminary preferred alternatives for the Draft EIS for Groundfish EFH. The spectrum of preferred alternatives was extremely broad, ranging from options that would effectively "freeze the footprint" of the trawl fishery to close large areas to trawling. Industry representatives discussed this range of alternatives with members of the Pacific Council, trying to gain insights into the thinking of the Council collectively and the possible final outcome of this process.

Several Council members strongly suggested that the trawl industry should engage in discussions which could lead to the development of an industry proposal that would include suggestions for areas to be closed to future bottom trawling for groundfish.

During March and April of 2005 a series of meetings occurred that involved approximately 50 individuals involved in groundfish trawling along the Pacific Coast. All of the meetings that occurred were open to all participants in the trawl fisheries. At these meetings, trawlers were given a presentation on the background of the EFH issue and a summary of the alternatives that have been developed. The PFMC preferred alternatives were highlighted and explained in greater detail.

The task of developing an industry proposal identifying areas to be closed to bottom trawl fishing was discussed and agreed to by those attending these meetings. It was suggested that a starting point for developing these area should be the areas that were identified in the Oceana proposal (Alternative 12). The coordinates for the Oceana proposal were entered into Nobeltec Visual Mariner, a widely used navigational charting program, and projected on a screen for fishermen to view.

Fishermen were told that they could either: 1) delete areas proposed by Oceana, 2) suggest modifications to the boundaries of the Oceana proposed areas, or 3) suggest entirely new areas that Oceana had not identified. The focus of these discussions was on the more near-shore areas that Oceana had proposed for closure. The trawl fleet had no concern for the off-shore areas around the seamounts. Trawlers examined each area very closely along the entire coast, from northern Washington to Point Conception. Since there has been no, or very little groundfish trawling south of Point Conception, no suggestion were made for that area of the coast. However, the Southern California Trawlers Association was contacted and made aware of the process that was underway. They were invited to provide suggestions for that area of the coast, since they were more familiar with the area. However, no suggestions were received from them.

The use of Nobeltec greatly added in this process. This program is quite flexible, allowing fishermen to zoom in and out of the scaleable charts, as well as to switch between bathometric charts and NOAA navigational charts which present loran-C lines. Thus fishermen were able to identify the exact location of where they would normally fish and see the impact that the proposed closed areas would have upon their fishing activities.

Through this process fishermen strived to minimize the impact upon fishing, while setting aside areas that could be protected from future fishing. Fishermen did not approach this task with the goal of setting aside any particular amount of area in total or an amount of any particular habitat.

Proposal

The industry proposal includes 25 locations from Cape Flattery to Point Conception. As well as the area west of 1000 fathoms (2000 meters) and the area shoreward of the three miles off Washington and California (Figure 1). Below is a listing of the areas and a brief description of the area contained within each. The names associated with each are reflect either a benthic feature such as a reef or some reference point onshore that helps locate the area offshore. The coordinates of the proposed closed areas are listed in Table 1.

In total the Industry proposal would close approximately 183,000 square nautical miles to trawling which would represent closing around 76% of the EEZ to the bottom trawling for groundfish (Table 2). Contained within the Industry proposal are a variety habitat types (Table 3), with a substantial amount of both hard and soft bottom area being set aside from bottom trawl fishing for groundfish, particularly north of Point Conception.

As stated above trawl fishermen were asked to propose areas to be closed based upon their knowledge and using Alternative 12 as a starting point for discussions. Figure 2a and Figure 2b show the location of the areas in the Industry proposal and compare these with the sites originally designated in Alternative 12. In some case the areas are identical while in others the boundaries have been shifted to minimize the impact upon prime fishing locations. This can be seen in Figure 3a and Figure 3b which shows the locations of both the Industry proposal and Alternative 12, with the location of tows that were made by Oregon trawlers. This data does not include those tows made by trawlers that made deliveries in Washington or in California. That data does exist, however, due to staffing and manpower constraints, that information was not available in a form that could be combined into one data set for charting. Given the desire to minimize the impact of closed areas upon the trawl fishery, it is anticipated that the data from the other two States would results in very similar displays of how the areas selected in the Industry proposal avoid areas of intense fishing.

The State of Oregon prepared an analysis across all of the alternatives found in the Draft EIS. Figure 4 presents a comparison of the Catch per Unit of Effort (CPUE) found within each of the areas. Clearly and not unexpectedly the CPUE in the areas of Industry proposal have the lowest rate. The overall economic impact from implementing each proposal the Industry proposal has one of the lowest negative economic impacts of all of the proposals in the Draft EIS (Figure 5).

Proposed closed areas

<u>Olympic:</u> Area of diverse topography containing submarine canyons up to 190 fm in depth, making up part of the larger Juan de Fuca Canyon. There is a large area of soft sediments that is home to juvenile flat fish as well as several large areas of both rough and smooth rock, gravels, and sands, approximately 60 to 90 fm in depth formed by glacial action. The area is surrounded by canyon walls of high relief containing many forests of hard corals as well as dispersed soft corals. Species of interest caught include wolf eels indicative of rocky crevasses

<u>Washington Deep:</u> Main feature is a large ridge of approximately 500 fm in depth at the top dropping off to 750 fm or more on the north and south sides. Additionally, the area substrate is composed of mud, silt, and hard areas of gravel and sand. Some areas contain high relief clay/mud banks. The area is strewn with granite boulders dropped by the Frazer River lobe of the continental glacier. Most interesting habitant is a unique glass coral which grows in a spiral column habit, clear in color except for a live exterior skin, stalk approx 3/4 inch in diameter, grows with a filtering top structure, several feet in length and attached to the bottom by a hold fast. The University of Oregon was sent a specimen 15 years ago since they did not have one. Species include deep water Tanner crab juveniles, red crab, shortspine thornyheads and longspine thornyheads, Dover, sable, and grenadiers,

<u>Willapa:</u> Submarine canyon with rocky shallow areas as well as clay and mud banks on walls of canyons. There are areas of high relief, and both jagged and smooth hard bottom.

<u>Columbia:</u> Deep water canyon between Grays Canyon and Astoria Canyon. The site consists of sedimentary slopes, canyon basins and deep sea rises. The sediment is primarily green mud and is rich in biota. Portions of Willapa Canyon

and Guide Canyon are in the site, as well the area in which they converge to create a larger sea canyon. The inner 1/3 of the area has been fished for Sablefish and Longspine thornyheads. Tanner Crab, Grenadier, Long nose cat shark, deepwater sole, Slick head and Pacific Flat nose are the primary by-catch by the trawl fishery as well as several species of starfish, corals and sponges. Annelid worms and Sea Anemones are also occasionally brought to the surface in this area

Cape Falcon: An offshore ridge comprised of three mountains the largest rising from a depth of around 900 fathoms to a height of 340 fathoms. The site has a rich diversity of bottom types. Rocky canyon-walls on offshore ridges are found in this site have some of the steepest ridge walls found on the west coast. Seabed depressions believed to be caused by methane gas escapement are found in this area, which may create unique aquatic communities. The lower portions of the Astoria Canyon contain a starfish not commonly found elsewhere. Alluvial mud is primary sediment on the seafloor, though the area is known to have glacial boulders as well as sand and gravel patches. A rich mixture of non-commercial species occur is this area.

Cascade Head: The area runs from the beach and out to 40 fathoms. The shape of the area is a large rectangle, although the maps show it as a triangle. The area is sandy bottom near shore and contains three major reefs. These are basalt pinnacles surrounded by sand. Known habitat for juvenile red rock.

Siletz Bay: An area containing a large bowl. The rim of the bowl is around 800 fathoms and the bottom drops to over 1000 fathoms.

Stonewall Banks: South End is jagged basalt, inshore is hard clay boulder patch. North end rough with a few sand slit in the middle.

Heceta Banks: Two major undersea mountains with very jagged rock formations. The area contains a large of amount of habitat for rockfish species.

Coos Bay: This is a large tract of continental slope which begins at around 700 fathoms.

Bandon: A nearshore area of continental shelf which begins on shore and ranges out to around 60 fathoms. The area is rocky nearshore and is sand, gravel, and hard mud offshore.

Rogue River: Depths ranging from 55 to 120 fathom deep. Bottom littered with pinnacles and large ridges that run east to west on the southern end of the area. It is excellent habitat for all of the shelf rockfish species and lingcod. Minimal amount of bottom trawl done in this area do to the high relief.

Rogue River Deep: A large area of continental slope beginning at around 700 fathoms.

Crescent City Deep: A large area of continental slope beginning at around 700 fathoms.

Eel River: This area contains the Eel River Canyon from depths from just over 100 fathoms at the canyon head along the canyon walls seaward to depths of around 1000 fathoms. The area fans out encompassing the alluvial plane. The area contain hard rock bottom through the canyon and soft sediments offshore at the canyon base.

Mendocino Ridge: This area begins with the nearshore rocky habitat roughly between Cape Mendocino and Punta Gorda. It contains two very large and significant marine canyons, Mendocino Canyon and Mattole Canyon. The area continues west bounding the Mendocino Escarpment and fracture zone.

Point Arena: Encompasses a shallow water area on the continental shelf with depths between 55 fathoms and 75 fathoms. The substrate is mixture of areas of clay and sandy bottom with little slope.

Fish Rocks: The area is ranges from continental shelf at 60 fathoms and over the edge on to the continental slope to depths around 300 fathoms. The nearshore substrate is mostly sandy bottom that transitions to rocky areas on the slope. There is a band of various corals running through this area from the northwest to southeast that follows the hard bottoms area.

Cordell Banks: This area surrounds the entire Cordell Bank and includes a large area of continental slope south of the banks, as well as a large area reaching shoreward to 40 fathoms. The bottom type ranges from sandy areas nearshore to the rocky banks. The area includes areas with “glass coral” and “bamboo coral” on the southern part of the area.

Farallon Islands: This area contains the Farallon Island and the area surrounding them. The area is identical to that proposed by Oceana and found in Alternative 12.

Halfmoon Bay: This is a shallow continental shelf area with depths that range from 25 to 50 fathoms. The bottom is composed of areas with sand, gravel, mud, and rocks.

Monterey Bay: The Monterey Bay area contains the very large Monterey Bay Canyon along with the smaller Sequel Canyon and Carmel Canyon. The area contains the canyon heads, rocky shores, particularly from Monterey to south of Carmel, and through the canyon to very deep offshore waters.

Point Sur: Contained within this area is a deepwater nearshore ridge. The western side of the area is around 800 fathoms that rises to around 450 fathoms at the top of the ridge. Move further east the ridge drops back to depths of 600 fathoms before moving into the onshore shallow water. On top of this ridge is found “glass coral” and “bamboo coral”.

Piedras Blancas: This is a very large offshore basin that ranges in depth from 500 fathoms to 700 fathoms.

Point Conception: This is the largest of the onshore tracts. It ranges in depth from 30 to 40 fathoms nearshore and continues offshore to depths over 1000 fathoms. The more onshore area contains numbers small canyons that continue offshore. The area is also the dividing point between the Northern California coast and the Southern California bight.

Re: June 15, 2005 Meeting Agenda Item C.3: Adoption of a Final Preferred Alternative for the 2005 EIS for Pacific Coast Groundfish Essential Fish Habitat

Dear Chairman Hansen:

Thank you for the opportunity to comment on the adoption of a final preferred alternative for the Environmental Impact Statement (EIS) for Essential Fish Habitat Designation for the Pacific Coast Groundfish Fishery Management Plan, at the June 15, 2005 meeting of the Pacific Fishery Management Council (Council). This letter contains comments of the California Artificial Reef Enhancement Program (CARE). CARE is a nonprofit organization which, through public education and scientific research, promotes awareness and understanding of the potential value to be derived from artificial reef ecosystems in offshore California, and supports the preservation and enhancement of artificial reefs when recognized as beneficial to the marine environment.

CARE urges the Council to adopt Alternative B.8, the designation of the oil and gas platforms offshore of southern California as "Habitat Areas of Particular Concern" (HAPC) under the Magnuson-Stevens Fishery Conservation and Management Act, as the final preferred alternative for purposes of the Final EIS. For the reasons stated in our previous comments regarding the scope and content of the Draft EIS, submitted to NOAA Fisheries on October 5, 2004 and May 11, 2005, we believe that the Final EIS should include and evaluate additional scientific information that strongly supports the designation of the platforms as HAPC, as part of the comprehensive strategy to conserve and enhance essential fish habitat for fish species managed under the Pacific Coast Groundfish Fishery Management Plan. For the benefit of Council members now considering the preferred alternative, we are providing these comments and supporting scientific literature. Please contact me at (805) 320-8456 if you have any questions or would like any further information that CARE may be able to provide.

Sincerely,

George Steinbach

George Steinbach
Executive Director

Comments of CARE on the Selection of a Preferred Alternative for the Pacific Coast Groundfish EFH EIS

Comment 1:

CARE urges the Pacific Fishery Management Council ("Council") to select Alternative B.8, the designation of oil and gas platforms offshore of southern California as "Habitat Areas of Particular Concern" ("HAPC"), as the Final Preferred Alternative for the Pacific Coast Groundfish Environmental Impact Statement ("EIS"). The information submitted with these comments and with our comments dated October 5, 2004 (Exhibit 1) strongly supports this designation.

Comment 2:

The Draft EIS ("DEIS"), p. 2-10, states that Alternative B.8 was developed to be consistent with 50 CFR § 600.815(a)(8)(i), which is one of four distinct criteria on which HAPC designation may be based. Under Section 600.815(a)(8)(i), one of the criteria for HAPC designation is the "importance of the ecological function provided by the habitat." The DEIS notes on page 2-10 that high concentrations of groundfish species, including overfished bocaccio and cowcod, have been observed associated with many platforms. In fact, considerable additional scientific information is now available which demonstrates that the platform reefs[1] provide important ecological functions, supporting the environmental benefits of Alternative B.8:

(i) Platform reefs provide habitat for different life stages of rockfish (i.e., larvae, juveniles, adults) (Love et al., 2000) (Exhibit 2), (Love et al., 2001) (Exhibit 3), (Love et al. 2003) (Exhibit 4), (Love 2005) (Exhibit 5).

(ii) Platform reefs create hard bottom habitat (via the lattice-work of legs and cross members) in areas that are primarily soft bottom habitat (Love et al., 2003). Each platform reef creates a variety of habitat (again, via the lattice-work of legs and cross members) (Love et al., 2003).

(iii) Love (2005) found that the number of juvenile bocaccio found around six platforms in the Santa Barbara Channel constituted 20 percent of the average number of juvenile bocaccio that survive in a year for the species' entire range. He determined that, when adults, these bocaccio will contribute about one percent of the additional amount of fish needed to rebuild the Pacific Coast population. His research demonstrates that, although platform reefs provide a relatively small

[1] In these comments, we use the term "platform reefs" to refer to the valuable groundfish habitat that oil and gas platforms provide. This term is meant to emphasize that scientific research demonstrates that the underwater portions of oil and gas platforms serve as de facto reef habitat. In addition, the term emphasizes that only the underwater portion of the platform is relevant to the discussion of groundfish Essential Fish Habitat ("EFH") and HAPC.

amount of habitat area, this habitat can be crucial for rebuilding an overfished species.

(iv) The higher densities of adult rockfishes found at platform reefs are so pronounced that, in some locations, platform reefs provide much or all of the adult fishes of some heavily fished species and thus contribute disproportionately to those species' larval production. (Love et al., 2003.)

(v) Platform reefs recruit larval fish, which grow into juveniles that live in the midwaters and are found in greater densities than at natural reefs (Love et al., 2003; Love 2005). Platform reefs recruit larval fish that would otherwise have perished in the absence of the platform reef (Love 2005). Love et al. (2003) concluded that the recruitment of juvenile fishes to platform reefs that are far from shore or in deep waters is from maternal sources, rather than attraction from natural outcrops. Platform reefs located nearer to shore or in shallow waters may attract juveniles from natural habitats because these platform reefs are located in areas in which it is relatively easier for juveniles to move between habitats. The converse is also true: juveniles may be attracted from platform reefs to natural habitats. However, because higher densities of young-of-the-year rockfishes are found at platform reefs, Love et al. (2003) concluded that platform reefs are functionally more important as groundfish nurseries.

(vi) Because platform reefs have more adults in higher densities than natural reefs, they produce a disproportionate share of larvae in the region (Love et al., 2003; Love 2005). Love (2005) compared the density and size of bocaccio and cowcod found on platform reefs to those found on natural outcrops. The results indicate that platform reefs are more important producers of bocaccio and cowcod larva than natural habitat. At Platform Gail in particular, which had the highest densities of mature bocaccio and cowcod of any natural or man-made habitat surveyed, Love estimated that for bocaccio one hectare of sea floor at that platform reef was equivalent to 68 hectares at an average natural reef, and for cowcod one platform reef hectare was equivalent to 26 hectares at an average natural reef.

(vii) Furthermore, recent research by Love (2005) indicates that platform reefs recruit larva that would not have survived were the platform reefs not there. By simulating surface currents in 1999 and 2002 originating at Platform Irene to model juvenile bocaccio distribution patterns, Love estimated that only seven percent and 23 percent, respectively, of young bocaccio that recruited to Platform Irene would have survived to reach natural nursery habitat.

(viii) Different life stages of the same species inhabit different depths along the platform reef (i.e., adults inhabit the deep waters and juveniles inhabit the midwaters), thereby reducing predation by adults on juveniles (Love et al., 2003).

(ix) Juveniles living at platform reefs may grow to adulthood and remain there throughout their lives (Love 2003). Research on the growth rate of young blue rockfish living around platform reefs demonstrates that they grow faster than fishes living around natural reefs in the same area (Love 2005).

The research discussed above demonstrates that platform reefs perform much like natural outcrops, in that both produce and attract rockfishes. However, there is a difference in scale favoring platform reefs, which indicates that some platform reefs are important to regional rockfish production. (Love et al., 2003; Love 2005.) This ecological role is of significant value especially to the recovery of the many overfished rockfish species that populate the platform reefs, such as bocaccio and cowcod.

Comment 3:

The second criterion for designation of HAPC, 50 CFR § 600.815(a)(8)(ii), is the "extent to which the habitat is sensitive to human-induced environmental degradation." As the DEIS notes in section 4.3.3 (p. 4-13), "Oil platforms are subject to removal from the ocean as they are decommissioned." In fact, Gebauer et al. (2004) (Exhibit 6) estimates that removal of the oil platforms located in federal waters along the California coast will begin in 2010 and be completed by 2025. The habitat created by the platform reefs off of the coast of California is dependent on the platforms' presence and subject to elimination if they are removed under platform decommissioning regulations. As such, the platform reefs are sensitive to human-induced environmental degradation by removal of the structures.

Comment 4:

The third criterion for designation of HAPC, 50 CFR § 600.815(a)(8)(iii), is "whether, and to what extent, development activities are, or will be, stressing the habitat type." Again, complete removal of the oil and gas platforms will eliminate the type of groundfish habitat that the underwater platform reef portions provide.

Comment 5:

The fourth criterion for designation of HAPC, 50 CFR § 600.815(a)(8)(iv), is the "rarity of the habitat type." As the DEIS explains (p. 2-10): "The platforms rise steeply from the bottom and provide unique high relief habitat." The "uniqueness" of the platform reef habitat should be emphasized, given that "rarity of the habitat type" is one of the factors to be considered in designating HAPC. As the DEIS acknowledges, the latticework of footers and crossbars that comprise the underwater features of platform reefs provide unique high relief habitat. Pinnacle reefs are the only natural formations that provide a similar type of high relief habitat. However, natural pinnacle reefs are very rare off of the California coast, with only one such reef located in the Santa Barbara Channel (Love 2005, personal communication; DEIS p. 3-9). Consequently, the majority of this rare type of habitat is provided by platform reefs. In addition, as discussed in these comments, platform reefs provide hard bottom habitat that is rare in the areas in which the platform reefs are located.

Comment 6:

EFH decisions must be based on "the best scientific information available" (50 CFR § 600.815(a)(1)(ii)(B)), and this information must be interpreted "in a risk-averse fashion" (*id.* at § 600.815(a)(1)(iv)(A)). On that point, it is critical to note that ***the designation of platform reefs as HAPC will not have any adverse environmental consequences***. Rather, as the DEIS acknowledges, this designation would "enhance NMFS' [National Marine Fisheries Service] opportunity to fully consider their potential contribution to rebuilding overfished species before they are removed." (DEIS, p. 4-13.) Whatever scientific uncertainties may yet remain can be considered when NMFS consults regarding decommissioning plans for particular platforms. On the other hand, once the structures are removed, NMFS will have no opportunity for further evaluation because the platform reef habitat and thriving ecological communities will be destroyed. Moreover, since the removal of oil and gas platforms is typically carried out by using explosives to sever the jacket, removing the platform reefs will kill the marine animals and fishes in the vicinity when the explosives are detonated. (Gitschlag et al., 2000) (Exhibit 7). This is a serious adverse consequence for the program of rebuilding these overfished stocks, especially since some of the highest observed populations of some rockfish species are associated with platform reefs. (Love et al., 2003).

Comment 7:

During the November 2004 Council meeting, a concern was raised by one Council member about the "questionable motives" of those who advocate designating oil and gas structures as HAPC. It is unclear what motives the Council member was referring to. As a general matter, however, the Magnuson-Stevens Fishery Conservation and Management Act balances a variety of interests, including commercial, recreational and environmental interests, in the management of U.S. fisheries. The only relevant issue is whether a suggested course of action conserves and enhances EFH and assists in the recovery of fish populations.

Comment 8:

Second, concerns were raised during the Council meeting that designating platform reefs as HAPC would set a precedent that would allow discarded articles, such as furniture, oil cans and sunken boats to be left in the ocean as artificial reefs. Such actions would not be allowed under the extensive laws and regulations that govern the construction, siting and placement of artificial reefs. The National Fishing Enhancement Act of 1984 (33 U.S.C. §§ 2101 *et seq.*) established national standards for artificial reef development, (*id.* at § 2102), directed the National Oceanic and Atmospheric Administration to create a National Artificial Reef Plan ("NARP") (*id.* at § 2103), and authorized the U.S. Army Corps of Engineers ("Corps") to issue permits for artificial reefs (*id*. at § 2104; *see also* 33 CFR § 322.5(b)). The NARP and the Corps' regulations establish guidelines for siting, materials, design, construction, management and liability, among others. In particular, the NARP provides that materials proposed for artificial reefs must be of proven stable design, which would prohibit designating discarded junk as artificial reefs. Moreover, state and federal natural resource agencies, the Council, NMFS and the public all participate in the artificial reef permitting process, which ensures that only appropriate materials will be utilized. Finally, artificial reef permits issued by the Corps are subject to environmental review under the National Environmental Policy Act (42 U.S.C. §§

4321 *et seq.*), which further ensures that the concerns about the suitability of a particular material will be addressed.

California also has an artificial reef program. Cal. Fish & Game Code §§ 6420-6425. Under California's program, the Department of Fish and Game has authority over the design, placement and monitoring of artificial reefs within state waters. Approximately 34 artificial reefs have been constructed along the California coast under the state program. Some of these artificial reefs were built before the NARP was adopted, however the recently constructed artificial reefs were built in accordance with NARP guidelines.

Comment 9:

A third concern raised during the Council's consideration of Alternative B.8 was whether "man-made" habitat should be preferred over "natural" habitat in EFH and HAPC designations. The EFH regulations do not draw this distinction. EFH is defined as "those waters and substrate necessary to fish for spawning, breeding, feeding or growth to maturity." 50 CFR § 600.10. Substrate "includes sediment, hard bottom, **structures underlying the waters**, and associated biological communities." *Id.* (emphasis added). "Structures underlying the waters" means artificial (i.e., man-made) structures. NMFS has made it clear that artificial structures qualify as EFH because "such structures can provide valuable habitat for managed species." *Magnuson-Stevens Act Provisions: Essential Fish Habitat (EFH)*, 67 Fed. Reg. 2343, 2347 (Jan. 17, 2002) (preamble to final rule). Nothing in the definition of HAPC is to the contrary. To the extent that the habitat characteristics of platform reefs qualify them as HAPC, the fact that they are artificial in origin must be considered irrelevant.

Comment 10:

The DEIS's discussion of the habitat value of platform reefs on pages 3-8 to 3-10 is based exclusively on *The Ecological Role of Natural Reefs and Oil and Gas Production Platforms on Rocky Reef Fishes in Southern California* (OCS Study MMS 99-0015) ("1999 MMS Report"). Several important scientific studies of the habitat value provided by platform reefs located off of California have been published since the 1999 MMS Report, including: Love et al. (1999) (Exhibit 8); Love et al. (2000); Love et al. (2001); Love et al. (2003). In addition, Love (2005) summarizes several articles that are based on his latest research, which have been submitted for publication in scientific journals.

The research by Love (2005) confirms that many platform reefs harbor higher densities of both juvenile and adult fishes than do most natural reefs. Moreover, new seafloor maps produced in 2004 by the U.S. Geological Survey demonstrate that the seafloor of much of the Santa Barbara Channel is composed of mud and sand. These studies corroborate the 1999 MMS Study and provide important additional evidence that platform reefs provide EFH for rockfish, and that platform reefs should be designated as HAPC.

Comment 11:

The DEIS (p. 4-13) states that:

> One view holds that scientific research indicating an abundance of fish species located at oil rig platforms is a benefit to the ecosystem. Others refer to Holbrook et al. (2000) to stress that this research is inconclusive with regard to whether the observed fish abundance and densities indicate increased fish productivity or attraction of fish populations away from natural reef systems (Chabot, personal communication: Charter, personal communications).

The citation of Holbrook et al. (2000) is out of date. More recent research (presented in the attached Exhibits and summarized in comment 2, above) has addressed a number of the uncertainties that existed at the time that the Holbrook paper was written. Moreover, the manner in which the DEIS frames the issue — that platform reefs either increase fish productivity **or** attract fish populations away from natural reef systems — misleads the public and decisionmakers. Current research demonstrates that platform reefs have both effects: platform reefs are important habitat for rockfish and function just as natural reefs do, in that they both produce **and** attract fish depending on species, site, season and ocean conditions. The DEIS, relying on the outdated reference to Holbrook et al. (2000), wholly fails to take into account these crucial findings in discussing the environmental consequences of Alternative B.8. In selecting a final preferred alternative, the Council should consider the more up-to-date scientific evidence that is now available.

Comment 12:

Based on comments from others, the DEIS (p. 4-13) lists a number of concerns regarding designation of platforms as HAPC. However, no scientific evidence is cited as a basis for these assertions. On the contrary, the scientific evidence contradicts the drawbacks suggested:

- Regarding the speculation that HAPC designation would prevent the restoration of soft-bottom hiding places for rockfish: The soft-bottom habitat under and around the platform reefs is virtually devoid of hiding places. (Love 2005.) The only hiding places that exist are provided by the latticework of beams and cross members that make up the platform reef structure. Moreover, returning the area under and around platform reefs to soft-bottom habitat will require the destruction of existing hiding places and thriving habitat and kill large numbers of the resident fish. (Gitschlag et al., 2000.) The alternative that would enhance hiding places for rockfish is designating platform reefs as HAPC.

- Regarding the claim that platform reefs could "attract increased effort by fishermen … resulting in increased net mortality": As the DEIS acknowledges, and as corroborated by Love et al. (2003) and USEPA (2000) (Exhibit 9), platform reefs are not currently heavily fished and, in fact, act as de facto marine refuges. This is due in part to U.S. Coast Guard regulations that restrict access of large fishing boats to the waters near platforms. In addition, the physical structure significantly restricts the use of both commercial and recreational fishing gear to fish the resident species. Designation of platform reefs as HAPC will not change the Coast Guard's regulation of navigation near the platform reefs nor will the designation alter the physical structure of platform reefs. Accordingly, designation of platform reefs as HAPC will not result in increased effort by fishermen.

- Regarding the claim that platform reefs could attract "increased predators resulting in increased net mortality": Available scientific evidence suggests that the predation by adult fishes on young fishes on platform reefs is probably lower than that on natural outcrops. This is due to the fact that platform reefs occupy the entire water column and that the fish assemblages are distributed differently than on most natural outcrops. Natural outcrops in the area of platform reefs are typically 5 to 15 feet in height, putting all fish, both young and adults in close proximity. On platform reefs, the adult fishes are found near the bottom while young fishes occupy the midwaters. This separation implies lower mortality rates for young fishes residing at platform reefs. (Love et al., 2003.) Further, other natural predators, such as pinnipeds, do not appear to be attracted to platform reefs. (Love 2005, personal communication.)

- Regarding the claim that platform reefs have "the potential to be a hazard to navigation": The U.S. Coast Guard is responsible for maritime safety in the navigable waters of the U.S. where the platform reefs are located. It has established requirements for all oil and gas platforms regarding the operation and maintenance of aids to navigation and other measures to insure marine safety. According to M. Boyes, Waterways Management Officer, U.S. Coast Guard, District Eleven (2005 personal communication), no vessel operator has lodged a formal complaint that any oil and gas platforms off of California created a navigation hazard. Similarly, according to G. Kasprzak, Artificial Reef Coordinator, Louisiana Department of Fish and Wildlife (2005 personal communication), no hazard complaints have been lodged by vessel operators regarding oil and gas platforms or artificial reefs in the Gulf of Mexico, where many platforms have been turned into artificial reefs. The U.S. Coast Guard's regulatory oversight will not be affected by the designation of these platform reefs as HAPC.

Comment 13:

In addition, based on comments of others, the DEIS (p. 4-13) raises a concern regarding levels of mercury in fish caught near oil platforms. Again, no scientific evidence is cited as a basis for this assertion. On the contrary, the Department of the Interior, Minerals Management Service ("MMS"), has studied the issue of mercury contamination from drilling muds in the Gulf of Mexico and reached the opposite conclusion. As the MMS states on its website: "While the issue of mercury in seafood in the Gulf of Mexico is the subject of an increasing amount of research particularly because of global and regional inputs, the results of research to date generally supports the conclusion that oil and gas platforms do not play a significant role in elevating levels of mercury in fish and other seafood." (*See*: http://www.gomr.mms.gov/homepg/regulate/environ/mercury.html). The MMS bases its conclusion, in part, on the following studies:

- Kennicutt et al. (1996) (Exhibit 10) found that total mercury is not concentrated to any greater extent in organisms living near the oil and gas platforms (less than 100 meters away) when compared to those living far away from the oil and gas platforms (over 3000 meters). From these results the scientists concluded that oil and gas platforms do not contribute to higher mercury levels in marine organisms.

- Trefry et al. (2002) (Exhibit 11) determined that concentrations of methyl mercury ("MeHg") in sediments around drilling platforms do not vary significantly with concentrations found at sites that were far from drilling. He concluded that elevated levels of MeHg around oil and gas platforms are not widespread in the Gulf of Mexico.

- The MMS Subcommittee on Mercury in the Gulf of Mexico ("MMS Subcommittee"), which was established to independently evaluate existing scientific literature on whether OCS oil and gas activities were causing mercury pollution, corroborated these findings (Creselius et al., 2002) (Exhibit 12). The MMS Subcommittee determined that high levels of total mercury around oil and gas drilling sites is directly correlated with the drilling mud weighting agent barite. However, the increase in sediment concentrations of MeHg at or adjacent to OCS oil and gas drilling sites is not directly attributable to mercury introduced with barite, and discharges at OCS oil and gas drilling sites do not create conditions that enhance the conversion of mercury to MeHg.

- Preliminary results from a study currently being conducted by the Battelle Marine Sciences Laboratory indicate that barite is only minimally soluble and that the mercury in barite is not bioavailable to marine animals. (Cimato 2005, personal communication.)

Accordingly, the available scientific evidence does not support a high level of concern regarding mercury levels.

HABITAT AREAS OF PARTICULAR CONCERN (HAPC) DESIGNATIONS FOR OFFSHORE OIL & GAS PLATFORMS IN SOUTHERN CALIFORNIA

October 5, 2004

Submitted by:

California Artificial Reef Enhancement Program (CARE)
1008 Tenth Street #298
Sacramento, CA 95814
www.calreefs.org

This paper is submitted by the California Artificial Reef Enhancement Program (CARE) in connection with the Environmental Impact Statement (EIS) being prepared by NOAA Fisheries for the designation of Essential Fish Habitat (EFH) for Pacific coast groundfish, which will be used by the Pacific Fisheries Management Council to update the EFH provisions in its Pacific Coast Groundfish Fishery Management Plan. We understand that NOAA Fisheries will be considering a number of alternatives for the designation of EFH and Habitat Areas of Particular Concern (HAPC) for inclusion in the EIS, including an alternative that would designate certain existing oil and gas production platforms as HAPC. CARE strongly supports the full evaluation of this alternative in the EIS. CARE also believes that the HAPC designations are appropriate based on the considerable evidence of habitat value, which is summarized in this report.

Background on the Existing Platforms off California:

The oil and gas industry began installing steel platforms for the development of offshore oil fields in Southern California in the late 1950's. Today, 27 platforms remain out of the original number of 34 constructed. The seven platforms no longer in service were completely removed from the seabed and disposed of onshore.

Of the remaining 27 platforms, 23 are in Federal Outer Continental Shelf (OCS) waters under leases from the U.S. Department of the Interior Minerals Management Service (MMS) and 4 are in State waters under leases from the California State Lands Commission.

The platforms are located between 1.2 and 10.5 miles from shore and in water depths from 35 to 1198 feet. The platforms are made almost entirely of structural steel tubular beams of up to 6 feet in diameter. The structures weigh from 1,000 to 70,000 tons, depending on water depth, and are very stable and long-lived.

Many of the platforms offshore California are in locations suitable as habitat for certain rockfish species, including overfished species such as bocaccio and cowcod. In addition to providing suitable habitat, most of these structures are not fished and act as de facto reserves.

The average age of the California platforms is approximately 25 years, with the last installation occurring in 1989. Although the operator determines the economic life of these platforms, the MMS estimates that all of the remaining OCS platforms will be decommissioned during the 2010 to 2025 timeframe. With a 3 to 5 year permitting process, it is possible that decommissioning planning and permitting will start within the next few years.

Current MMS regulations that govern decommissioning of offshore platforms require that the platforms be completely removed. The process of removal will completely destroy the habit that exists around these structures and kill most or all of the fishes that live there.

Criteria for Habitat Areas of Particular Concern:

EFH is defined as "those waters and substrate necessary to fish for spawning, breeding, feeding, or growth to maturity," and such "substrate" can include artificial structures underlying the water, such as oil and gas platforms. 50 C.F.R. § 600.10. Accordingly, under existing regulations it is appropriate for the EIS to include an alternative that explicitly recognizes the EFH value of the platforms by designating them as HAPC, if the structures satisfy the relevant criteria. As indicated in CARE's letter dated August 23, 2004, we believe that the HAPC designation is highly appropriate for the platforms in waters off California, based on the HAPC criteria stated in 50 C.F.R. § 600.815(a)(8):

(i) **importance of the ecological function provided by the habitat;**
The importance of the platforms to regional rockfish production is described in Love, M. S., Schroeder, D. M. & Nishimoto, M. M. (2003) *The ecological role of oil and gas production platforms and natural outcrops on fishes in southern and central California: a synthesis of information* (Minerals Management Service OCS Study MMS 2003-032) and other studies cited below. This research is ongoing, and recent findings indicate that the scope of impact of the platform habitat is greater than previously thought.

(ii) **the extent to which the habitat is sensitive to human-induced environmental degradation;**
The platform habitats are at risk for elimination due to the expected obsolescence and subsequent decommissioning of the platforms as required by current regulations. These regulations require the complete removal of the platforms, thereby destroying the habitats and killing all or most of the fish that live there.

(iii) **whether and to what extent development activities are, or will be, stressing the habitat type; and**
See (ii) above.

(iv) **the rarity of the habitat type.**
The platform habitats are unique in their size and proportions and in the fact that they provide relief through the entire water column. They also provide hard substrate that is limited in the vicinity of the platforms.

EFH determinations should be based on the best scientific information available. 50 C.F.R. § 600.815(a)(1)(ii)(B). If quantitative density or relative abundance data is available for the habitats occupied by the species at various life stages, the degree of habitat utilization can be assumed to be indicative of habitat value. Id. at § 600.815(a)(1)(iii)(B). If data regarding habitat-related growth, reproduction and/or survival by life stage are available, then habitat value should be assigned according to which habitat types support the highest growth rate, reproduction and survival. Id. at § 600.815(a)(1)(iii)(C). As indicated below, current research demonstrates the high habitat value of the oil and gas platforms for rockfish species based on these considerations.

Research on the Utilization of California Platforms by Rockfish:

Soon after the platforms were installed, it became obvious that marine life, both fishes and invertebrates, began to accumulate on and around the platforms. Operators began to periodically remove marine growth to insure platform stability. This removal process eventually became a commercial shellfish harvesting business. Recreational divers, underwater photographers, and marine scientists were drawn to the platforms by the extensive and diverse marine life.

Marine biologists began to examine the marine life in more detail starting in the 1980's, but it was not until 1995 when scientists at the Marine Science Institute (MSI) at University of California at Santa Barbara began to systematically survey the platforms. These surveys have been conducted annually with funding from United States Geological Survey (USGS), MMS and CARE (Love et al. 1999, Love et al. 2000, Love et al. 2001, and Love et al. 2003). Data on the densities of specific rockfish species (including overfished species) at specific platforms, compared to densities at natural reefs, are presented in Love et al. 2003.

MSI scientists have directly surveyed eighteen platforms and have reviewed ROV inspection tapes for five additional platforms. The overall results indicate that most of the platforms are important to rockfish species. Using both direct evidence and analogy, it is probable that a total of 23 platforms (listed in Appendix A) are important to rockfish species. The remaining four platforms (listed in Appendix B), while harboring numerous other fish species, are probably less important to rockfish. Key findings from this research which relate to the group of 23 platforms is summarized below:

1. Although generalizations about the platforms are possible, each platform habitat has unique features due to location, water depth, water temperature, ocean currents, platform configuration and other variables.
2. A total of 42 species of rockfish have been identified as living around the platforms. Rockfish species dominate platforms and platform habitats.
3. Platforms provide habitat for most rockfish species that is better than or equal to natural reefs.
   - Some platforms harbor higher densities of young rockfishes than do many natural reefs.
   - Some platforms harbor higher densities of some species of adult rockfishes than do most natural reefs.
   - In general, compared to platforms, natural reefs harbor higher densities of primarily dwarf rockfish species.
4. Platforms provide habitat for several critically depleted rockfishes and lingcod:
   - Platform Gail has the highest densities of adult bocaccio and cowcod of any location surveyed in Central or Southern California.
   - Some platforms have higher densities of young bocaccio, cowcod, and lingcod than do most natural reefs.

5. Platforms act as nursery grounds for rockfishes:
   - It is probable that platforms provide habitat for recruiting pelagic stages of some rockfishes that would otherwise have perished. Some rockfishes that are recruited to the platforms appear to stay there until they reach maturity. Some rockfishes may stay for life.

This research is ongoing and continues to generate new findings. Recently the 2003 platform survey results for young-of-the-year (YOY) bocaccio were incorporated into the STATC model for fish stock assessments. It was found that, in some years, a significant number of all YOY bocaccio on the entire Pacific Coast live around the platforms. This is a surprising finding given the small scale of the platforms relative to the entire Pacific Coast. The study has been submitted for publication in a scientific journal, and details will be available for discussion once it is published. We will provide copies when available for consideration by NOAA Fisheries in preparing the EIS.

Uniqueness of Habitat:

As documented by Love et al. 1999, Love et al. 2000, Love et al. 2001, and Love et al. 2003, offshore platforms provide unique structural features that make them particularly suited for rockfish habitat. Perhaps the most obvious of these is the fact that the platforms provide relief through the entire water column. Most natural reefs in the vicinity of the platforms consist of rock features of no more than 30 feet above the sea floor. Thus, platforms are easier for larval fish to find and recruit to. Platforms also provide a variation of depths for different life stages of rockfish. Juveniles are found in the mid-waters and adults dominate the bottom. This separation may lead to lower predation rates for juveniles than on natural reefs where the different ages are in closer proximity.

Another feature of many platforms is that they provide sheltered hiding places where platform legs and cross-members near the seafloor leave small openings and crevices that suit rockfish behavior patterns. Adults are found taking advantage of this shelter where the cross-members are close to the bottom and are generally absent where there are no cross-members.

The location of the platforms in the Southern California Current put them in the path of a substantial supply of plankton. The combination of shelter and a plentiful food supply, make them well suited for rockfish habitat.

Finally, the platforms provide hard substrate in some areas where this habitat type is limited. The platform substrate has had, on average, 25 years to develop relatively undisturbed into mature, diverse and thriving reef communities that include substantial rockfish populations.

Benefits of HAPC Designation:

As the oil and gas platforms off California become obsolete, platform operators will propose decommissioning projects to meet applicable regulatory requirements. Since full removal is currently required, operators will be forced to seek permits that will result in the permanent destruction of this habitat. HAPC designation for this habitat will highlight the habitat value to the agencies leading the permitting process. A full and complete evaluation of this habitat weighed against all other factors in the decommissioning process will result in the best project decisions with a minimum of adverse impacts.

Recommendation

Based upon the best available scientific information, CARE recommends that the EIS being prepared by NOAA Fisheries for Pacific groundfish EFH include full evaluation of an alternative for the designation of the 23 platforms listed in Appendix A as Habitat Areas of Particular Concern for rockfish species. As new information becomes available through ongoing studies, our recommendation may be revised to add or delete individual platforms.

The four existing platforms off California that are excluded from this recommendation all have extensive marine life and provide habitat to many fish species. However, at this time, they are not known to be important to rockfish. See Appendix B.

Santa Barbara, California 93106
E-mail address: (for M. S. Love): love@lifesci.ucsb.edu

Abstract.—In 1996 we surveyed the fishes living on and around seven offshore oil platforms in the Santa Barbara Channel area. We conducted belt transects at various depths in the midwater and around the bottoms of each platform using the research submersible *Delta*. The bottom depths of these platforms ranged from 49 to 224 m and the midwater beams ranged from 21 to 196 m. We found that there were several distinct differences in the fish assemblages living in the midwater and bottom habitats around all of the platforms. Both midwater and bottom assemblages were dominated by rockfishes. Platform midwaters were dominated by young-of-the-year (YOY) or juveniles up to two years old. Rockfishes larger than about 18 cm total length were rarely seen in the midwater. The fish assemblages around the bottoms of the platforms were dominated by larger individuals, primarily subadults or adults. Density of all fishes was similar between the bottoms and midwater of any given platform. However, the total biomass was much greater on the bottoms, owing to larger fish living there. There was a consistently greater number of species on the bottom than in the midwater of each platform, likely because of a larger variety of habitat types on the bottom. The fish assemblages also differed among platforms. We found significantly higher densities of young-of-the-year rockfishes around platforms north of Pt. Conception compared with those in the Santa Barbara Channel, probably because the more northerly platforms are located in the more productive waters of the California Current.

Manuscript accepted 16 August 1999.
Fish. Bull. 98:96–117 (2000).

Petroleum production has been a part of the southern California economy since the nineteenth century. The earliest drilling took place on land, but by the early twentieth century a large number of piers lined the coast, tapping into offshore oil deposits. Hazel, the first offshore oil platform, was constructed off Summerland in 1958 (Carlisle et al., 1964). At the peak of oil drilling in the early 1980s, there were 30 platforms operating in southern and central California. Currently, there are 19 platforms in operation in the Santa Barbara Channel and off Point Conception (Fig. 1).

Oil platforms provide considerable habitat for marine organisms. The earliest structures were relatively small (23 m long at the surface), newer platforms, however, are over 100 m long (MBC[1]). Sessile invertebrates (primarily mussels, barnacles and anemones) encrust the pilings and well pipes and cover the bottom to form additional habitat.

Oil platforms have a finite economic lifespan and a number of them are becoming uneconomical to operate. In 1996, four platforms were removed from the Santa Barbara Channel, although not without controversy. There is considerable debate regarding the fate of these structures. Some interest groups would like to leave part or all of them in place, claiming protection of fish habitat; others favor complete removal. Understanding the biological communities on the platforms is crucial to making rational decisions regarding the fates of these structures. In addition, research on these platforms could also address questions regarding the role that artificial reefs might play in coastal fish communities. Ultimately, this research will allow us to contrast the fish assemblages on platforms with those of nearby reefs.

Currently, very little is known about the fish fauna around these platforms. One relatively comprehensive SCUBA survey examined fish populations around two shallow inshore platforms, Hazel and Hilda, during Hazel's first three years and Hilda's first year of operation (Carlisle et al., 1964). Additional cursory surveys were conducted around these two platforms in 1970 and 1975; Bascom et al., 1976; Allen and Moore[2]). With the exception of a short-term study of fishes around platform Hidalgo using a remotely operated vehicle (ROV) (Love et al., 1994) and a survey of recreational fishing around Santa Bar-

bara Channel platforms (Love and Westphal, 1990), no other research has been published on the fishes of any California oil platform.

In 1995, we began a survey of the fishes living on and around several platforms in the Santa Barbara Channel area. The surveys were of two types: a scuba-based study in the surface waters (to 30 m) of the platforms and a submersible survey that examined the deeper sections of these structures. However, in 1995, we could not survey any platform bottoms because of inclement weather. This paper discusses the results of the 1996 deep survey.

Materials and methods

Study sites

We surveyed fish assemblages around oil platforms situated in and just northwest of the Santa Barbara Channel. Surveys were conducted around the bottom of six platforms and in the midwater of seven platforms in 1996 (Fig. 1; Table 1). The bottom depth of these platforms ranged from 49 to 224 m. The midwater depths ranged from 21 to 196 m.

The platforms are situated in an area with a complex oceanographic regime. The Santa Barbara Channel is semi-enclosed, faces east-west, and is bordered by the Northern Channel Islands on the south and the mainland on the west. It is embedded within the much larger California-Baja California coastal current regime (Brink and Muench, 1986; Hickey, 1992). Surface waters to the north and west of the Channel are typically cool because the California Current flows equatorward from high latitudes yearround and upwells in the Point Conception and Point Arguello areas during spring and summer. At the same time, the cyclonic circulation pattern in the southern California bight brings warm water flowing poleward along the coast from the east and south of the Santa Barbara Channel. In general, water is cooler and more productive in the area of Points Arguello and Conception than in the Santa Barbara Channel, particularly compared with the more eastern end of the channel.

Surveys

Using the submersible *Delta*, we conducted belt transects around each platform. The submersible maintained a speed of approximately 0.5 knots and stayed approximately 2 m from the structure. Transects were made around the bottom of the platform (from the substrata to approximately 2 m above the substrata) and around each set of cross beams to a minimum depth of about 20 m below the surface. Dives were conducted during daylight hours, between one hour after sunrise and two hours before sunset.

During the transects, researchers made their observations from the central starboard-side viewing port. An externally mounted Hi 8-mm video camera with associated lights filmed the same viewing field as seen by the observers. Observers identified and counted all fishes and verbally recorded those data on the video. All fishes within 2 m of the submarine were counted. Fish lengths were estimated by using

[1] Midwater survey only.

a pair of lasers mounted on either side of the external video camera. The projected reference spots were 20 cm apart and were visible to the observer. An environmental monitoring system aboard the submarine continuously recorded date and time, depth, and altitude of the vessel above the sea floor. After the dive, these data were overlaid on the original videotape.

Transect videos were reviewed either aboard the research vessel or in the laboratory. For each fish, we recorded 1) its species, to lowest identifiable taxa; 2) its estimated total length to the nearest cm; and 3) the microhabitat it occupied (e.g. pipe, sand, mussel shell mounds, mud). We defined young-of-year fishes (YOYs) from published estimates of size at age. Subadults are defined as juveniles in their second year up to, but not including, maturity.

During the survey at platform Gail, all greenspotted (*Sebastes chlorostictus*) and greenblotched rockfishes (*S. rosenblatti*) were inadvertently identified as greenspotted rockfish. In reviewing the videotape, it was clear that some of the individuals that were recorded as greenspotted rockfish were in fact greenblotched rockfish. In order to correct for this potential misidentification, the total number of both species was adjusted by using the proportion of greenblotched to greenspotted rockfishes (ratio=2.2) observed at platform Gail during the following year's survey (Love, unpub. data). Similar numbers of the two species combined were observed during the two years (1996: n=186,1997: n=209).

Analyses

We estimated length of those transects conducted on the bottom by first determining the submersible speed. This was done by evaluating a ten-second segment for every one minute of transect. The video was manually forwarded frame by frame and the number of 20-cm segments passing the lasers in a ten-second section was counted. The number of 20 cm segments per 10 seconds was divided by 2 to obtain speed in centimeters per second. All subsamples were then averaged to obtain mean transect speed (cm/s). The mean speed was then multiplied by the number of seconds in the transect and divided by 100 to obtain transect length in meters. The length was then multiplied by 2 m (the transect width) to obtain transect area, allowing us to present both densities (fish/m^2) and biomass (kg/m^2). Biomass was estimated for all species by using length-weight relationships derived empirically or obtained from the literature. No biomass estimates were made for species that could not be identified to the family level.

In the midwater, we could not see the lasers pass before fixed points; therefore, we could not directly measure the length of the midwater transects. Without knowledge of the length of the midwater transects, we could not calculate density or biomass per unit area as done on the bottom transects. However, we were able to estimate the length of midwater transects for use in estimating both fish density and biomass. We did this by converting density and biomass on the midwater transects from number and kilogram per minute to number and kilogram per m^2, respectively. This conversion was accomplished by calculating the equation for the regression of density in terms of number per m^2 on density in terms of number per minute for the bottom transects where both values were known (Fig. 2A). The same relationship was calculated for biomass (Fig. 2B). Given the regression equations, density per m^2 and biomass per m^2 could be calculated from number per minute and kilograms per minute. We called these calculations "estimated density" (number/m^2) and "estimated biomass "(kg/m^2).

This method of estimating transect length and hence fish density and biomass relies on the assumption that the submersible travels at the same speed in both habitats. Although we did not have data on submersible speed, every attempt was made to maintain the submersible at the same speed on all transects during the survey. However, because of debris on the bottom and water currents in the midwater, if there were differences in speed, the submersible was likely to travel slightly faster in the midwater habitats than on the bottoms. In this case, the submersible would cover more area per unit time and the true fish density in the midwater may actually be slightly lower than our estimated density. We consider the potential bias introduced by differences in submersible speed to be minor in relation to the magnitude of the observed differences in fish densities between the midwater and bottom transects (see "Results" section).

We calculated both species richness (number of species) and species diversity. We used the Shannon-Weiner diversity index (H') for all species diversity comparisons (Shannon and Weaver, 1949). We also calculated a percent similarity index (PSI) that quantifies how similar two assemblages are in terms of their species composition (i.e. the relative abundance of those species). The index ranges from 0 (no species shared) to 100% (identical composition and relative abundances). The formula for PSI is

$$PSI = \left\{\sum \min(p_{xi}, p_{yi})\right\} \times 100,$$

where, p_{xi} and p_{yi} are the proportion of the ith species in habitat x and habitat y. PSI was calculated for each pair of platform bottom assemblages.

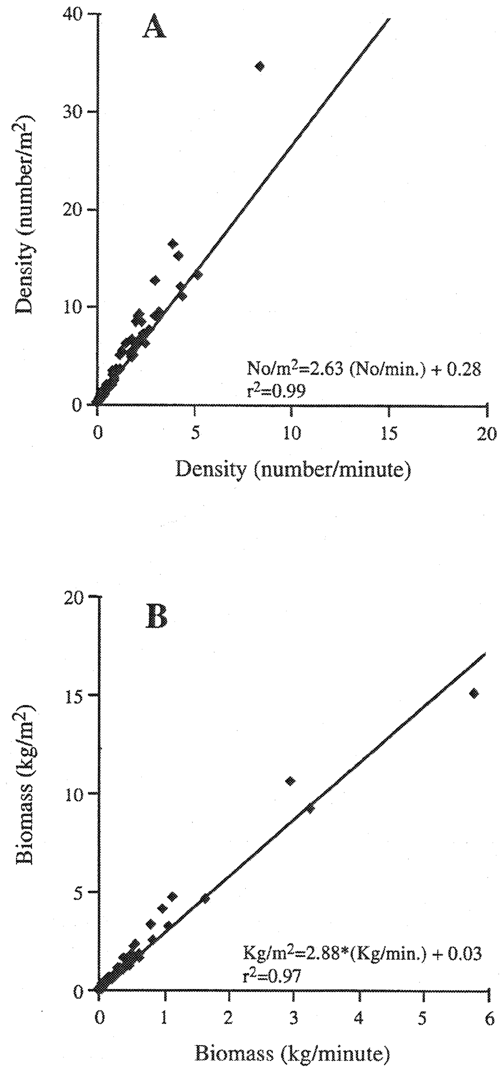

Figure 2
Regressions of (**A**) density in terms of number per minute on density in terms of number per m^2 and (**B**) biomass in terms of kilograms per minute on biomass in terms of kilogram per m^2 for bottom transects on all platforms. The regression equations were used to calculate density and biomass from number and kilogram per minute into number and kilogram per m^2 on the midwater transects. See "Methods" section for explanation of the conversion.

Results

Bottom versus midwater transects

We found that there were several distinct differences in the fish assemblages living in the midwater and bottom habitats around all of the platforms. We calculated percent similarity indices (PSI) between the bottom and midwater assemblages for each platform. These PSIs ranged from 1% to 34% (mean 13.3%). Although both midwater and bottom assemblages were dominated by rockfishes, platform midwaters were dominated by young-of-the-year (YOY) or slightly older juveniles (<10 cm). Rockfishes larger than about 20 cm were rarely seen in the midwater (Fig. 3). The fish assemblages around the bottoms of the platforms were dominated by subadults or adults (11–20 cm) and occasionally harbored very large individuals (up to 48 cm) (Fig. 3).

Average density per platform of all fishes combined was not significantly different on the bottom versus the midwater transects (bottom mean density

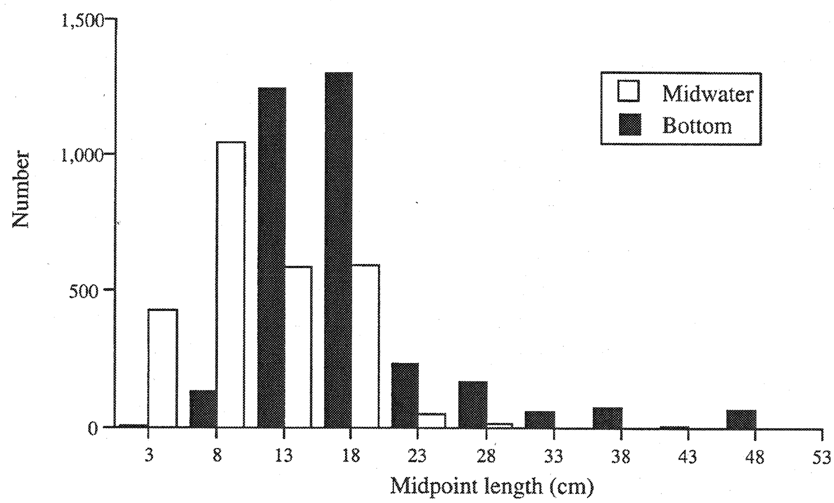

Figure 3
Length-frequency distribution for all rockfish species and all platforms combined. Midpoint length is the midpoint of 5-cm length bins.

(SE)=141.4 fish/100m^2 (49.0), n=6 platforms; midwater mean density (SE)=115.8 fish/100m^2 (32.2), n=7 platforms; t-test, t=0.44, P=0.66). On three platforms, density was higher on the bottom than in midwater and on three other platforms the reverse was true. However, there was a much larger and consistent difference in biomass between bottom and midwater transects. For most families and all platforms, total biomass was higher on bottom than midwater transects (Table 2). Average biomass per platform (SE) for all species combined was 19.06 kg/m^2 (2.5) on the bottom and 6.47 kg/m^2 (2.3) in the midwater (t-test, t=3.75, P=0.003). This consistent difference was due to the lack of adult fishes in the midwater.

Fewer species lived on the midwater structures than on the bottom. Species richness for all rigs combined was 24 in the midwater versus 40 on the bottom. Average species richness per platform was significantly higher on the bottom than in the midwater (bottom mean richness (SE)=14.7 species (1.5); midwater mean richness (SE)=8.2 species (1.4); t-test, t=3.26, P=0.008). Average species diversity (H′) across platforms was identical between bottoms and midwaters (bottom mean H′ (SE)=1.2 (0.2); midwater mean H′ (SE)=1.2 (0.2); t-test, t=0.09, P=0.99). We present the remaining results for bottom and midwater habitats separately.

Bottom habitat

All platforms We identified at least 40 fish species around the platform bottoms (Table 2). Twenty-seven species were rockfishes; they were by far the most speciose group. Rockfishes made up 92.7% of all fishes on the bottom (Table 3) and represented 96.7% of the biomass (Table 2).

Halfbanded, greenspotted, copper, vermilion, widow, and flag rockfishes, and bocaccio were among the most commonly observed rockfishes (Table 3). Our observations indicated that vermilion rockfish, flag rockfish, and bocaccio of all sizes were always closely associated with the platform structure (Fig. 4A). Larger copper and greenspotted rockfishes also were more likely to be very close to the platform. In particular, flag rockfish were most often seen tucked well into the space formed by the bottom of the lowest crossbeam and the bottom (Fig. 4B). Flag and greenspotted rockfishes were almost always seen on or very close to the bottom. Halfbanded rockfish, as well as smaller greenspotted and copper rockfishes, were less bound to the platform and were often seen well away from the structure. Juvenile greenspotted and copper rockfishes were usually nestled within or just above the mussel, shell-covered substrata. Vermilion rockfish, and to a certain extent copper rockfish and bocaccio, would occasionally ascend up platform legs as much as 5 m.

Flag rockfish, as well as larger bocaccio and vermilion rockfish, often were solitary or found in small groups. The exception occurred at platform Gail, where one school of bocaccio comprised at least 100 individuals. Smaller adult or subadult vermilion and copper rockfishes tended to aggregate, often in mixed groups containing 50 or more individuals. The few

[1] *Sebastomus* group may include greenblotched, greenspotted, pinkrose, rosethorn, rosy, starry, or swordspine rockfishes.

canary rockfish we noted tended to associate with vermilion rockfish. Halfbanded rockfish were almost always seen in schools, sometimes containing hundreds of individuals (Fig. 4C).

In the greenling family, Hexagrammidae, both lingcod and painted greenling, were common; together they represented about 5.3% of all fishes seen. Larger lingcod were solitary and tended to remain near the bottom of the platform (Fig. 4D). They were usually seen sitting motionless on the bottom or slowly swimming just above it. Juvenile lingcod rarely came within a meter of the platform, they were usually seen lying among the mussel shells away from the structure (Fig. 4E). Painted greenling sat on the crossbeams, along the pilings and on the mussel shells, always found as solitary individuals.

Among platform comparisons The bottom fish assemblages around each platform were all different (Tables 4 and 5). Pairwise percent similarity indices (PSI) for each combination of platforms ranged from 0% (platforms Gail and Holly) to 70.1% (platforms Grace and Hidalgo) (Table 4). The average percent similarity was 20.0%. Despite a low average similarity value, rockfishes, as measured by number, density and biomass, dominated the bottom assemblages around all of the platforms (Table 5). Lingcod were the only nonrockfish species among the top four most common species at any platform.

Around platform Irene, subadult and adult copper and vermilion rockfishes were most abundant. Irene also was unique among the platforms in having large numbers of juvenile lingcod. Halfbanded rockfish, painted greenling, and pile perch were also commonly seen. Halfbanded and greenspotted rockfish were most common at platform Hidalgo, along with flag rockfish, lingcod, bocaccio, and vermilion rockfish. Similar to that around Hidalgo (PSI=60%), the bottom fish assemblage around platform Hermosa was characterized by greenspotted and halfbanded rockfish, with lesser numbers of flag rockfish and lingcod (Table 4). Vermilion, calico, widow, copper, and squarespot rockfishes were most often seen at Holly, along with lesser numbers of halfbanded rockfish, pile perch, rosy rockfish, and painted greenling. Very large schools of halfbanded rockfish were observed at Grace, along with some flag, greenspotted, and vermilion rockfishes. The dominance of halfbanded rockfish at Hidalgo and Grace resulted in the highest PSI among platform pairs (70.1%). Members of the rockfish subgenus *Sebastomus*, primarily greenblotched and greenspotted rockfishes and bocaccio were most abundant at platform Gail. Gail had by far the highest number and density of bocaccio of any of the platforms.

We observed between 8 and 21 species around the bottom of the platforms (Fig. 5A). We found no significant relationship between species number or diversity (H′) and platform bottom depth (linear regression: species richness vs. depth, r^2=0.58, P=0.07, diversity (H′) vs. depth, r^2=0.19, P=0.37, Fig. 5A). Although neither relationship was significant, there was a tendency for platforms in shallower water to have both higher species richness and species diversity. Location of the platforms within the Santa Barbara Channel and Santa Maria Basin also did not explain the differences among platforms. There was no correlation between northwest to southeast orientation and either species richness or diversity (Spearman rank correlation: species richness vs. orientation, r_s=–0.26, P=0.6, diversity (H′) vs. orientation, r_s=–0.6, P=0.2). In fact, the two most

similar assemblages were on platforms near the geographic extremes (Hidalgo and Grace).

Density and biomass of all species combined also varied among rigs but in a pattern different from species richness and diversity (Fig. 5B). However, similar to richness and diversity, density and biomass differences could not be explained by bottom depth or by geography (linear regression: density vs. depth, r^2=0.22, P=0.35, biomass vs. depth, r^2=0.06, P=0.64; Spearman rank correlation: density vs. orientation, r_s=-0.31, P=0.54, biomass vs. orientation, r_s=-0.37, P=0.46).

Although bottom depth did not explain the patterns of abundance of all species combined, the abundance patterns of individual species did relate more strongly to bottom depth. Among the more commonly observed species, eight showed depth-related patterns of abundance (Fig. 6). Copper and vermilion rockfishes, lingcod, and painted greenling were most dense around the bottoms of some of the shallower platforms (especially platform Irene). Halfbanded and flag rockfishes were most dense on the bottoms of the middepth structures and bocaccio and greenspotted rockfish were most common at the bottom of the deeper platforms.

Irene	1.4	4.7	41.5	3.8	10.0

Midwater habitat

All platforms Rockfishes also dominated the midwater portions of the platforms, but were primarily YOYs and slightly older juveniles. Rockfishes represented 91.4% of the individuals (Table 3) and 85.9% of the biomass (Table 2) in the midwater. Although it was difficult to identify many of the smaller individuals, widow rockfish were by far the most common species, representing 35.0% of all fishes seen. It is likely that many of the small, unidentifiable YOYs also were widow rockfish. YOY bocaccio also were fairly abundant around some of the platforms and occasionally schooled with widow rockfish. Both species formed relatively tight, polarized schools, loosely associated with the pilings and crossbeams (Fig. 4F). When disturbed, the schools immediately swam inward underneath the platform structure. We also saw small numbers of what we tentatively identified as YOYs of the complex of kelp, copper, gopher and black-and-yellow rockfishes (*S. chrysomelas*). These were found in smaller, much less coherent aggregations and were more likely to move in closer to the substrata when disturbed.

Painted greenling, primarily small individuals, were the most commonly seen nonrockfish species. We often saw solitary individuals resting on the crossbeams. Other species occasionally seen near or

Table 5

Number, densities, and biomasses of fishes observed around the bottoms of six oil platforms off central and southern California. Platforms are listed geographically, from northwest to southeast. Species are ranked by number observed. YOY means "young-of-year." We computed minimum number of species by assuming that each unidentified taxa (flatfish, poacher, ronquil and seaperch) represented one species.

[1] *Sebastomus* group may include greenblotched, greenspotted, pinkrose, rosethorn, rosy, starry, or swordspine rockfishes.

on midwater structure included juvenile greenspotted and flag rockfishes, as well as sharpnose seaperch, pile perch, and blacksmith.

Among platform comparisons The midwater assemblages also differed among rigs, although the variability was less than among the bottom assemblages. Species richness ranged from 6 to 11 species per platform (Fig. 7A). Species diversity also showed less variability among platform midwaters than platform bottoms (midwater H' range: 0.7 to 1.8, Fig. 7A).

The midwater around platform Irene was dominated by widow rockfishes (primarily YOYs, but also one-year-old fishes), unidentified YOY rockfishes (probably primarily widow rockfish) and YOY bocaccio. Almost no other fishes were noted (Table 6). The species composition at platforms Hidalgo and Harvest was similar to that at platfrom Irene, although painted greenling were also occasionally seen. Far fewer fishes were noted at platform Hermosa, although the species composition was similar, with the addition of small numbers of Pacific hake. Fewer fishes were seen at platform Holly. Here, YOY rockfish (probably widow rockfish), painted greenling, sharpnose seaperch and squarespot rockfish were the most common species. Smaller numbers of juvenile widow rockfish, YOY rockfish, and juvenile chilipepper characterized platform Grace. We saw fewest fishes in the midwaters around platform Gail where YOY rockfish (again probably widow rockfish) were the most common.

In general, the platforms at the western end of the Santa Barbara Channel harbored a higher density of fishes in the midwater than did those towards the east (Fig. 7B). There was a significant relationship between density and northwest-southeast rank (Spearmans r_s=0.89, P=0.006). This pattern was due to higher density of YOY rockfishes, especially widow rockfish and bocaccio, at platforms Irene and Hidalgo. YOY rockfishes were abundant only at Irene and Hidalgo, they were much less common at the platforms farther east. There was not a significant relationship between biomass and northwest-southeast rank (Spearmans r_s=0.64, P=0.11).

Length-frequency comparisons

Relatively few species were abundant in both the midwater and bottom assemblages. For those species that were found in both environments, such as copper, flag, and greenspotted rockfishes, there was a tendency for juveniles to be found in the midwater and older individuals on the bottom. Bocaccio were the extreme example, with smaller juveniles occurring only in midwater and larger individuals only on the bottom (Fig. 8). The painted greenling was one of the few species that occurred in virtually all size classes in both the midwater and on the bottom (Fig. 8).

There were considerable differences in the size frequencies of the major species around the platforms (Fig. 8). Some species, such as copper rockfish and vermilion rockfish, were found primarily as juveniles and subadults. At the extreme, we did not identify any mature widow rockfish. Numerous other species (i.e. painted greenling, bocaccio, greenspotted rockfish,

flag rockfish, and halfbanded rockfish) were found over a wide size range, encompassing most life stages. Although a wide size range of lingcod was observed, it is noteworthy that most of the small fish were found around platform Irene; relatively few of these young individuals inhabited the other platforms.

Discussion

Although we found large variability in many of the attributes of the fish assemblages living around these seven oil platforms, several consistent patterns were evident. Around all of these structures, the midwater fish assemblage was quite different from that inhabiting the platform bottoms. Juvenile rockfishes were by far the dominant group occupying the midwater. Although the density of all species combined was similar between the bottom and midwater of any given platform, the biomass was much greater on the bottom, owing to larger fish living around the bottom. In addition, there was a consistently greater number of species on the bottom than in the midwater around each platform. The bottom of the

bination with the wells, crossbeams, and pilings provide a greater degree of habitat complexity and thus, may allow a greater number of species to coexist.

Platforms north of Pt. Conception in the Santa Maria Basin contain far more YOY rockfishes than those in the Santa Barbara Channel to the south. This geographic difference is almost certainly due to the difference in water masses of the two areas. Platforms north of Pt. Conception are more exposed to the California Current; those south of the Point are more influenced by Southern California Bight water (Brink and Muench, 1986; Hickey, 1992). There is considerable evidence that, within much of the Southern California Bight, juvenile rockfish recruitment has been poor for a number of years (Stephens et al., 1984, 1994; Love et al., 1998), probably due to decadal-long changes in oceanographic conditions. Since the late 1970s, waters off Southern California have warmed significantly and upwelling has declined. This situation has led to reduced zooplankton production (Roemmich and McGowan, 1995) and a reduction in the survival of many marine fish species in early life stages (Holbrook and Schmitt, 1996). The present regime is probably part of a long-term

Table 6

Number, densities, and biomasses of fishes observed on the midwater transects of seven oil platforms off central and southern California. Platforms are listed geographically, from northwest to southeast. YOY means "young-of-year." We computed minimum number of species by assuming that each unidentified taxa (flatfish, poacher, ronquil, and seaperch) represented one species. Both density and biomass on midwater transects are estimates calculated from transect minutes (see text for explanation of the conversion).

alternation of warm- and cold-water conditions that have occurred over millennia (MacCall, 1996).

Previous surveys of rockfishes at the two most inshore platforms of the Santa Barbara Channel, Hilda and Hazel, provide some evidence for the plasticity of rockfish populations in the Santa Barbara Channel. In the late 1950s, Carlisle et al. (1964) found large numbers of bocaccio and olive, copper, and brown rockfishes. Most of these fishes were either YOYs or older juveniles. By 1975, olive and brown rockfishes were still abundant, but bocaccio and copper rockfishes were uncommon (Bascom et al., 1976). In this latter survey, blue rockfish, not reported by Carlisle et al. (1964), were abundant.

Thus, we believe that the relative dearth of juvenile rockfishes around Southern California Bight platforms is not a permanent condition but represents a fluctuating system. It is likely that as oceanographic conditions in the Southern California Bight become more favorable to rockfish recruitment, offshore platforms in the Santa Barbara Channel may well harbor far greater numbers of juvenile rockfishes than at present. In fact, indirect evidence implies that juvenile rockfishes were at one time far more abundant around southern California platforms. This conclusion comes from observations we made in the mid-1970s, a period of relatively strong juvenile rockfish recruitment off California (Love and Westphal, 1990). During that period, we observed a significant recreational fishery directed at juvenile widow rockfish and bocaccio (and to a certain extent olive and blue rockfishes) at platform Holly, as well as at a number of other Santa Barbara Channel platforms. We estimate that tens of thousands of these YOY and 1- and 2-yr-old fishes were caught over the course of about three years.

The absence or relative rarity of such common nearshore species as kelp bass (*Paralabrax clathratus*), opaleye (*Girella nigricans*), black seaperch (*Embiotoca jacksoni*), and white seaperch (*Phanerodon furcatus*) from the upper waters was particularly striking. This is in contrast to the inshore platforms and reefs of this area that harbor many of these species (Carlisle et al., 1964; Ebeling et al., 1980; Schroeder[3]). A most important cause for the absence of nearshore species is the isolation of these offshore structures; relatively deep water separates them from the mainland. This distance may effectively cut these species off from source populations of many shallow-water species. Thus, it may be difficult for the young of many species to either reach these platforms or become established there. Seaperches are viviparous and produce fully developed

Length-frequency distributions of nine common species on midwater and bottom transects on all platforms combined. Midpoint length is the midpoint of 5-cm length bins.

young that do not disperse widely, making it unlikely that they commonly find their way to platforms. Kelp bass and opaleye produce pelagic larvae and although it is likely that some may settle to the platforms, conditions at these structures may preclude their survival after settlement. Young opaleye seem to require quiet intertidal waters and kelp bass YOY may need algae or thick benthic turf to avoid predation (Carr, 1994; Stephens[4]). Both of these conditions are lacking at platforms. Moreover, in the study area kelp bass recruitment is only sporadic and may not have occurred in the recent past. Thus, strong currents and lack of suitable habitat around platforms may reduce the amount of successful recruitment of these and other nearshore species.

A few species, notably painted greenling, do seem to be well adapted to a substrate-associated life in the midwaters. Judging from the very small individuals we observed, it is likely that larvae of this species recruit directly to the platform and settle out in the shallower portions. We saw a wide range of sizes, from newly settled individuals to adults, sitting on the crossbeams and hanging vertically on the pilings. Other than painted greenling, only a few juvenile flag, greenspotted, copper, swordspine, gopher, and rosy rockfishes were seen sitting on the platform in midwater.

Although juvenile rockfishes dominated the platform midwater, for some species platform bottoms tended to harbor a wider range of life stages. For some rockfishes (such as copper and greenspotted rockfishes), the entire range of stages from YOY to adults were present. In these species, the smaller individuals tended to live somewhat away from the legs and crossbeams and more among those parts of the mussel shell mounds a few meters from the platform. Although juvenile vermilion rockfish were common on several of the shallower platforms, we saw no YOYs around any of these structures. Vermilion rockfish tend to settle out in the nearshore, relatively shallow waters, and it is likely that even the shallowest of the surveyed platforms were situated in waters too deep for successful recruitment. This supposition was born out in our SCUBA diver surveys of platform Gina, located off Port Hueneme, southern California. Platform Gina is located in waters about 33 m deep. Divers have surveyed the entire structure and on several occasions have noted YOY vermilion rockfish at the bottom of the platform.

The situation with lingcod is particularly interesting. Including observations from all platforms, we observed all life stages from YOYs to large adults. However, almost all the young fish lived around platform Irene, in relatively high densities. From the lengths of these animals (Miller and Geibel, 1973), we determined that these fish were either YOYs or one-year-olds. We noted that most were sitting in the mussel shells on the bottom slightly away from the structure. In an underwater survey that encompasses seven platforms and 61 natural reefs in central and southern California, we have never encountered juvenile lingcod densities approaching the levels noted around platform Irene. Similar submersible research farther north, off Big Sur-Monterey (Yoklavich[5]) and Alaska (O'Connell[6]) also implies that such aggregations are very rare. The aggregation around Irene may also be relatively stable because we saw similar high densities in the subsequent 1997 survey. It is unclear what attracts young lingcod to this location. A large juvenile aggregation was noted off Big Sur on a sandy bottom covered with ripple marks (Yoklavich[4]). Perhaps young lingcod seek out substrate with at least some vertical relief and, at Irene, mussel shell mounds provide this type of relief.

Many bottom fishes tended to be patchily distributed around individual platforms. This is particularly true of the aggregating species, such as bocaccio and vermilion and halfbanded rockfishes. Whether this is in response to current pattern, variations in platform structure, or to other parameters is not clear at this point. We have also observed a tendency for small individuals, such as halfbanded rockfish or juvenile greenspotted rockfish, to be found away from larger, presumably predacious, individuals. Smaller fishes also tend to be found farther away from the platform, again probably to avoid the larger fishes nestled in the structure.

Fishing pressure is intense over most of the natural reefs in southern California and platforms may act as refuges for rockfishes and lingcod. An example is the relatively high numbers of bocaccio living around platform Gail. Historically, bocaccio were very important recreational and commercial fish along all of California and owing to a combination of over-fishing and poor juvenile recruitment, their populations have drastically decreased (Ralston et al., 1996). Our survey of the fish assemblages of 61 natural reefs off southern and central California shows that platform Gail has by far the highest density of adult bocaccio of all of these sites (10.5 fish/100 m^2 on platform Gail

compared with 4.4 fish/100 m^2 on the highest density natural reef). The reef was located on the northern side of the passage between San Miguel and Santa Rosa islands. The average density of bocaccio across all natural reefs surveyed in 1996 was only 1.26 fish/ 100 m^2. The large numbers of bocaccio around Gail may reflect the minimal fishing pressure around this platform. Fishing by recreational or commercial vessels near platforms is generally discouraged by platform operators. In addition, because larger fishes tend to live close to or inside the platforms, they are difficult to catch because the habitat close to or inside the platforms eludes most fishing gear.

We realize that the data presented in this paper represent a "snapshot" in time and thus issues of seasonality or interannual variation in assemblage structure remain to be addressed. Longer-term surveys of the fish fauna on two platforms in the Gulf of Mexico as well as one in the Santa Barbara Channel showed considerable diel and seasonal variation in the number of species present (Carlisle et. al 1964; Hastings et. al. 1975). In addition, monthly SCUBA observations on one shallow-water platform indicate that there may be large temporal changes in assemblage structure (Schroeder[2]). Despite this, the differences we observed in fish assemblages among and within platforms suggest that each platform may have unique characteristics.

There has been considerable discussion regarding the role of artificial structures in aggregation or enhanced production of marine species (or both) (Carr and Hixon, 1997). Based on this study, it appears that oil platforms may serve to do both. First, large adult fishes of several species were present on several platforms where no juveniles of those species had previously been observed, e.g. vermilion rockfish. It appears that those adults may have settled away from the platforms and migrated to them at some life stage. On the other hand, several platforms had very large numbers of very young fish that presumably settled to the platforms directly from the plankton, e.g. widow rockfish. If we assume that some of these young fishes would not have found appropriate settling habitat, then platforms, at least in the short term, do play some role in enhancing production. To ultimately assess the role of platforms in production of reef fishes, it will be necessary to understand the fate of the young fish settling to them.

Acknowledgments

We would like to thank Bob Lea, Mary Nishimoto, Donna Schroeder, Rick Starr, and Mary Yoklavich, all of whom were instrumental in helping us collect data. We would also like to express our appreciation to the crew of the RV *Cavalier*, Douglas Morse, Jonathan Blackman, Don Chesnut, Don Tondro, Nancy Stewart, Erik Kohnhorst, and the pilots of the submersible *Delta*, Chris Ijames, and Dave Slater, for their very professional handling of the technical aspects of this survey. Lyman Thorsteinson was, as always, extremely supportive and we thank him. This research was based on an information need identified by the Minerals Management Service's Pacific OCS Region and funded through the U. S. Geological Survey Biological Resources Division's National Offshore Environmental Studies Program (1445-CA-0995-0386).

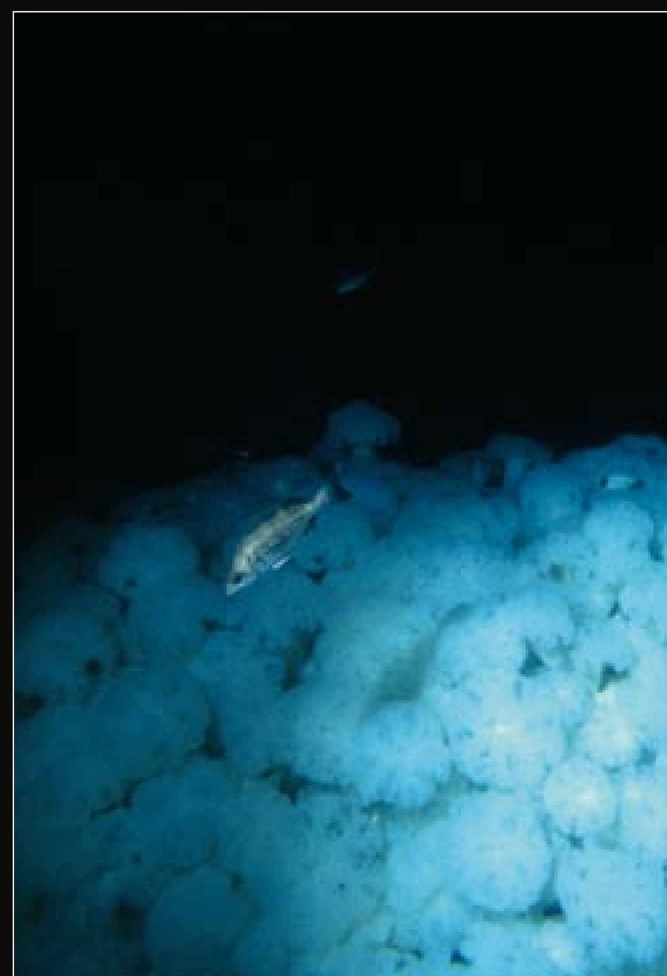
Mexican rockfish at bottom of Platform Gail.



EXECUTIVE SUMMARY

Information Needed

Production of oil and gas from offshore platforms has been a continual activity along the California coast since 1958. There are 26 oil and gas platforms off California, 23 in federal waters (greater than 3 miles from shore) and 3 in state waters. The platforms are located between 1.2 to 10.5 miles from shore and at depths ranging from 11 to 363 m (35–1,198 ft.). Crossbeams and diagonal beams occur about every 30 m (100 ft.), from near the surface to the seafloor. The beams extend both around the perimeter of the jacket and reach inside and across the platform. The beams and vertical pilings (forming the jacket) and the conductors on all platforms are very heavily encrusted with invertebrates and provide important habitat for fishes. The seafloor surrounding a platform is littered with mussel shells. This "shell mound" (also called "mussel mound" or "shell hash") is created when living mussels, and other invertebrates, are dislodged and fall to the seafloor during platform cleaning or storms.

Once an industrial decision is made to cease oil and gas production, managers must decide what to do with the structure, a process known as *decommissioning*. Platform decommissioning can take a number of forms, from leaving much, or all, of the structure in place to complete removal. Along with the platform operator, many federal and state agencies are involved in the decommissioning process. All oil and gas platforms have finite economic lives and by the beginning of the twenty-first century, seven platforms in southern California had been decommissioned and a number of others appeared to be nearing the end of their economic lives.

Management decisions regarding the decommissioning of an oil and gas platform are based on both biological and socioeconomic information. This study addressed the need for resource information and better understanding of how offshore oil/gas platforms contributed to the fish populations and fishery productivity in the Santa Maria Basin and Santa Barbara Channel. Prior to our studies, there was almost no biological information on Pacific Coast platform fish assemblages. This necessary research involved broad scale sampling at numerous oil/gas platforms and natural reefs. Research objectives included 1) characterizing the fish assemblages around platforms and natural reefs, 2) examining how oceanography affects patterns of recruitment and community structure of reef fishes, and 3) describing the spatial and temporal patterns of fish diversity, abundance and size distribution among habitat types (e. g., platforms and natural outcrops).

Research Summary

Between 1995 and 2001, we studied oil and gas platforms sited over a wide range of bottom depths, ranging between 29 and 224 m (95 and 739 ft.) and sited from north of Point Arguello, central California to off Long Beach, southern California. However, most of the platform research occurred in the Santa Barbara Channel and Santa Maria Basin. The Santa Barbara Channel and Santa Maria Basin are situated in a dynamic marine transition zone between the regional flow patterns of central and southern California. The Santa Barbara Channel is about 100 km long by about 50 km wide (60 x 20 miles) and is bordered on the south by the Northern Channel Islands (San Miguel, Santa Rosa, Santa Cruz, and Anacapa). This area is bathed in a complex hydrographic system of currents and water masses. Generally, cool coastal waters from the California Current enter the Santa Barbara Channel through its west entrance at Point Conception. Warm waters from the Southern California Bight flow in the opposite direction into the channel through its eastern entrance. Surface waters are substantially warmer in the Bight than north of Point Conception due to less wind-induced vertical mixing, the solar heating of surface waters, and currents of subtropical waters entering from the south. The convergence of different water masses in the Santa Barbara Channel results in relatively large scale differences in physical parameters (e.g., temperature, salinity, oxygen, and nutrient concentrations) and biotic assemblages (e. g., flora and fauna).

Scuba surveys were conducted at shallow depths and submersible surveys, using the research submarine *Delta*, at greater depths. We also surveyed shallow-water and deeper-water rock outcrops, many in the vicinity of platforms. Nine nearshore, shallow-water rock outcrops, seven on the mainland and two at Anacapa Island, were monitored annually from 1995 to 2000. These natural outcrops are geographically distributed across the Santa Barbara Channel providing opportunities for spatial comparisons. In addition, we surveyed over 80 deeper-water outcrops, in waters between 30 and 360 m (100

Opposite: Juvenile widow rockfish in platform midwater. (Photograph by Lovelab, UC Santa Barbara) and 1,180 ft.) deep, located throughout the Southern California Bight and off Points Conception and Arguello. These sites included a wide range of such habitats as banks, ridges, and carbonate reefs, ranging in size from a few kilometers in length to less than a hectare in area. On these features, we focussed on hard bottom macrohabitats, including kelp beds, boulder and cobble fields, and bedrock outcrops. Most of these deeper-water sites were visited once, a few were surveyed during as many as four years and one outcrop, North Reef, near Platform Hidalgo, was sampled annually.

Most of our oil and gas platform surveys were conducted at nine structures (Platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Gilda, Grace, Gina, and Gail) located in the Santa Barbara Channel and Santa Maria Basin. Between 1995 and 2000, we conducted annual surveys on the shallow portions of these nine platforms. The shallowest of the nine platforms, Gina, was surveyed from surface to bottom depths using scuba techniques. Deep-water surveys conducted between 1995 and 2001, using the research submersible, *Delta*, studied the same platforms excluding the bottom of Gilda and all of Gina. In 1998, one submersible survey was conducted around Platform Edith, located off Long Beach. In 2000 partial submersible surveys were completed around Platforms C, B, A, Hillhouse, Henry, Houchin, Hogan, and Habitat.

Patterns in Shallow-Water Habitats

Regional and local processes influenced patterns of outcrop fish assemblages in shallow waters. At regional spatial scales, outcrop fish abundance patterns often shifted abruptly as oceanographic patterns changed, roughly defining a cool-temperate assemblage in the western Santa Barbara Channel, and a warm-temperate assemblage in the eastern Santa Barbara Channel. This distinctive spatial pattern was observed in both oil and gas platform and natural outcrop habitats. In shallow waters, there was greater variability in platform species assemblages and population dynamics compared to natural outcrop assemblages, and this was most likely caused by the greater sensitivity of platform habitats to changing oceanographic conditions. Local processes that affected fish distribution and abundance were related to habitat features, where depth, relief height, and presence of giant kelp all played important roles. On platform habitat, we found that the majority of newly settled rockfish juveniles resided at depths greater than 26 m (86 ft.), although there were differences among species.

Characterization of the Deepwater Platform Fish Assemblages

With the exception of the shallow-water Platform Gina, all of the platforms we surveyed were characterized by three distinct fish assemblages: midwater, bottom, and shell mound. Rockfishes, totaling 42 species, dominated these habitats. Fish densities at most platforms were highest in the midwater habitat reflecting the depth preferences of young-of-the-year rockfishes. Young-of-the-year rockfishes represented the most abundant size classes in platform midwaters. Platform midwaters were nursery grounds for rockfishes as well as for a few other species, including cabezon and painted greenling. The young-of-the-year of at least 16 rockfish species inhabited these waters. Settlement success was affected by oceanographic conditions. Densities of young-of-the-year varied greatly between years and platforms. Young-of-the-year rockfish densities often varied by an order of magnitude or greater among survey years and platforms. From 1996 through 1998, rockfish settlement was generally higher around the platforms north of Point Conception as compared to platforms in the Santa Barbara Channel. This finding is reflective of the generally colder, more biologically productive waters in central California during the 1980s and much of the 1990s. Colder waters in 1999 were associated with relatively high levels of rockfish recruitment at all platforms surveyed. In 2000 and 2001, juvenile rockfish recruitment at platforms in the Santa Barbara Channel remained higher than pre-1999 levels, possibly reflecting the oceanographic regime shift to cooler temperatures that may be occurring in southern California.

Subadult and adult rockfishes and several other species dominated the bottom habitats of platforms. The bottom habitat of some platforms is also important nursery habitat as, in some instances, young-of-the-year rockfishes were observed in very large numbers. In general, more than 90% of all the fishes around platform bottoms were rockfishes. Bottom depth strongly influenced the number of species, species diversity, and density of fishes living around platform bases. This is distinctly different than the pattern observed in platform midwaters. The platform base provides habitat for not only fishes but also their prey and predators.

Shell mounds supported a rich and diverse fish assemblage. As at other platform habitats, rockfishes comprised the vast majority of the fishes. The many small sheltering sites created by mussels, anemones, and other invertebrates on the shell mounds created a habitat occupied by small fishes. Many of these fishes were the young-of-the-year and older juveniles of such species as lingcod and copper, flag, greenblotched, and pinkrose rockfishes and cowcod. The adults of these species also inhabited the platform bottom.

Platform versus Reef Fish Assemblages

We compared the species composition of the fish assemblages at Platform Hidalgo and at North Reef, an outcrop located about 1,000 m (3,300 ft.) from the platform. The assemblages were quite similar, both were dominated by rockfishes. In general, the distinctions between the platform and outcrop assemblages were based on differences in species densities, rather than species' presence or absence. Most species were more abundant at Platform Hidalgo. Halfbanded, greenspotted, flag, greenstriped, and canary rockfishes, and all three life stages of lingcod (young-of-the-year, immature, adult) and painted greenling had higher densities around the platform. Five species (pink seaperch, shortspine combfish, pygmy, squarespot, and yellowtail rockfishes) were more abundant at the outcrop. Young-of-the-year rockfishes were found at both Platform Hidalgo (primarily in the midwaters) and at North Reef. Young-of-the-year rockfish densities were higher at the platform than at the outcrop in each of the five years studied. In several years, their densities were more than 100 times greater at Platform Hidalgo compared to North Reef.

Rockfishes numerically dominated the fish assemblages at almost all of the platform and hard seafloor habitats in our study. Overall species richness was greater at the natural outcrops (94) than at the platforms (85). There was a high degree of overlap in species between platforms and outcrops and differences were primarily due to generally higher densities, of more species, at platforms. In general, canary, copper, flag, greenblotched, greenspotted, greenstriped, halfbanded, vermilion rockfishes, bocaccio, cowcod, and widow rockfish young-of-the-year, painted greenling and all life history stages of lingcod were more abundant at platforms than at all or most of the outcrops studied. Yellowtail rockfish and the dwarf species pygmy, squarespot, and swordspine rockfishes were more abundant on natural outcrops.

Findings

Our research demonstrates that some platforms may be important to regional fish production. The higher densities of rockfishes and lingcod at platforms compared to natural outcrops, particularly of larger fishes, support the hypothesis that platforms act as de facto marine refuges. High fishing pressure on most rocky outcrops in central and southern California has led to many habitats almost devoid of large fishes. Fishing pressure around most platforms has been minimal. In some locations, platforms may provide much or all of the adult fishes of some heavily fished species and thus contribute disproportionately to those species' larval production.

Platforms usually harbored higher densities of young-of-the-year rockfishes than natural outcrops and thus may be functionally more important as nurseries. Platforms may be more optimal habitat for juvenile fishes for several reasons. First, because as structure they physically occupy more of the water column than do most natural outcrops; presettlement juvenile or larval fishes, transported in the midwater, are more likely to encounter these tall structures than the relatively low-lying natural rock outcrops. Second, because there are few large fishes in the midwater habitat, predation on young fishes is probably lower. Third, the offshore position and extreme height of platforms may provide greater delivery rates of planktonic food for young fishes. Most of the natural outcrops we found that had high densities of young-of-the-year rockfishes were similar to platforms as they were very high relief structures that thrust their way well into the water column.

Our research, and reviews of existing literature, strongly implies that platforms, like natural outcrops, both produce and attract fishes, depending on species, site, season, and ocean conditions. Platform fish assemblages around many of the deeper and more offshore platforms probably reflect recruitment of larval and pelagic juvenile fishes from both near and distant maternal sources, not from attraction of juvenile or adult fishes from natural outcrops. Annual tracking observations of strong year classes of both flag rockfish and bocaccio imply that fishes may live their entire benthic lives around a single platform. A pilot study showed that young-of-the-year blue rockfish grew faster at a platform than at a natural outcrop indicating that juvenile fishes at platforms are at least as healthy as those around natural outcrops.

Management Applications

In this report, we discuss the ecological and political issues that surround platform decommissioning in California, including the ecological consequences of the four platform decommissioning alternatives: (1) Complete Removal, (2) Partial Removal and Toppling, and (3) Leave-in-Place.

Complete Removal: In complete removal, operators may haul the platform to shore (for recycling, reuse, or disposal) or it can be towed to another site and reefed.

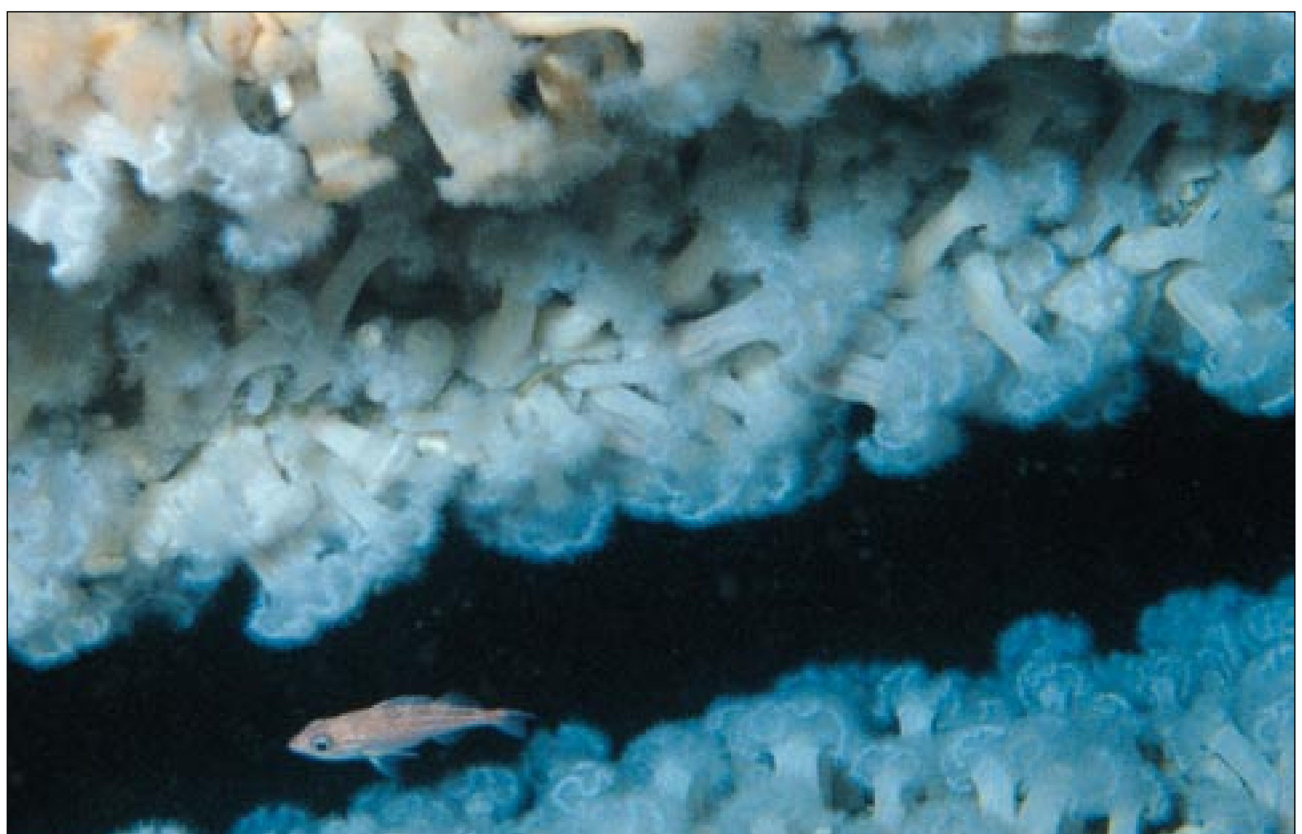
A typical full-removal project begins with well abandonment in which the well bores are filled with cement. The topsides, which contain the crew quarters and the oil and gas processing equipment, are cut from the jacket and removed and the conductors are removed with explosives. Finally, the piles that hold the jacket to the seabed are severed with explosives and the jacket is removed.

Completely removing a platform for disposal on land will kill all attached invertebrates. If some of the platform structure is hauled to a reef area and replaced in the water, some of these animals may survive, depending on water depth and the length of time the structure is exposed to the air. The explosives used to separate the conductor and jacket from the seafloor kill large numbers of fishes. In a study in the Gulf of Mexico, explosives were placed 5 m (15 ft.) below the seafloor to sever the well conductors, platform anchor pilings and support legs, of a platform in about 30 m (100 ft.) of water. All of the fishes on or near the bottom and most of the adult fishes around the entire platform suffered lethal concussions. Marine mammals and sea turtles may also be indirectly killed by damage to the auditory system.

The use of explosives to remove or topple a platform may also complicate fishery-rebuilding programs. Cowcod, a species declared overfished by NOAA Fisheries, provides an example. This species is the subject of a federal rebuilding plan that severely limits catches. In 2001, this was 2.4 metric tons or about 600 fish. Based on our research, there are at least 75 adult cowcod on Platform Gail. If explosives are used to remove Gail, all of these fish will be killed. The loss of at least 75 adult cowcod may be sufficiently large to complicate the rebuilding plan.

Partial Removal and Toppling: Under both partial removal and toppling the topsides are removed. In partial removal, the jacket is severed to a predetermined depth below the surface and the remaining subsurface structure is left standing. In toppling, the conductors and piles are severed with explosives and the jacket is pulled over and allowed to settle to the seafloor. In both partial removal and toppling, conductors need not be completely removed. Retaining conductors would add habitat complexity to a reefed platform.

While the immediate mortality impact to attached invertebrates of partial removal is greater than leaving the platform structure in place, mortality risks to both fishes and invertebrates are much lower than in both toppling and total removal. Partial removal causes fewer deaths than does toppling for two reasons. First, because partial removal does not require explosives (as does toppling), there is relatively little fish, marine mammal, sea turtle, and motile invertebrate (such as crab) mortality. In addition, when a platform is partially removed, vertebrate and invertebrate assemblages associated with the remaining structure are likely to be minimally affected. In contrast, when a platform is toppled, the jacket falls to the seafloor, and, depending on bottom depth, many, if not most of the attached invertebrates die.



*Whitespeckled rockfish and white anemones (*Metridium *sp.).*

Both partial removal and toppling would produce reefs with somewhat different fish assemblages than those around intact platforms. With the shallower parts of the platform gone, it is likely that partial removal would result in fewer nearshore reef fishes, such as seaperches, basses, and damselfishes. However, young-of-the-year rockfishes of many species recruit in large numbers to natural outcrops that have crests in about 30 m (100 ft.) of water or deeper. Thus, it is possible that partial removal would result in little or no reduction in young-of-the-year recruitment for many rockfish species. The pelagic stage of some rockfish species, particularly copper, gopher, black-and-yellow and kelp, may recruit only to the shallowest portions of the platform. For these species, both partial removal and toppling would probably decrease juvenile recruitment, depending on the uppermost depth of the remaining structure. Young-of-the-year rockfishes, which make up the bulk of the fish populations in the platform midwater habitat, would probably be less abundant around a toppled platform compared to a partially removed one. Because most California platforms reside in fairly deep water, toppled platforms might reside at depths below much rockfish juvenile settlement. Thus, toppling might result in lowered species composition and fish density. However, depending on the characteristics of the platform, a toppled structure, with twisted and deformed pilings and beams, might have more benthic complexity than one that is partially removed. This might increase the number of such crevice dwelling fishes as pygmy rockfishes.

It is difficult to catch fishes that live inside the vertically standing platform jacket. Our observations demonstrate that many of the rockfishes living at the platform bottom, such as cowcod, bocaccio, flag, greenspotted, and greenblotched rockfishes, dwell in the crevices formed by the bottom-most crossbeam and the seafloor. To a certain extent, these fishes are protected from fishing gear by the vertical mass of the platform, a safeguard that would persist if the platform were partially removed, particularly if the conductors remained in place. It would be much easier to fish over a toppled platform, as more of the substrate would be exposed to fishing gear.

Coast Guard regulations do not require a minimum depth below the ocean surface to which a decommissioned platform must be reduced. The decision on how much of the jacket and conductors is left in place is based on both a Coast Guard assessment and the willingness of the liability holder to pay for the navigational aids required by the Coast Guard. As mussels become rare below about 30 m (100 ft.) on most platforms, the mistaken assumption that all partially removed platforms must be cut to 24–30 m (80–100 ft.) below the surface has led some to conclude that this will inevitably lead to a severe reduction in the amount of mussels that fall to the bottom and, thus, to a change in or end to, the shell mound community. This is not necessarily the case.

Leave-in-Place: A platform could be left in its original location at the time of decommissioning. The topsides would be stripped of oil and gas processing equipment, cleaned, and navigational aids installed. If a platform were left in place, the effect on platform sea life would be minimal.

Pacific Coast Platforms

In this report we have also included a brief summary of information on all of the Pacific Coast platforms (Appendix 1), densities of all fishes observed at each platform during scuba and submersible surveys (Appendix 2 and Appendix 3, respectively), and a list of the 20 most important sites, both platforms and natural outcrops, for the most abundant species in our deepwater study (Appendix 4).

Research Needs

Our research demonstrates that additional biological information is needed in the decommissioning process. These information needs fall into three categories: (1) A comparison of the ecological performance of fishes living at oil platforms and on natural outcrops, (2) A definition of the spatial distribution of economically important species (of all life history stages) within the region of interest and a definition of the connectivity of habitats within this region, and (3) An understanding of how habitat modification of the platform environment (e.g., removal of upper portion or addition of bottom structure) changes associated assemblages of marine life at offshore platforms.

Major questions remaining to be addressed include:

What Fishes Live Around Platforms and Nearby Natural Reefs?

In order to assess the relative importance of a platform to its region, it is essential to conduct basic surveys not only around the platform, but also at nearby reefs. A majority of platforms have not been surveyed.

How Does Fish Production around Platforms Compare to that at Natural Outcrops?

It is possible to compare fish production between habitats by examining (1) fish growth rates, (2) mortality rates, and (3) reproductive output. A pilot study compared the growth rates of young-of-the-year blue rockfish at Platform Gilda and Naples Reef and another examining young-of-the-year mortality rates is planned. Additional work is needed to determine larval dispersal patterns and differences in densities at various study sites. For example, we now have enough data to study the relative larval production per hectare of cowcod and bocaccio at Platform Gail versus that on natural outcrops.

What Is the Relative Contribution of Platforms in Supplying Hard Substrate and Fishes to the Region?

This research would put in perspective the relative contribution of platforms in supplying hard substrate and reef fishes to their environment.

First, this requires knowledge of the rocky outcrops in the vicinity of each platform; this is derived from seafloor mapping. Once the mapping is complete, visual surveys of the outcrops, using a research submersible, will determine the fish assemblages and species densities in these habitats. Knowing the areal extent of both natural and platforms habitats and the densities of each species in both of these habitats, it is then possible to assess the total contribution of each platform to the fish populations and hard substrate in that region.

How Long Do Fishes Reside at Oil/Gas Offshore Platforms?

It is unclear how long fishes are resident to platforms. For instance, does the large number of fishes, particularly such species as the overfished bocaccio and cowcod, remain around the platforms for extended periods? Knowledge of the residence time of these species would allow us to more accurately determine if platforms form optimal habitat for these species.

What are the Effects of Platform Retention or Removal on Fish Populations within a Region?

As an example, what effect would platform retention or removal have on young-of-the-year fish recruitment? Would the young rockfishes that settle out at a platform survive in the absence of that platform? Our surveys demonstrate that planktonic juvenile fishes, particularly rockfishes, often settle to platforms in substantial numbers. If that platform did not exist, would these young fishes have been transported to natural outcrops? Knowing how long it would take rockfish larvae to reach suitable natural outcrops, and what percent of these larvae would likely die before reaching these outcrops, will give a sense of the importance of a platform as a nursery ground.

Similarly, using a synthesis of oceanographic information, it is possible to model the fate of larvae produced by fishes living at a platform.

How Does Habitat Modification of the Platform Environment (e.g., Removal of Upper Portion or Addition of Bottom Structure) Change Associated Assemblages of Marine Life?

All decommissioning options except leave-in-place involve modification of the current physical structure of offshore platforms. Is it possible to increase fish diversity and density by altering the seafloor or the platform itself? For instance, it would be useful to add complexity, in the form of quarry rock or other structure, to the shell mound around a platform, and follow the changes in fish assemblages.

Descriptive information such as depth distribution and life history information is also useful in determining how decommissioning options affect the environment. Experimental research, using a BACI design or similar approach, can aid in predicting how the biotic community will respond to such structural changes.

Chapter 1

INTRODUCTION

Milton S. Love, Donna M. Schroeder, and Mary M. Nishimoto

Goals and Objectives

Production of oil and gas from offshore platforms has been a continual activity along the California coast since 1958. All oil and gas platforms have finite economic lives and at the beginning of the twenty-first century, seven platforms in southern California have been decommissioned and a number of others appear to be nearing the end of their economic lives.

Once an industrial decision is made to cease oil and gas production, managers must decide what to do with the structure, a process known as *decommissioning*. Platform decommissioning can take a number of forms, from leaving much, or all, of the structure in place to complete removal (see Chapter 4, page 4-1). Along with the corporation that owns the platform, federal agencies that are involved in the decommissioning process include the Minerals Management Service (for Outer Continental Shelf platforms), U. S. Coast Guard, U. S. Army Corps of Engineers, National Marine Fisheries Service, U. S. Environmental Protection Agency, U. S. Occupational Safety & Health Administration. California State agencies include the California State Lands Commission (for platforms in State waters), California Regional Water Quality Control Districts (for platforms in State waters), California Coastal Commission, and California Fish and Game Commission. At the local level the County Air Pollution Control Districts and agencies such as the County Energy Division would also play a role.

Off California, three platforms, Harry (in 1974), Helen (in 1978), and Herman (in 1978) were decommissioned through complete removal without a great deal of controversy. Public debate arose over decommissioning of platforms Hilda, Hazel, Hope, and Heidi when a recreational angler's group, desiring to continue fishing on these structures, began to lobby for their retention. Ultimately, the four platforms were removed in 1996. It appears certain that future decommissioning of California platforms will be controversial because of conflicting desires regarding the fate of platforms on the part of various marine stakeholders (see Chapter 4, page 4-1).

Since 1995, our group, first funded by the Biological Resources Division of the U. S. Geological Survey, the Minerals Management Service and most recently by the California Artificial Reef Enhancement Program, has conducted research on the fishes that live around the platforms and on natural rock outcrops. Our goals have been to determine the patterns of fish assemblages around both platforms and outcrops and to identify the processes that may have generated these patterns. In addition, we are attempting to understand the linkages between habitats among different fish life history stages.

Previous Research

Decommissioning decisions in California will have a biological as well as socioeconomic and cultural component. Therefore, it is timely to summarize what is known about the biology and ecology of the fauna of these structures. Our emphasis has been on the fish assemblages.

Our research on platforms and outcrops occurred between 1995 and 2001. Before our research began, only a few fish surveys had been conducted around California platforms. Most of this work was conducted around platforms Hilda and Hazel, two shallow-water platforms off Summerland, just below Santa Barbara (Carlisle et al. 1964; Allen and Moore 1976; Bascom et al. 1976). Both of these structures were removed in 1996. Carlisle et al. (1964) found an average of about 6,000 fish under each platform. Allen and Moore (1976) estimated an average of about 20,000 fishes, occasionally reaching at least 30,000. Rockfishes, particularly young-of-the-year fishes, and sea perches dominated the assemblages, kelp and barred sand bass were also abundant. Large numbers of young bocaccio and widow rockfish living around platforms A, B, and C in the Santa Barbara Channel were tagged by the California Department of Fish and Game (Hartmann 1987). Six bocaccio were recovered as adults. All had traveled to natural outcrops, one 148 km (94 miles) away from the platforms. Love and Westphal (1990) compared fishes captured around oil platforms and at two nearby natural outcrops in the Santa Barbara Channel. Rockfishes were the most commonly taken species. Young rockfishes were most abundant at the platforms, rockfishes on natural outcrops tended to be older. A pilot survey of fishes, using a remotely operated vehicle at Platform Hidalgo and nearby natural outcrops (Love et al. 1994), identified large numbers of young rockfishes at the platform and few at natural outcrops. Benthic rockfishes were more abundant at natural outcrops.

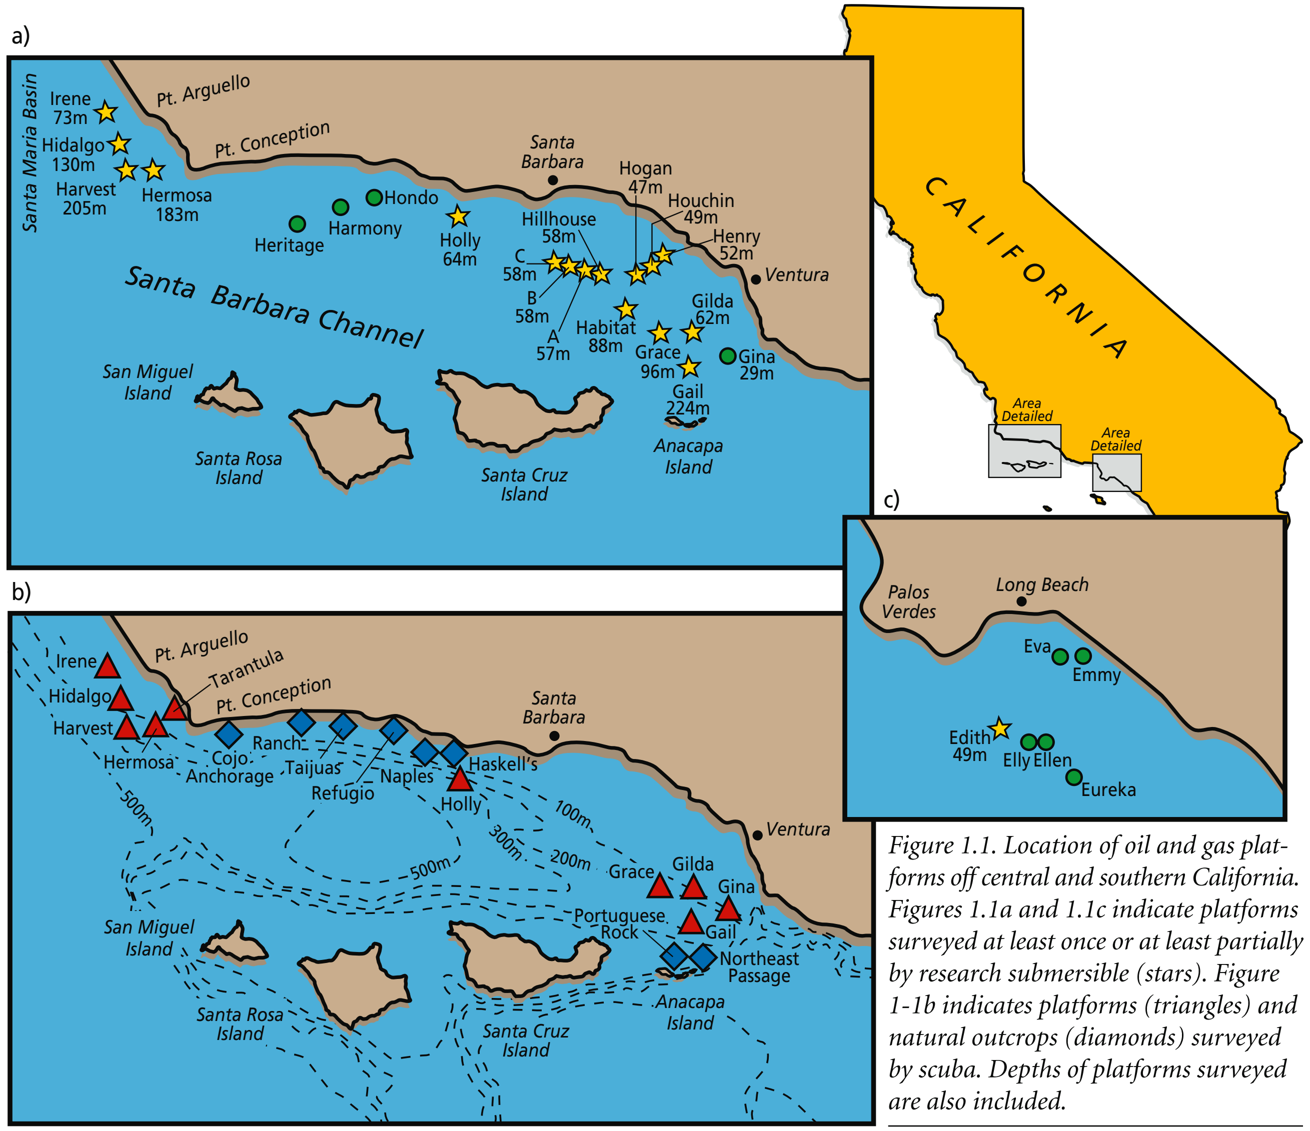


Figure 1.1. Location of oil and gas platforms off central and southern California. Figures 1.1a and 1.1c indicate platforms surveyed at least once or at least partially by research submersible (stars). Figure 1-1b indicates platforms (triangles) and natural outcrops (diamonds) surveyed by scuba. Depths of platforms surveyed are also included.

Our current research began in 1995, preliminary data is found in Love et al. (1999, 2000, 2001) and Schroeder et al. (1999) and we have incorporated that information into this report.

Study Area

Platforms

There are 26 oil and gas platforms off California, 23 in federal waters (greater than 3 miles from shore) and 3 in state waters (Figures 1.1a, b, and c). The platforms are located between 1.2 to 10.5 miles from shore and at depths ranging from 11 to 363 m (35–1,198 ft.). Information regarding location, depth, and other physical features of California's offshore platforms are described in Appendix 1.

All California platforms are similar in design (Figure 1.2); they primarily vary in size. The above-water structures, including oil and gas processing equipment and crew living and working quarters are termed the *topside* (also *topside facilities* and *deck*). The vertical pipes that carry the oil and gas are the *conductors.* The parts of the structure that are embedded in the bottom and protrude through the surface to support the topside structural components form the *jacket* that includes the crossbeams, legs, and the piles inside the legs. In general, the jackets of California platforms are made of carbon steel and the topsides are composed of steel plate and other structural steel components. Platforms also contain a relatively small amount of cement.

Crossbeams and diagonal beams occur about every 30 m (100 ft.), from near the surface to the seafloor. The beams extend both around the perimeter of the jacket and reach inside and across the platform. This web work of cross beams provides a great deal of habitat for both invertebrates

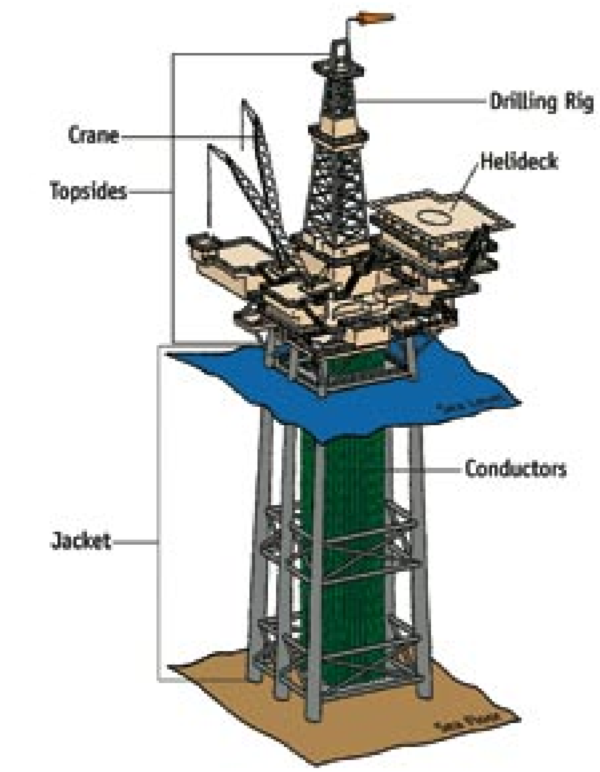

Figure 1.2. A typical oil/gas platform off southern California. Adapted from Manago and Williamson (1998).

and fishes. All of the platforms we studied have a crossbeam on the seafloor, although portions of the beam may be either buried in sediment or undercut by currents.

The seafloor surrounding a platform is littered with mussel shells. This "shell mound" (also called "mussel mound" or "shell hash") is created when living mussels, and other invertebrates, are dislodged during platform cleaning or storms. We observed shell mounds under and around all of the platforms we surveyed. Only a few of the more shallow shell mounds (around platforms Gina, Grace, Henry, and Houchin) have been accurately mapped (Sea Surveyor Inc. 2003). These mounds ranged from 4–6 m (13–19 ft.) high and were either oval or round in shape. Dimensions of these four mounds were: Gina, oval, 45 x 64 m (150 x 210 ft.); Grace, oval, 61 x 118 m (200 x 390 ft.); Henry, round, 76 m (250 ft.) in diameter; Houchin, round, 85 m (280 ft.) in diameter. Current patterns, rate of shell deposition, and age of platform all play a role in the size of shell mounds.

Rock Outcrops

An objective of our research was to compare fish assemblages and fish productivity at platforms and natural outcrops in central and southern California. Understanding spatial variability and trends in fish populations at these sites is important as it aids in understanding the regional importance of platforms as fish habitat. These sites included a wide range of such mesohabitats as banks, ridges, and carbonate buildups, ranging in size from a few kilometers in length to less than a hectare in area. On these features, we focussed on hard bottom macrohabitats, including kelp beds, boulder and cobble fields, and bedrock outcrops following standard, statistically based sampling methods and techniques.

Physical Oceanography and Biogeography of the Platform Study Area

General Description

The study area includes the Santa Barbara Channel and Santa Maria Basin (Figure 1.1). These oceanographic bodies are situated in a dynamic marine transition zone between the regional flow patterns of central and southern California. The Santa Barbara Channel is about 100 km long by about 50 km wide (60 x 20 miles) and is bordered on the south by the Northern Channel Islands (San Miguel, Santa Rosa, Santa Cruz, and Anacapa). Within the Santa

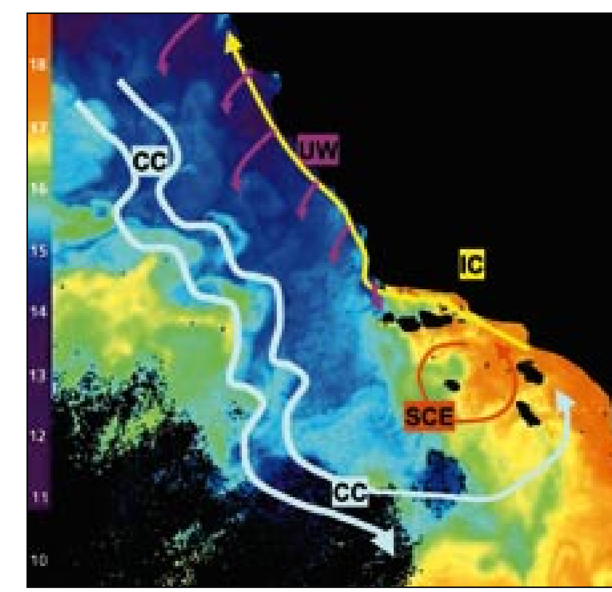

Figure 1.3. Satellite image of sea surface temperature (SST) and a diagram of the large-scale current patterns off the central and southern California coast. This image shows the predominant, large-scale SST pattern along with smaller scale features such as eddies and fronts (temperature scale, degrees Celsius). The generalized flow of the California Current (CC), the Inshore Countercurrent (IC), and Southern California Eddy (SCE) overlay the SST image. Plumes of cold, nutrient-rich, upwelled water (represented by dark blue and purple) originate near the coast and are directed offshore (magenta arrows).

The invertebrate communities of the jacket, conductors and shell mounds

DAN DUGAN

Rock crab

The jackets and conductors of all platforms are very heavily encrusted with invertebrates. Depth zonation of the invertebrate community is evident. An extremely thick layer of mussels extends from the intertidal zone to depths of at least 30 m (100 ft) (and to at least 44 m, 145 ft., on some platforms). Both *Mytilus galloprovincialis* and *M. californianus* occur in these upper depths, although *M. galloprovincialis* is more common in the shallower portions of this zone (J. Dugan, personal communication). Although mussels dominate this habitat, other invertebrate taxa are abundant in this upper layer. Common inhabitants include barnacles, seastars (primarily *Pisaster giganteus*), rock scallops (*Crassadoma gigantea*), rock oysters and jingle shells (*Chama arcana* and *Pododesmus cepio*), sea anemones (*Anthopleura xanthogrammica*, *Metridium* sp.), caprellid amphipods, rock crabs (*Cancer antennarius*), limpets (including *Lottia gigantea*, *Lottia* sp., *Tectura* spp., and *Acmaea mitra*), gooseneck barnacles (*Pollicipes polymerus*), and sessile tunicates. With greater depth, the diverse mussel community wanes and tends to be replaced by a blanket of club anemones (*Corynactis californicus*). At greater depths yet, white anemones (*Metridium* sp.) and sponges begin to dominate these platform structures. These organisms, along with crabs (*Munida* sp.) and sea stars, characterize the deepest parts of the deepwater platforms we surveyed (J. Dugan, personal communication; M. Love, unpublished observations).

Our observations indicate that, depending on bottom depth, a number of invertebrate species are abundant on the shell mounds. Common mound species include three species of seastars (*Pisaster brevispinus, P. giganteus,* and *P. ochraceus*), sunstars (*Pycnopodia helianthoides, Rathbunaster* sp.), bat stars (*Asterina miniata*), brittle stars, rock crabs (*Cancer anthonyi, C. antennarius,* and *C. productus*), king crabs (*Paralithodes rathbuni*), opisthobranchs (*Pleurobranchaea californica*), spot prawns (*Pandalus platyceros*), octopi (*Octopus* spp.), and sea anemones (*Metridium* sp.) (M. Love, unpublished observations).

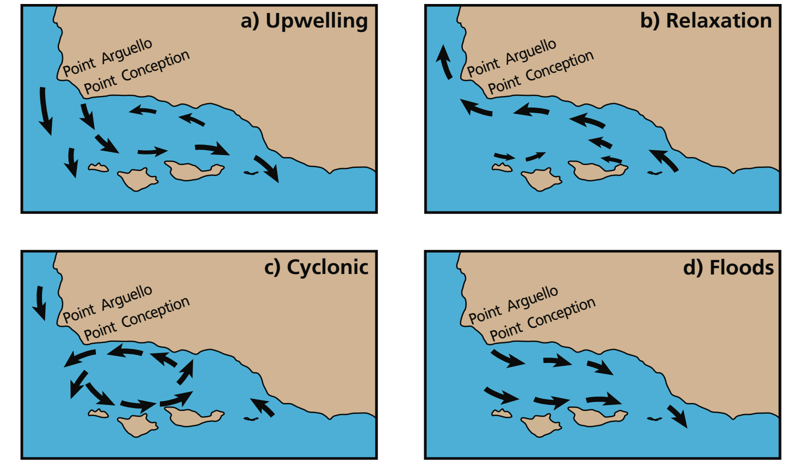

Figure 1.4. Generalized circulation patterns in the Santa Barbara Channel. (a) Upwelling; (b) Relaxation; (c) Cyclonic; (d) Flood east (shown) or west. Westward propagating train of cyclonic and anticyclonic eddies have also been observed (not shown). Adapted from Harms and Winant (1998).

Barbara Channel is a basin that is about 500 m (1,650 ft.) deep. The predominant large-scale patterns of sea surface temperature distributions off California and smaller scale, but persistent, features such as eddies, fronts (strong temperature gradients), and plumes of cold, upwelled water that extend offshore from coastal headlands are depicted in Figure 1.3. The coastal current patterns are embedded in the complex California Current System (CCS) that extends from the Strait of Juan de Fuca at the Canada-US border to the tip of Baja California, Mexico (Hickey 1998). A generalized scheme of the CCS is presented in Figure 1.3. Waters off northern and central California are typically cool because of the southerly flowing California Current offshore the continental shelf and upwelling events generated over the shelf. Upwelling, which is most intense during the spring and summer, is generated by winds that blow toward the south along the coast. Cool coastal waters enter the Santa Barbara Channel through its west entrance at Point Conception. Warm waters from the Southern California Bight flow in the opposite direction into the channel through its eastern entrance. The geographic orientation of the Southern California Bight shelters it from the winds that generate upwelling. Surface waters are substantially warmer in the Bight than north of Point Conception due to less wind-induced vertical mixing, the solar heating of surface waters, and currents of subtropical waters entering from the south (Lynn and Simpson 1987). The convergence of different water masses in the Santa Barbara Channel results in relatively large scale differences in physical parameters (e.g., temperature, salinity, oxygen, and nutrient concentrations) and biotic assemblages (e. g., flora and fauna).

Circulation in the Santa Barbara Channel is complex and highly variable (Hendershott and Winant 1996; Harms and Winant 1998; Winant et al. 1999). Santa Barbara Channel circulation typically is characterized by westward flow along the northern boundary of the Channel and eastward flow along its southern boundary (Figure 1.4). The relative strength of these opposing flows varies on scales of days to weeks and seasonally. Two opposing forces drive channel circulation: a wind gradient that is strongest in the west and a pressure gradient that is caused by higher water temperatures in the east. When these forces are balanced, a singular cyclonic (counter-clockwise rotating) eddy forms in the western channel over its central basin. Cyclonic circulation is observed to be the strongest in the summer and weakest in the winter. Unidirectional currents toward the east or west throughout the Santa Barbara Channel occur predominantly in the winter and tend to be short in duration. Throughout the year, smaller cyclonic and anticyclonic eddies, fronts, and jets are common in the Santa Barbara Channel and may be ephemeral or persistent for days to weeks. Circulation within this channel at any particular time is affected by a tendency for cyclonic flow and by the variability in the alongshelf currents that are of a scale larger than the channel.

The complex flow patterns and ocean conditions within the Santa Barbara Channel are affected by larger-scale oceanographic and atmospheric processes associated with intra-annual (e.g., storms and seasonal patterns) and inter-annual (e.g., El Niño and La Niña events) variability and interdecadal climate regime shifts. These events are teleconnected to tropical Pacific and Pacific basin-wide atmospheric phenomena. Oceanographic conditions within the Santa Barbara Channel and along the California coast at-large changed dramatically between 1997 and 1999. Strong, warm-water El Niño conditions began late in the summer of 1997 and continued into the summer of 1998. Cool-water La Niña conditions manifested in early 1999 (Lynn et al. 1998; Hayward et al. 1999). El Niño events are linked to delayed and reduced phytoplankton productivity, reduced zooplankton biomass, reduced growth and reproduction of coastal fishes, and increased mortality during their planktonic larval phase (Lenarz et al. 1995; McGowan et al. 1998; Kahru and Mitchell 2000). Our findings indicate that fish populations responded rapidly to the shift from El Niño to La Niña conditions along the coast.

Superimposed on the inter-annual variability, which include the El Niño and La Niña anomalies, are climate-ocean changes that occur throughout the entire North Pacific Basin on decadal scales. A well documented climatic shift occurred rapidly during 1976 to 1977. It was marked by abrupt changes in sea surface temperature patterns and the circulation of a predominant atmospheric feature of the northeast Pacific known as the Aleutian Low. Since that time in the northeast Pacific, macrozooplankton biomass and a number of nearshore fish stocks in the California Current system have declined (Roemmich and McGowan 1995). In 1999, a number of physical and biological changes in the northeast Pacific indicated another shift from a warm to cool regime (Bograd et al. 2000). Recruitment of young-of-the-year rockfishes to platforms in the Santa Barbara Channel was exceptionally high in 1999. The permanence of this shift to cool conditions is uncertain.

Small-Scale Oceanographic Variability within the Santa Barbara Channel

Interesting patterns of fish abundance are related to the complexity and dynamics of the hydrography and circulation within the Santa Barbara Channel. Certain aspects of our research are focussed on the biological significance of fronts and eddies to the transport and survival of early juvenile stages of marine fishes. Typically, these features are generated by local-scale interactions of wind, opposing water mass currents, and tides. This is especially true where the coastline is characterized by irregular topography and bathymetry, as is the case in the Santa Barbara Channel and the Southern California Bight (Owens 1980) (Figure 1.1). As mentioned, fronts and eddies affect how fishes are pelagically distributed in the region and may ultimately affect the timing and location of young-of-the-year settlement. For example, we sampled high densities of pelagic juvenile fishes within an eddy in the Santa Barbara Channel. The location of the eddy was determined by analysis of surface current maps generated from remote-sensing radar (Nishimoto and Washburn 2002). Furthermore, we have discovered that sea surface temperature fronts can be used to identify boundaries that separate reef habitat with high and low levels of juvenile rockfish settlement (Love, Nishimoto, Schroeder, and Caselle 1999). Mesoscale features that are visible in sea surface temperature images and surface current maps potentially can be used along with other oceanographic data to identify areas where benthic recruitment is likely.

The Santa Barbara Channel as a biological transition zone

Marine organisms from distinctively different northern and southern biogeographic communities occur in the Santa Barbara Channel as resident populations or as seasonal or occasional visitors making this a rich, biological transition zone (Horn and Allen 1978). A few examples of warm-temperate and subtropical fishes that are more common in southern California (defined as south of Point Conception) than in central California and that we have observed at platforms in the Santa Barbara Channel are Mexican rockfish, kelp bass, yellowtail, and Pacific barracuda. Examples of cool-temperate fishes that have distributions centered from central California to the Pacific Northwest and may occur at platforms include cabezon, kelp greenling, lingcod, and many rockfishes (e.g., blue, canary, widow, and yelloweye).

Methods

A major research objective of this project was to describe and compare the spatial and temporal patterns of fish assemblages around platforms and natural rock outcrops. Between 1995 and 2001, we surveyed platforms sited over a wide range of bottom depths, ranging between 29 and 224 m (95 and 739 ft.) and sited from north of Point Arguello to off Long Beach. We also surveyed shallow-water and deep-water rock outcrops, many in the vicinity of platforms. Scuba surveys were conducted at shallow depths (< 36 m, 119 ft.), and submersible surveys at deeper depths.

Most of our platform surveys were conducted at nine structures (Platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Gilda, Grace, Gina, and Gail) located in the Santa Barbara Channel and Santa Maria Basin (Figure 1.1). Between 1995 and 2000, we conducted scuba surveys on the shallow portions of these nine platforms (Figure 1.1b). The shallowest of the nine platforms, Gina, was surveyed from top to bottom using scuba. Deeper-water surveys between 1995 and 2001, using a research submersible, surveyed the same platforms excluding the bottom of Gilda and all of Gina (Figure 1.1a). In 1998, we made one submersible survey around Platform Edith, located off Long Beach (Figure 1.1c) and in 2000 we made partial submersible surveys around platforms C, B, A, Hillhouse, Henry, Houchin, Hogan, and Habitat (Figure 1.1a). Poor

water visibility prevented us from completing the surveys around the latter eight structures. Appendix 1 lists all of the platforms and includes their dimensions, depths, locations, and the years these structures were surveyed.

Nine nearshore, shallow-water rock outcrops, seven on the mainland and two at Anacapa Island were surveyed from 1995 to 2000 by scuba (Figure 1.1b). These surveyed natural outcrops are distributed across the Santa Barbara Channel region and are exposed to water masses similar to that of the surveyed oil platforms. In addition, we surveyed over 80 deeper-water outcrops, in waters between 30 and 360 m (100 and 1,180 ft.) deep (Figure 1.5). Most of these deeper-water sites were visited once, a few were surveyed during as many as four years and one outcrop, North Reef near Platform Hidalgo, was sampled annually.

Shallow Portions of Platforms and Nearshore Natural Outcrops

Scuba surveys estimated density (individuals per hectare), mean size (total length), and species composition of reef fishes in shallow portions of platforms (0–36 m, 0–119 ft. depth) and natural outcrops (6–20 m, 20–66 ft.) (Figure 1.6). Typically, we performed three surveys from July to November of each year during 1995 to 2000, although some platforms were sampled less frequently. Fish enumeration methods consisted of fish counts and fish size estimates using both visual and underwater videography methods. Visual surveys recorded fish density and size (total lengths) using underwater plastic sheets and slates. All divers performing visual counts had received training in size estimation. Additional size estimates were obtained using a Hi-8 mm video camera and laser calibration system. The visual estimates of size and relative abundance were used first in data analyses and video size data were occasionally used to supplement visual estimates.

In each platform survey, scuba divers recorded observations while swimming a pattern which incorporated all four corner legs and the major horizontal crossbeams and portions underneath the platform jacket at three different depths (Level 1 range 6–10 m, 20–33 ft.; Level 2 range 12–21m, 40–70 ft.; Level 3 range 25–36 m, 83–119 ft.) (Figure 1.7). Natural reef surveys consisted of diver observations

Figure 1.6. A scuba diver surveys fishes around Platform Gina.

collected along four haphazardly placed 30 m length x 2 m width x 2 m (100 x 7 x 7 ft.) height belt transects, two transects each at approximately 7 m (23 ft.) and 14 m (46 ft.) bottom depths corresponding to the inshore and offshore portions of the reef. Each transect included sampling of three strata: surface, midwater, and bottom portions of the water column, one above the other. Habitat measures using a random point count method (2 points/m) were taken along the same transects for characterization of physical and biological attributes. Quantified habitat features included relief height (0 to 0.1 m, 0.1 to 1 m, 1 to 2 m, and > 2 m), substrate type (sand/mud, cobble, and rock), and percent cover of sessile invertebrates and fleshy algae. We also measured the percent cover of surface canopy of giant kelp, *Macrocystis pyrifera*, and stipe density of large kelps, especially *M. pyrifera*, *Pterygophora californica*, and *Eisenia arborea*, along the transects.

Deeper Portions of Platforms and Deeper Natural Outcrops

Below scuba depths, we surveyed fish assemblages using the *Delta* submersible, a 4.6 m, 2-person vessel, operated by Delta Oceanographics of Oxnard, California (Figure 1.8). Aboard the *Delta,* we conducted belt transects about two meters from the substrata, while the submarine maintained a speed of about 0.5 knots. At the platforms, transects were made around the bottom of the platform and around each set of cross beams to a minimum depth of 20–30 m (66–100 ft.) below the surface (e. g., midwater habitat). The belt transect was also used to sample the shell mounds and natural rock outcrops. The shell mounds and outcrops were sample in consistently the same fashion as the platform method described above.

Submersible surveys were conducted during daylight hours between one hour after sunrise and two hours before sunset. During each transect, observations were taken from one viewing port on the starboard side of the submersible. An externally mounted Hi-8 mm video camera with associated lights filmed the same viewing fields as seen by the observer. The observer identified, counted, and estimated the lengths of all fishes and verbally recorded those data on the video. All fishes within 2 m (7 ft.) of the submarine were counted. Densities were calculated as fish per 100 m^2. Fish lengths were estimated using a pair of parallel lasers mounted on either side of the external video camera. The projected reference points were 20 cm (8 in.) apart and were visible both to the observer and the video camera. An environmental monitoring system aboard the submarine continuously recorded date, time, depth, and altitude of the vessel above the seafloor. The environmental data was overlaid on the original videotape upon completion of each survey.

Transect videos were reviewed aboard the research vessel or in the laboratory. Field observations were transcribed into a database. For each fish, we recorded the following

information: (1) species (if known); (2) estimated total length; (3) the habitat it occupied (e.g., rock, sand, mud, cobble, boulder); (4) its position relative to the substrate (e. g., in crevice, on reef crest, on slope, above structure); and (5) the distance of the fish from that substrate.

Midwater Trawling and Oceanographic Surveys

Recruitment, the settlement to a benthic habitat of pelagic juveniles or larvae, is an important process influencing the fish assemblages found on platforms and natural outcrops. To better understand spatial and temporal patterns of recruitment and sources of recruitment variability, we conducted annual midwater trawling and oceanographic surveys in the vicinity of the Santa Barbara Channel and Santa Maria Basin. Our goal was to describe how regional patterns of circulation and distribution of hydrographic features (such as fronts and eddies) influenced the distribution and relative abundance of pelagic juvenile fishes. Our focus on this life stage would allow emphasis on settlement and delineation of nursery habitats, including both platforms and natural outcrops.

Annual midwater trawling and oceanographic surveys were conducted from 1995 through 2000. Sampling was conducted during June to coincide with the time when the most juveniles of the early spring spawning rockfishes would be present in the water column. A modified anchovy trawl with a codend of 9 mm mesh was used to collect samples at depths between 20 m and 55 m (66–182 ft.) below the surface (Figure 1.9). Towing speed was about 2 knots, and trawling time was 15 minutes at the targeted depth. All fishing was conducted at night to minimize net avoidance. Fishes were identified to species if possible and measured in the laboratory. The shipboard surveys included vertical profiling of water properties at all trawling stations so that we could associate patterns of fish abundance with local hydrographic conditions. Salinity, potential temperature, and potential density anomaly, and dynamic height were derived from the data collected using a conductivity-temperature-depth (CTD) profiler (SBE-19, SeaBird Electronics). The CTD was lowered to 200 m (660 ft.) or to about 10 m (33 ft.) above the bottom at shallower stations. Daily satellite imagery, hourly sea surface current maps, and underway sea surface temperature observations were used to direct sampling when it was based on the location of surface circulation features such as fronts and eddies. The specific objective of each survey differed from year to year, see Love et al. (1997, 1999, 2001), Nishimoto (2000), and Nishimoto and Washburn (2002) for details. Surveys were conducted throughout the Santa Barbara Channel, in adjacent waters outside of the channel, and around the Northern Channel Islands (Figure 1.10).

Chapter 2

A BRIEF HISTORY OF OIL DEVELOPMENT IN SOUTHERN CALIFORNIA

Milton S. Love

Oil and gas seeps, often the result of geological deformation of the oil-saturated strata, are a common global occurrence. The famous La Brea tarpits, found near downtown Los Angeles, is just one of many seeps found in California. Offshore, seeps are visible on the ocean surface as oil slicks or gas bubbles. As noted by California Resources Agency (1971), "Some [seeps] remain dormant for extended periods of time and then become reactivated, probably by pressure buildup or earth movement. Because of the transient nature of many seeps, an accurate count is difficult to obtain; however, it appears that there are probably 50 to 60 seeps and seep areas on the ocean floor between Point Conception in Santa Barbara County and Huntington Beach in Orange County."

Native Americans in many parts of California, but particularly along the southern California coast, mined those land seeps that contained hard, high-grade asphaltum. The soft tar derived from offshore seeps and diverted to beaches was rarely, if ever, used. California Native Americans used asphaltum in a variety of ways. Baskets and water bottles were made watertight, arrowpoints and hook barbs attached to shafts, broken stone vessels repaired, canoes caulked and sealed and shell decorations were inlaid on various objects. The Chumash of coastal southern California melted asphaltum and mixed it with pine resin to create an effective adhesive for many of these uses.

Early European explorers noted the presence of these seeps. "The Spanish explorer Fages, in 1775, said that 'At a distance of two leagues from this mission [San Luis Obispo] there are as many as eight springs of a bitumen or thick black resin…' Fr. Pedro Font, in 1776, while near Goleta in Santa Barbara County wrote '…much tar which the sea throws up is found on the shores, sticking to the stones and dry. Little balls of fresh tar are also found. Perhaps there are springs of it which flow out into the sea, because yesterday on the way the odor of it was perceptible, and today…the scent was as strong as that perceived in a ship or in a store of tarred ship tackle and rope" (Heizer 1943).

While European settlers in California also utilized asphalt from terrestrial seeps in limited ways, primarily for water proofing and lubrication, there was relatively little interest in oil seeps until about 1850, when it became more widely known that kerosene, an excellent substitute for whale oil in lamps, could be distilled from crude oil. While Dr. Abraham Gesner, a Canadian geologist, is officially credited with inventing this process in 1849, others may also have stumbled onto this idea. In California, the first person known to use partially refined oil for illumination was General Andreas Pico, the brother of Pio Pico, the last Mexican governor of California. In 1850, General Pico distilled kerosene from oil taken from hand dug pits in Pico Canyon (near Newhall, southern California) and used it for lighting a home. By 1854, miners had excavated into Sulphur Mountain in Ventura County (southern California), were hauling out the oil that seeped into their tunnels and had set up stills to produce kerosene. Throughout the 1850 and 1860s, various companies mined seeps for petroleum and produced kerosene or kerosene-like products.

In California, the first well (as opposed to hand-dug pit) that was designed to produce oil was a failure. It was drilled in Humboldt County in 1861 and it, along with others in the same county between 1861 and 1864, came up dry. However, the first productive well, drilled in 1865, came in from this county. This was quickly followed up by successful wells in Ventura and other localities. It was not until 1876 that the first truly commercial well was developed in Pico Canyon, the site of General Pico's first pit mine. The next 20 years saw production rapidly escalate, with new fields explored and developed in a number of locations in central and southern California.

The first oil production from submarine strata in California occurred in Summerland, a sleepy village south of Santa Barbara formally founded in 1889 as a spiritualist colony. For years, Summerland residents had noted both the heavy scent of oil that frequently hung over the community and the numerous seeps that dotted their coastline. In fact, natural gas was so plentiful that when boys wanted to play baseball at night "…they would drive short pieces of pipe into the ground about four or five inches, and would light them, and there would be a gas flame at least a foot high from the top of the pipe. Fifteen or twenty of these pipes along the edge of the road gave plenty of light for them to play after dark. When they got called in to go to bed, each had a flat board, and they would whack the board down over the flame, and out it would go." (Lambert 1975).

In the late 1880s and early 1890s, several Summer-

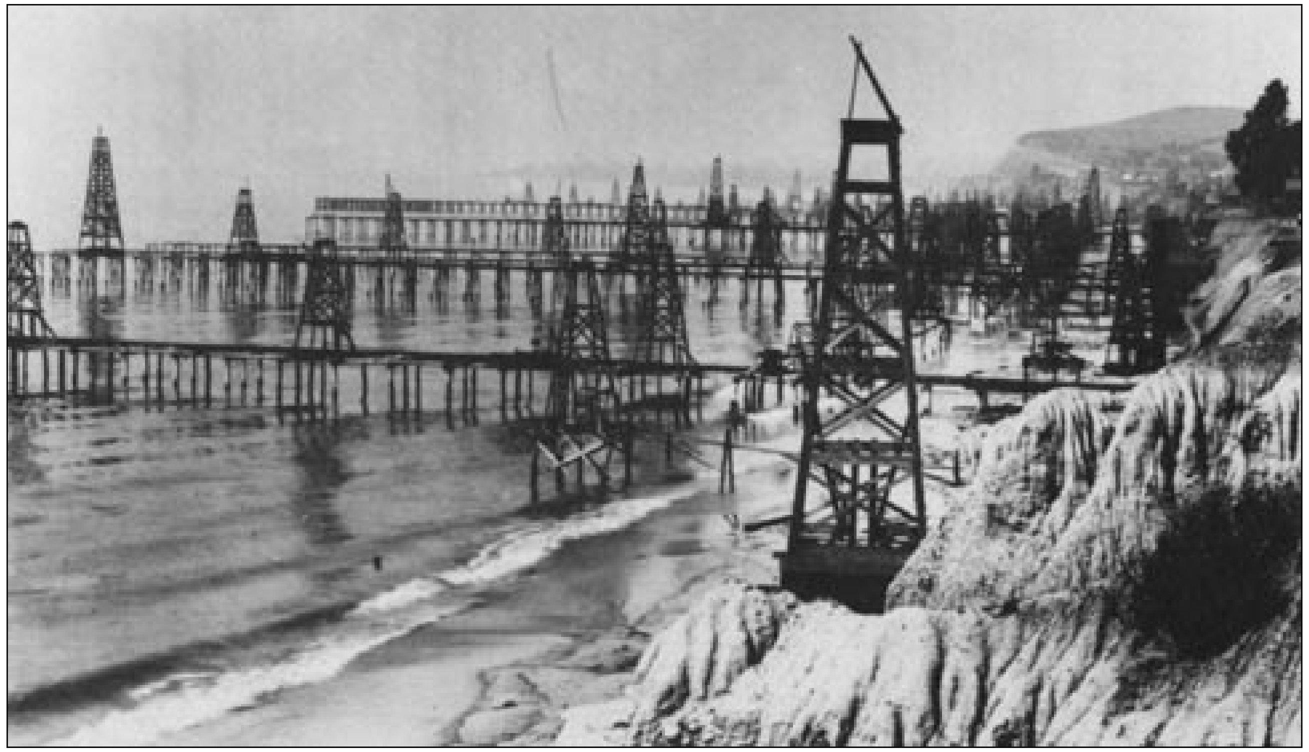

Figure 2.1. Oil piers off Summerland, California, about 1904 (from Rintoul 1990).

land residents had struck oil while digging water wells and at least one would fill barrels from a bucket, haul them by buckboard to Santa Barbara, and sell the oil to laundries. Drilling for oil just back from the ocean commenced shortly after and by 1897 both the beaches and short stretch between ocean and coastal hills were blanketed with drilling rigs. In 1896, W. L. Watts of the California State Mining Bureau reported that "It is also evident that the oil yielding formations extend south into the ocean…At low tide, springs of oil and gas are uncovered on the seashore." (Rintoul 1990).

True to the prediction, the first pier holding a well was built in 1897. This was perhaps the world's first well brought in over water, a record also reportedly claimed for the Baki (formerly Baku) (Republic of Azerbaijan) oil fields in the Caspian Sea and by Pennsylvania for drilling into Lake Erie. Within a few years there were 11 piers (harboring over 200 wells), one of them stretching 1,230 feet offshore (Figure 2.1). The Summerland piers continued to produce oil until 1939, when the last well was destroyed by high tides and high surf.

In the 1920s, a series of discoveries along the Santa Barbara Channel, particularly at Rincon (northwest of Ventura) and Ellwood and Capitan (west of Santa Barbara) led to additional offshore drilling. While all of these discoveries were made on land, development quickly extended onto piers. However, rather than being built of wood, these piers were more heavily constructed of steel pilings and reinforced concrete caissons.

The year 1932 saw the erection of the first oil platform off California and perhaps in the world. In that Depression year, the Indian Petroleum Company was faced with a dilemma. Geological evidence implied that productive oil-bearing strata lay offshore of Rincon (just northwest of Ventura). However, the costs of building a pier out to that formation were prohibitive. The company solved the problem by building part of a pier, located about 1,200 feet beyond the end of the nearest pier. Constructed of steel in 38 feet of water, the aptly named "Steel Island" was eventually home to three wells (Figure 2.2). It lasted until 1 January 1940, when "…mountainous waves battered the platform. The structure went down. There was no loss of life, but equipment was destroyed and wells damaged. Rohl-Connolly Company, marine contractors, removed equipment, derrick and steel pilings from the ocean floor; cut off casing at the floor of the ocean; and placed 6-foot cement plugs in the tops of the water strings" (Rintoul 1990).

Later oil and gas discoveries that were of importance to offshore development included those at Huntington Beach, Wilmington and Seal Beach. However, it was not until 1954, that the next step in offshore production oc-

PHOTO COLLECTION/LOS ANGELES PUBLIC LIBRARY

Figure 2.2. Built off Rincon, southern California, in 1932, the "Steel Island" was one of the first oil platforms in the world.

curred with the creation of the first man-made drilling island, "Monterey", situated 1.5 miles offshore of Seal Beach in 42 feet of water. Construction on the island commenced in 1952, but a lawsuit by the city of Seal Beach prevented drilling until 1954. The circular island "…75 feet in diameter, had an outer rim formed of interlocking sheet-steel piling driven into the ocean floor to depths of 15 to 20 feet. The interior was filled with rock and sand barged in from Catalina Island" (Rintoul 1990). In succeeding years five other oil islands (Grissom, White, Freeman, Chaffee, and Esther) were built.

Oil islands were only practical in relatively shallow waters and when industry-led seismic surveys and bottom coring discovered potential fields in deeper offshore waters, the stage was set for the development of oil platforms. In June 1958, the California State Lands Commission held its first sale of tidelands leases, ending a freeze that had held up offshore drilling on new sites. The first platform constructed was Platform Hazel, located about two miles offshore of Summerland in 100 feet of water. As noted in Rintoul (1990) regarding Hazel's construction, "In that same month, Standard [Oil] towed an imposing tower a distance of 210 miles… to the Summerland tract. The tower was 75 feet square and 170 feet high. It was a major component of Platform Hazel and was to serve as the foundation on which the 110-foot square deck would be mounted…The tower was floated to the job site on the four big caissons that formed the bottom portion of the tower's legs, each 40 feet high and 27 feet in diameter. Each caisson was pressurized to prevent leakage and also ballasted with 90 tons of sand for stability…Once on bottom, the caissons were sunk 22 feet into the ocean floor by means of high pressure water and air jets that literally hosed away the bottom sands, allowing the caissons to rest on hard ground. The final anchoring was accomplished by filling the caissons with 6,000 tons of sand

and concrete…The cost of building and installing the platform was $4 million." In September 1958, Standard Oil began drilling from the newly constructed platform and within one month the first well, bottoming out at 7,531 feet began producing 865 barrels per day. This was followed two years later by the construction of nearby Platform Hilda.

In subsequent years, a number of platforms were installed in both state and (beginning in 1967 with Platform Hogan) federal waters in southern California. However, expansion of offshore oil drilling came to an abrupt halt in 1969, with the disastrous blowout and subsequent oil spill at Platform A (installed in 1968) in the Santa Barbara Channel. And while discussion of both opposition and support for oil development are beyond the scope of this report (see Beamish et al. 1998, Nevarez et al. 1998, and Paulsen et al. 1998 for more information), it is safe to say that the subsequent environmental concerns about the safety of offshore oil exploration, development, and production delayed further drilling for a number of years. It was not until the late 1970s that installation of new platforms resumed. No new platforms have been erected since 1989 (Nevarez et al. 1998).

How do platforms get their names?

On the Pacific Coast, platform names have to conform to a set of rules promulgated by the U. S. Coast Guard. The Coast Guard created a series of zones ("15-minute quadrangles") along the Pacific Coast beginning at the U. S. – Mexican border. The names of all platforms in a zone must begin with the same letter. Platforms in the first zone, off San Diego, would begin with "A". The southern-most platforms (Emmy, Edith etc.) lie off Long Beach, in the "E" zone.

Industry personnel imply that the choice of names have often been made in a disarmingly casual way. For instance, the project engineer for Hermosa apparently named that structure after the elementary school attended by his daughter. Ellen and Elly are said to honor the wives of the engineers in charge of those platforms' construction. Hondo, meaning "big" in Spanish, was so christened because at the time it was the tallest (measured from the seafloor) of the California platforms. One story has it that, because a nearby platform was later installed to tap the same reservoir as Hondo, it was named Harmony. Hogan and Houchin were the surnames of two presidents of Phillips Petroleum.

Why do Platforms A, B and C, despite their locations in the H zone, not have "H" names? These were installed in the days before the Coast Guard regulations were mandatory.

CHAPTER 3

A REVIEW OF BIOLOGICAL AND OCEANOGRAPHIC SURVEYS: RESULTS AND ANALYSES

Milton S. Love, Donna M. Schroeder, and Mary M. Nishimoto

There was no single characteristic fish assemblage that could be described for the oil platforms and natural outcrops of central and southern California. However, we identified a number of patterns in fish diversity and abundance that corresponded to bottom depth, geographic area, and year. Depth played an important role because, in general, rockfishes numerically dominated fish assemblages around platforms and deep natural reefs, and rockfish species segregate themselves according to habitat depth. We also observed biogeographic partitioning in species composition, where northerly platforms show the influence of the Oregonian province and southerly platforms show the influence of the San Diegan province. These zoogeographic patterns were more conspicuous in shallow water fish assemblages. The large inter-annual fluctuations in juvenile fish recruitment observed during the studies may have been generated by the large inter-annual variability in oceanographic conditions (e.g., upwelling, El Niño-Southern Oscillation events). Since juveniles of many species inhabited shallow and midwater portions of oil platforms, the greatest temporal variability in fish abundance occurred at these depths.

We present more detailed summaries of fish assemblages identified by the two different survey methods (scuba and submersible) in the sections below. The common and scientific names of fishes observed in these studies are listed in Table 1.

1. Shallow Water Fish Assemblages: 0–36 m (119 ft.)

Findings at a Glance

A combination of regional and local processes influenced patterns of reef fish assemblages in shallow water. At regional scales, composition and relative abundance of reef fishes often shifted abruptly as oceanography changed. This shift delineated a cool-temperate assemblage in the western Santa Barbara Channel, and a warm-temperate assemblage in the eastern Santa Barbara Channel. This distinct spatial pattern was reflected in both platform and natural reef habitats. There was greater variability in platform species assemblages and population dynamics compared to natural outcrop assemblages and dynamics, and this was most likely caused by the offshore position and greater sensitivity of platform habitats to changing oceanographic conditions. Local processes which affected fish distribution and abundance were related to habitat features, where depth, relief height, and presence of giant kelp all played important roles. We found that the majority of juvenile rockfish recruits resided at depths greater than 26 m (86 ft.), although there were differences among species.

Except where noted, the following synopsis encompasses platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Grace, Gilda, Gail, and Gina and are based on diver surveys conducted between 1995 and 2000.

1a. General Patterns

The two primary research objectives were to (1) describe the spatial and temporal variability of shallow water (less than 36 m, 119 ft.) fish assemblages residing on oil/gas production platforms and natural outcrops, and (2) describe the relative importance of regional processes (e.g., oceanographic patterns) compared to local processes (e.g., habitat features) in generating observed patterns of reef fish assemblages. An understanding of mechanisms which structure marine populations is necessary to predict the outcome of resource management decisions related to marine fisheries, platform decommissioning, and marine protected areas on fish assemblages within the Santa Barbara Channel region (including the Santa Maria Basin). A list of species observed at each platform is given in Appendix 2.

We find that a combination of regional and local processes influenced patterns of reef fish assemblages in shallow water. At regional scales, composition and relative abundance of reef fishes often shifted abruptly as oceanography changed. This shift delineated a cool-temperate assemblage in the western Santa Barbara Channel, and a warm-temperate assemblage in the eastern Santa Barbara Channel. Rockfishes and surfperches dominated the cool-temperate assemblage, and damselfishes, wrasses, and sea chubs dominated the warm-temperate assemblage. This distinct spatial pattern was reflected in both platform and natural outcrop habitats.

Within each of the cool- and warm-temperate assemblages, local habitat features modified patterns of species abundance and distribution. For example, kelp surfperch and giant kelpfish were only observed on rocky outcrops that possessed stands of giant kelp, *Macrocystis pyrifera*. Other factors likely to have been important were outcrop or platform depth and relief height. These local scale features sufficiently decoupled sites within an oceanographic region (cool- or warm-temperate) to make broad generalizations about fish assemblages difficult, especially within platform habitats.

Temporal dynamics of reef fish assemblages also resulted from a complex, dynamic interaction between regional oceanography and local habitat features. The diverse array of oceanographic conditions that occurred during the six-year survey period appeared to strongly influence regional dynamics of fish assemblages. The 1997–1998 El Niño event corresponded to a large increase in juvenile recruitment of species which dominated the warm-temperate fish assemblage (e.g., blacksmith), while the 1999 La Niña event corresponded to a large increase of juvenile recruitment of species which dominated the cool-temperate fish assemblage (e.g., rockfishes). Severe winter storms that accompany El Niño events propagated into small-scale variability at some sites. For example, the scouring effect of severe storm waves depleted red algal turf (a forage base for small crustaceans and fish) on two shallow natural outcrops. This forage base reduction may have been the primary cause of the observed synchronous decline in surfperch abundance at the same outcrops.

1b. Shallow Water Fish Assemblages Surrounding Oil/Gas Production Platforms

As observed on natural outcrops (see Section 1d), shallow water fish assemblages surrounding oil/gas production platforms show distinct spatial patterns which correspond to oceanographic patterns in the Santa Barbara Channel. Rockfishes are numerically dominant in west channel platform fish communities, although 1999 was a strong recruitment year for juvenile rockfish at all platforms. Blacksmith and halfmoon are numerically dominant in east channel platform assemblages. Platform fish assemblages appeared to respond faster and more dramatically to changing oceanographic conditions than natural reef assemblages, perhaps due to their offshore position and higher proportion of juvenile fishes.

There were notable differences among platforms within an oceanographic region. These differences may be due to water depth in which the platform is positioned, where deeper water can inhibit species such as surfperches from migrating onto platform habitat. Among-platform differences may also be influenced by food availability or other factors. During the 1997–1998 El Niño event, juvenile blacksmith recruited onto all platforms, but did not recruit onto Tarantula Reef, the closest natural reef to west channel platforms surveyed in this study. This observation suggests that platforms may "capture" pelagic stages of some reef fish species that might have otherwise perished.

The fish assemblage observed at Platform Gina (depth 29 m, 95 ft.) is noteworthy because of its very high density of kelp bass and because of the large diversity of rockfishes that recruit to its shell mound habitat. Anecdotal observations at a nearby shipwreck did not record either of these characteristics in its local fish assemblage. High turnover of fish species diversity has also been noted at Platform Gina (Love, Nishimoto, Schroeder, and Caselle 1999).

JAMES FORTE

Kelp bass at a nearshore platform.

1c. Depth Distribution of Juvenile Fish Recruitment on Oil Platforms

For all fishes observed at all Southern California Bight platforms surveyed at shallow depths, approximately 27% were observed in the shallowest portions of platform habitat (6–12 m, 20–40 ft.). Most of these were pelagic fishes, such as anchovy and barracuda. Twenty-seven percent of all fishes were observed at intermediate depths (15–26 m, 50–86 ft.), and 46% were observed at deeper depths (27–36 m, 89–119 ft.). We observed that the majority of juvenile rockfish recruits resided at depths greater than 26 m (96 ft.) (Figure 3.1), although there were differences among species. The olive-yellowtail group and copper-complex species group (black-and-yellow, copper, gopher, and kelp rockfishes) had the largest percentages residing at shallower depths. Our observations on copper-complex rockfishes represent a somewhat different vertical distribution than that described by Holbrook et al. (2000). This disparity may be due to differences in surveyed platforms and program duration (6 platforms within one biogeographic area during 1995–7 versus 9 platforms in 3 biogeographic areas during 1995–2000). This difference underscores the importance of evaluating platforms on a case-by-case basis and in developing monitoring programs over multiple years.

Our results correspond with Holbrook et al. (2000) regarding vertical distribution of midwater juvenile rockfishes (e.g., bocaccio, blue, and widow) where the vast majority of individuals recruited to depths greater than 26 m (86 ft.). The majority of individuals of other rockfish species such as squarespot, treefish, and the *Sebastomus* subgenus (e.g., rosy, greenspotted, starry rockfishes, and others) are also found below 26 m (86 ft.). Kelp and painted greenling recruits, two species associated with the cool-temperate fish fauna, mimic the vertical distribution of rockfish recruits, preferring deeper portions. In contrast, garibaldi and blacksmith recruits, two species associated with the warm-temperate fish fauna, favor upper portions of platforms, suggesting temperature may play a role in determining depth distribution of juvenile fishes at platforms.

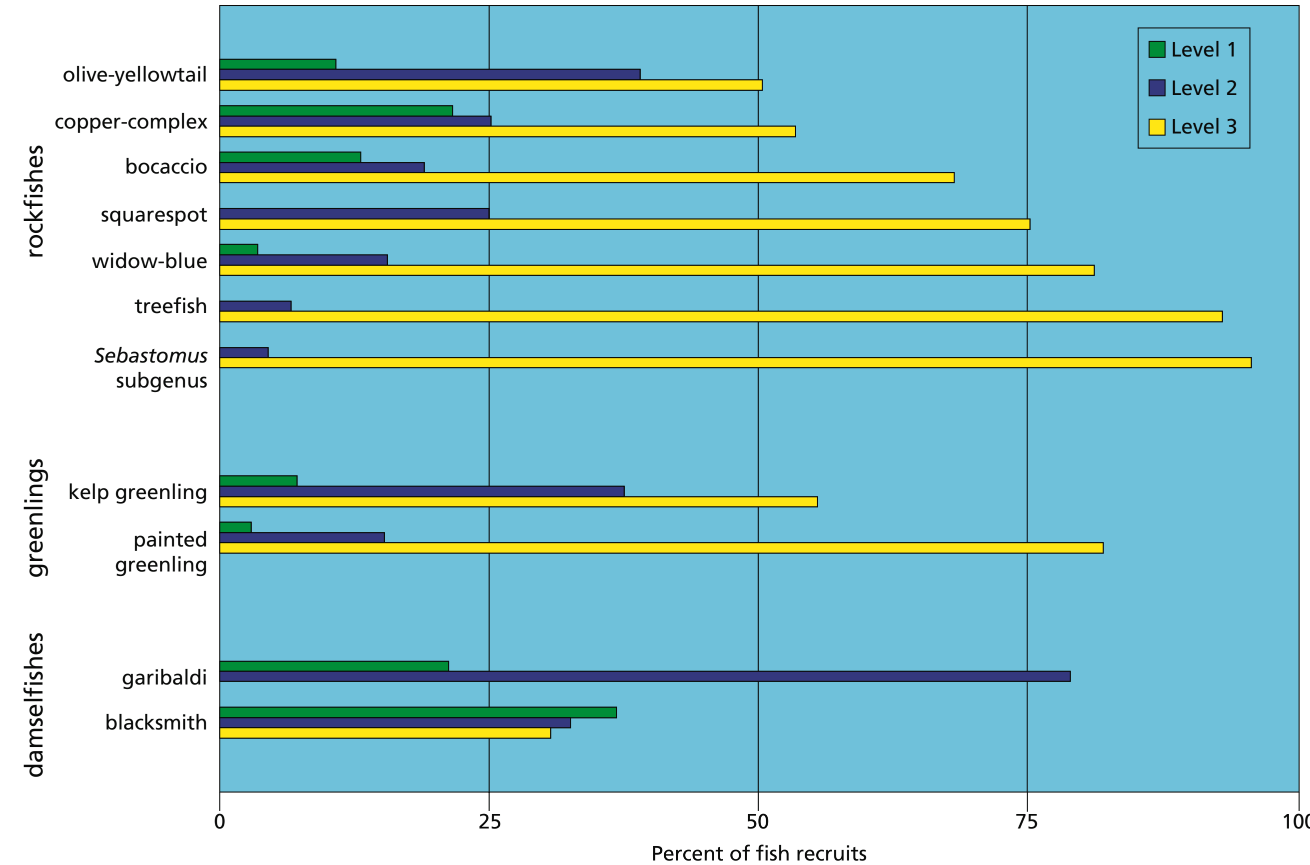

Figure 3.1. Percent of juvenile fish density observed during scuba surveys at different depths on offshore platforms during 1995–2000. Depth ranges for each strata: level 1 (6–12 m), level 2 (15–26 m), level 3 (27–36 m).

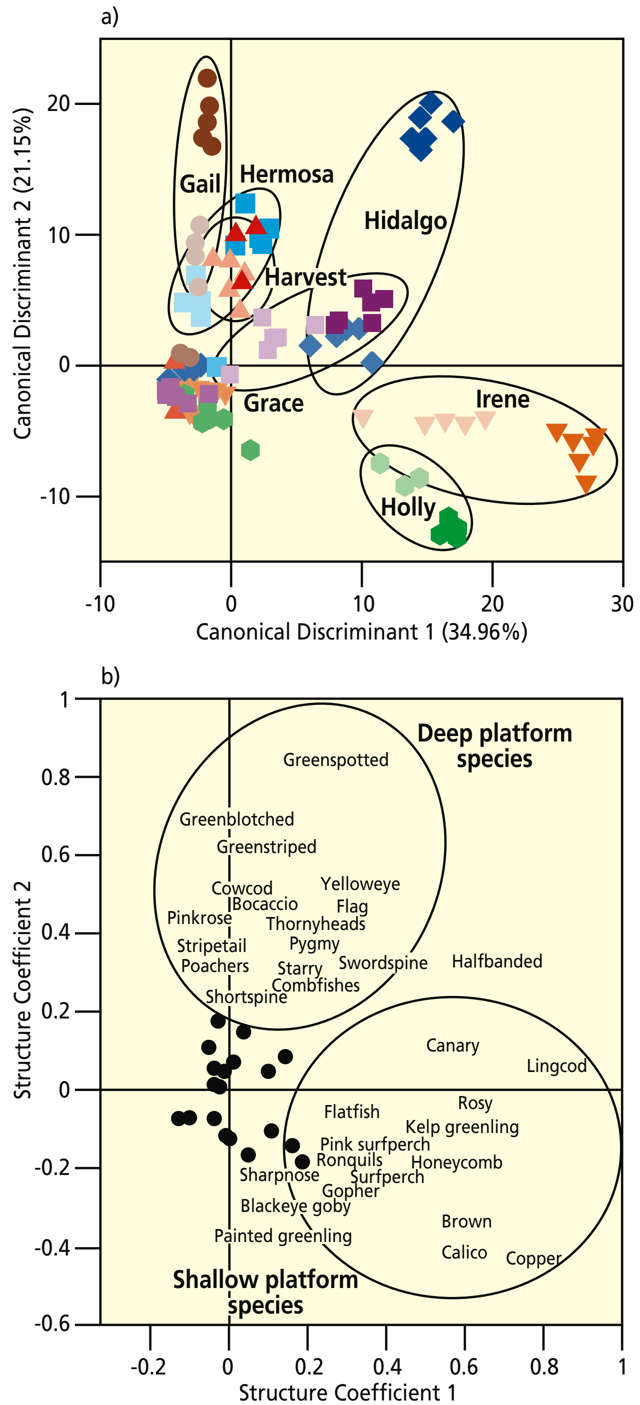
1d. Fish Assemblages on Nearshore Natural Outcrops

The relative importance of spatial versus temporal variability in structuring fish assemblages on shallow natural outcrops differed among sites. Ordination analysis revealed that natural outcrops in the west channel tended to be more sensitive to temporal variability than those outcrops positioned in the east channel. This seems intuitive since west channel outcrops are closer to areas of intense and temporally variable upwelling processes which affect mean water temperature, primary production, and dispersal processes of larvae.



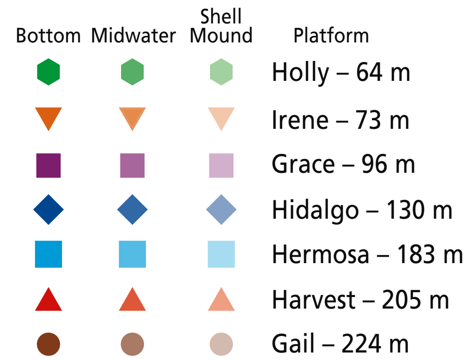


Figure 3.2. 3.2a. Canonical Discriminant Analysis of the bottom and shell mound fish assemblages at seven platforms, 1996–2001. 3.2b. Canonical Discriminant Analysis of the bottom and shell mound species found around seven platforms, 1996–2001. Two groups, one characteristic of shallow platforms, the other of deeper structures are apparent. Black dots represent species that were not strongly associated with either axis.

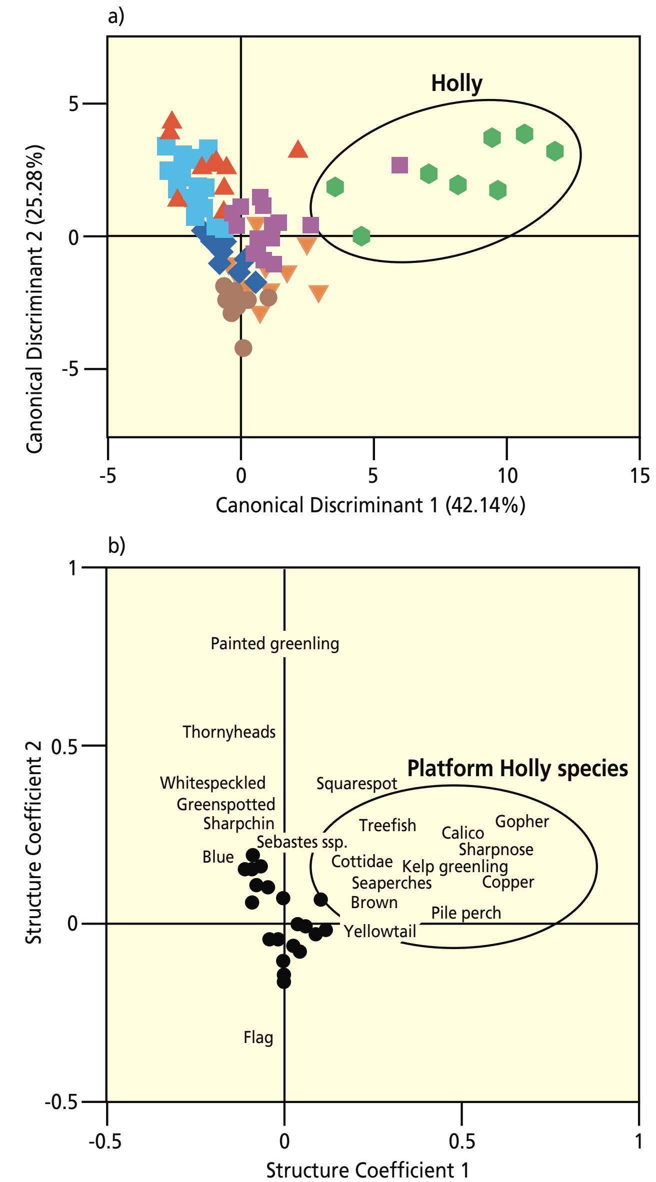
Similar to platform habitats, the fish assemblages on natural outcrops showed distinct spatial patterns that seemed to correspond to regional oceanographic patterns in the Santa Barbara Channel. Rockfishes and surfperches were important species in west channel fish communities, although 1999 was a strong recruitment year for juvenile rockfishes at most natural outcrops. Blacksmith, garibaldi, sheephead, opaleye, and rock wrasse were important species in east channel fish communities. Kelp bass, black surfperch, and senorita were abundant at all sites. Because we observed abrupt spatial changes in abundance for many species in the Santa Barbara Channel, it is tempting to attribute these patterns solely to oceanographic processes. However, habitat features may covary with oceanography, and we are currently unable to distinguish between these processes.

Dispersal of pelagic stages does not appear to be the primary factor in structuring fish assemblages. For the eight common species in the warm-temperate assemblage that have pelagic larvae, six species exhibited very low or no juvenile recruitment onto shallow rocky outcrops in the Santa Barbara Channel. This suggests that dispersal of benthic stages plays a critical role in the dynamics of reef fish communities and local temperature may be an important criterion in habitat selection. Some species important in the warm-temperate fish assemblage (e.g., kelp bass and opaleye) declined in abundance during the cold La Niña year of 1999. The response of reef fish communities to oceanographic regime shifts may be faster and less persistent than previously thought.

2. Deeper-water Platform Fish Assemblages: 31–224 m (103–739 ft.)

Except where noted, the following synopsis encompasses platforms Irene, Hidalgo, Harvest, Hermosa, Holly,



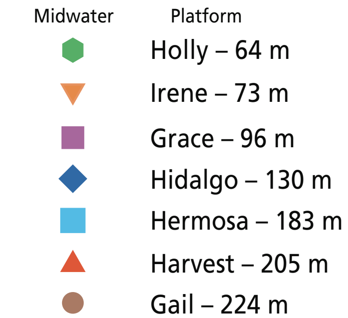


Figure 3.3. 3.3a. Canonical Discriminant Analysis of midwater fish assemblages at seven platforms, 1996–2001. Note that the Platform Holly fish assemblage is distinct from the others. 3.3b. Dots represent species that were not strongly associated with either axis.

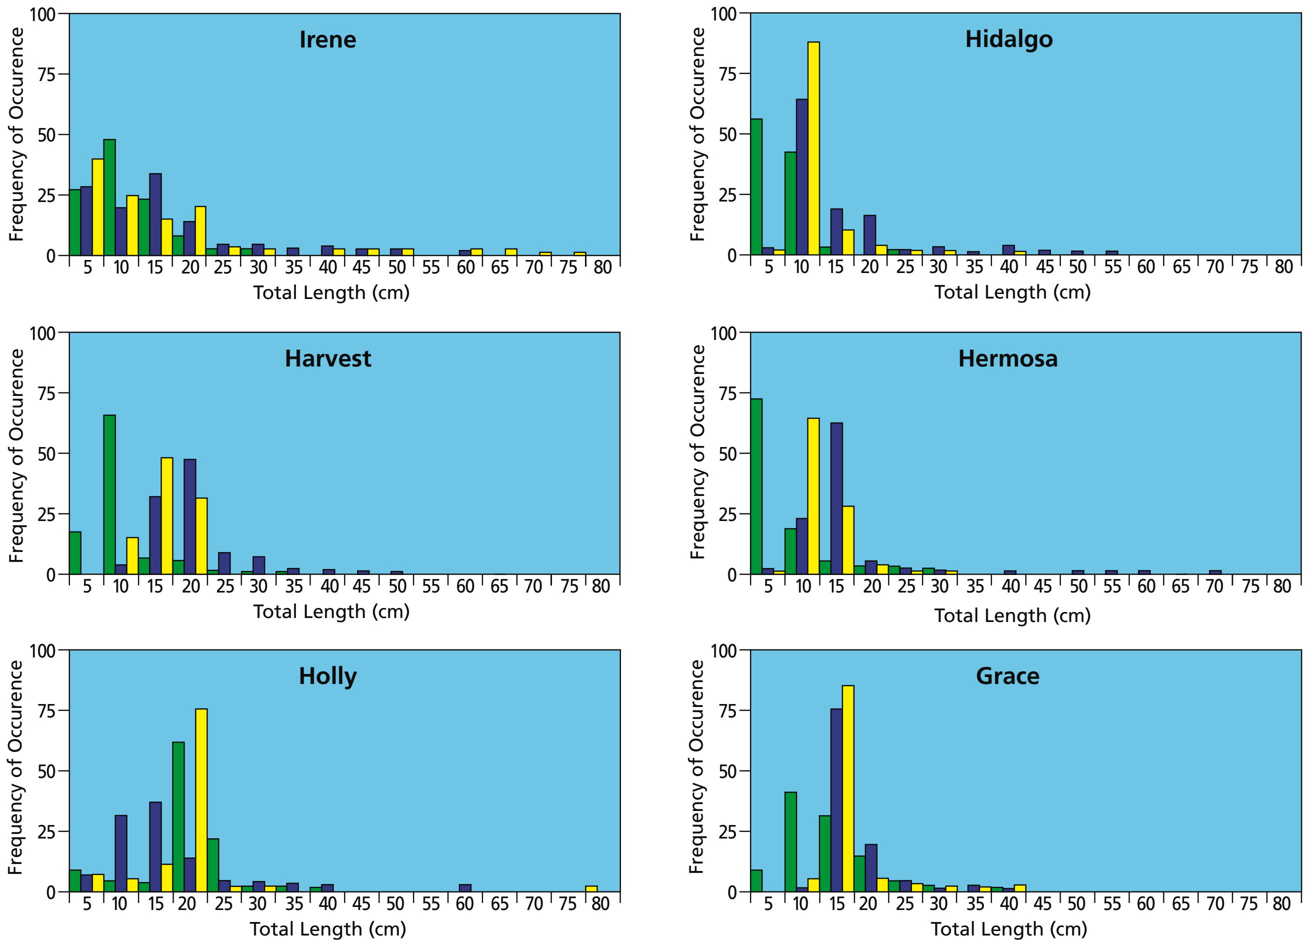
Grace, and Gail, based on surveys conducted between 1995 and 2001 from the research submersible *Delta*.

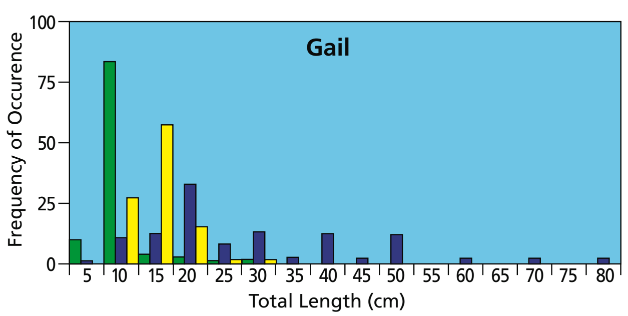
2a. General Patterns

All of the platforms studied by submersible had three distinct fish assemblages, midwater, bottom, and shell mound (Figure 3.2a). Rockfishes, totaling about 35 species, dominated all three fish assemblages. Fish densities at most platforms tended to be highest in the midwater reflecting the depth preferences of young-of-the-year rockfishes that represented the most abundant size class of fishes.

Midwater assemblages were more similar to each other regardless of platform location and bottom depth. The assemblage at Platform Holly had the only distinct midwater assemblage (Figure 3.3a). A suite of species (e.g., calico, copper, and gopher rockfishes, pile, and sharpnose seaperches) characterized this particular assemblage (Figure 3.3b). Holly has the shallowest bottom depth (standing in 64 m, 211 ft.), and it might be that these shallow demersal species were able to occupy these shallow midwater crossbeams. The midwater fish assemblages around the other platforms showed no systematic depth or geographic relationships.

The composition of platform bottom and shell mound fish assemblages was dependent on the bottom depth of the platform (Figure 3.2a) and certain species are characteristic of either shallow or deep benthic habitats (Figure 3.2b). Platforms Holly and Irene (64 m and 73 m; 211 and 241 ft., respectively) were dominated by brown, calico, copper, and vermilion rockfishes and lingcod. In deeper waters, Platforms Hermosa, Harvest, and Gail (183 m, 205 m, and 224 m; 604, 677, and 739 ft., respectively) were dominated by greenblotched, greenspotted, and greenstriped rockfishes. Platform Hidalgo, and to a certain extent Platform Grace, both at intermediate depths (130 m and 96 m, 429 and 317 ft., respectively), were inhabited by species common to both the shallower and deeper platforms. In general, our data suggests that shell mound fish assemblages most closely resemble the fish assemblages of their adjacent platform bottoms (Figure 3.2a). Fishes living on the shell mounds are generally smaller, and presumably younger, than the same species living around the platform bottom.





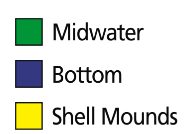


Figure 3.4. Frequency of occurrence of fishes in 5 cm size classes in midwater, bottom and shell mounds at seven platforms, 1996–2001.

The size distribution of fishes differed by habitat type. The midwater assemblages harbored few fishes over 20 cm (8 in.) long (Figure 3.4). Immature, mostly young-of-the-year rockfishes and young painted greenling dominated midwater depths. In addition, seaperches, blacksmith, and several less abundant species inhabited this zone. In contrast, older and larger rockfishes, lingcod, and several other benthic species, occupied the platform bottom habitat. Rockfishes also dominated the shell mounds. The size frequency of shell mound fishes tended to be intermediate between the two other habitats (Figure 3.4). This apparent partitioning of different size modes was most evident in the deepest platforms. Around shallow platforms, there was significant settlement of young-of-the-year rockfishes both in the midwater and at the bottom. This common feature blurred the distinctions between these two habitats.

Young-of-the-year rockfishes showed strong depth preferences around platforms (Figure 3.5). Young-of-the-year were often very abundant in the shallowest portions (above 30 m, 100 ft., depths) of the platform but were also abundant between 31 and 120 m depths (102–396 ft.). They were most abundant at depths between 61 and 90 m (201–297 ft.).

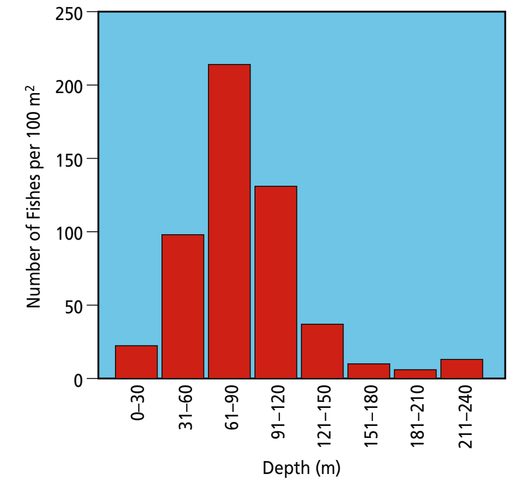

Figure 3.5. Density of young-of-the-year rockfishes observed from the Delta *submersible, by depth, at all platforms surveyed, 1995–2001. Note that large numbers of these fishes were also observed by scuba divers in the shallower sections of the platforms.*

Among platforms, total fish densities typically fell within a relatively small range (Figure 3.6). In general, platforms furthest offshore and in deepest waters had somewhat lower fish densities than did those closer to shore in shallower waters. However, the absolute number of fishes around deeper water platforms may be greater than those in shallower waters, as deeper platforms are much larger than shallower water structures.

2b. Midwater Assemblages

Findings at a Glance

Platform midwaters are nursery grounds for rockfishes as well as for other marine fish species such as cabezon and painted greenling. The young-of-the-year of at least 15 rockfish species inhabit these midwater habitats.

Benthic settlement success is greatly influenced by oceanographic conditions. During our study, densities of young fishes varied greatly between years and platforms. Young-of-the-year rockfish densities often varied

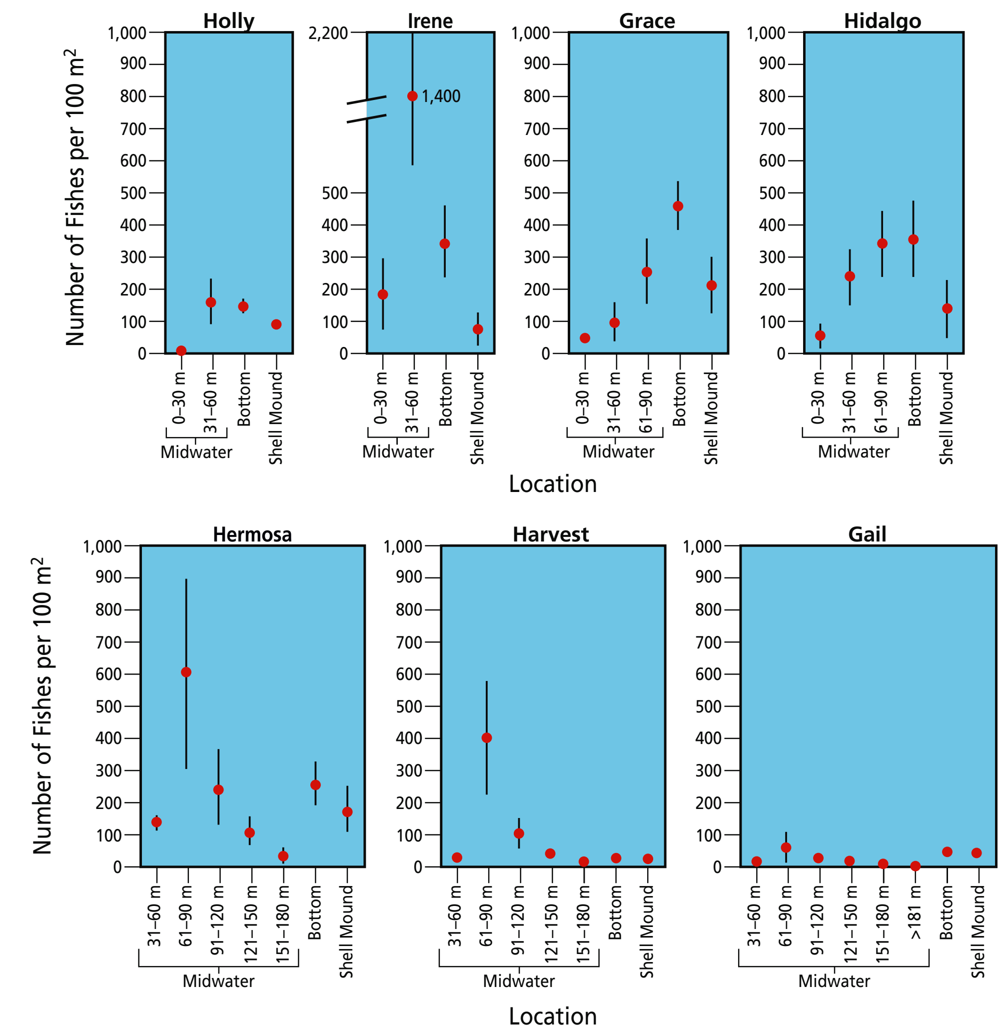

Figure 3.6. Density, with standard error bars, of all fishes in midwater (by 30 m depth zones), bottom and shell mounds, at seven platforms, 1996–2001.

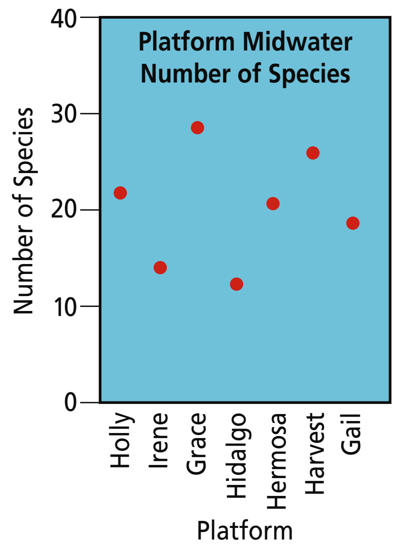

Figure 3.7. Number of species observed in the midwaters of seven platforms, 1996–2001. Platforms are listed from left to right, from shallowest to deepest.

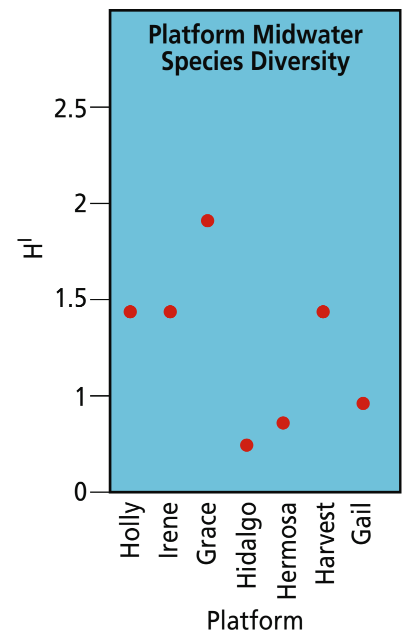

Figure 3.8. Species diversity of fishes in the midwaters of seven platforms, 1996–2001. Platforms are listed from left to right, from shallowest to deepest.

by a factor of 10 or even 100 among survey years at some platforms. From 1996 through 1998, rockfish settlement was generally higher around the platforms north of Point Conception compared to those structures in the Santa Barbara Channel, reflective of generally colder, more productive waters in central California. Colder waters in 1999 were associated with relatively high densities of young-of-the-year rockfish recruitment at all of the platforms surveyed. In 2000 and 2001, rockfish recruitment at platforms in the Santa Barbara Channel remained higher than pre-1999 levels. We hypothesize that this was related to the oceanographic regime shift to cooler temperatures that may be occurring in southern California.

Depending on platform location, we observed between 13 and 29 fish species in the midwater habitats below 31 m (102 ft.) depths (Appendix 3). There was no relationship between platform bottom depth and either the number of species or species diversity in the midwater habitat (Figures 3.7 and 3.8). Relatively abundant non-rockfish species included blacksmith, sharpnose seaperch, and juvenile painted greenling. Occasionally, we observed influxes of migratory species such as Pacific sardine, jack mackerel, and Pacific mackerel. However, because our surveys are snapshots in time, they do not adequately capture the importance of platform habitats to these and other pelagic species. The most abundant fishes were young-of-the-year and older juvenile rockfishes and blacksmith. These are planktivorous and thus are not dependent on the platform for food. They utilize these structures for orientation in the water column and as refuge from predation. Less common species, such as seaperches, painted greenling, opaleye, and cabezon do feed on animals or algae living on the platform jacket or conductors.

Our research shows that oil and gas platforms off California provide important nursery grounds for many species of rockfishes. The most conspicuous faunal characteristic of the platform midwaters below scuba depth is the dominance of young rockfishes. Over the course of the study, young-of-the-year and older juvenile rockfishes almost always comprised more than 90% of all fishes observed in this habitat (Appendix 3). In some years, young-of-the-year rockfishes were virtually the only fishes present at some platform midwaters (Appendix 3).

The young-of-the-year of at least 16 rockfish species (bank, blue, copper, darkblotched, flag, gopher, kelp, olive, pygmy, shortbelly, squarespot, widow, yellowtail rockfishes, bocaccio, cowcod, and one or more members of the subgenus *Sebastomus*) recruited to the midwater habitat. Many of the species that were most abundant (e.g., blue, olive, pygmy, squarespot, widow, and yellowtail rockfishes and bocaccio) are those that are epibenthic or semipelagic as adults. Of these diverse young rockfishes, widow rockfishes were consistently the most abundant species at platforms. Among adult rockfishes, kelp and whitespeckled rockfishes were commonly observed.

MARY NISHIMOTO

Juvenile bocaccio and widow rockfish, midwaters of Platform Grace.

Young-of-the-year and 1-yr old rockfishes of many species (e.g., bank, blue, olive, pygmy, shortbelly, squarespot, widow, and yellowtail rockfishes, and bocaccio) often formed highly mobile schools in the midwater habitat. During years of high abundance, these schools contained many thousands of individuals. Our experience suggests that these schools remained either inside the platform or ventured only a few meters outside it. Schools of young rockfishes tended to more closely associate with the jacket substrate during years of low recruitment or when water visibility was poor. However, when their numbers were high or water clarity was good, young rockfishes, while still living within the platform structure, only loosely associated with the crossbeams and vertical structure. In general, the schools occurred throughout 50 to 100 m or more (150–300 ft.) of the water column. Young copper, gopher, kelp, and flag rockfishes, treefish, and cowcod, as well as cabezon and painted greenling were generally observed either as solitary individuals or in small groups, usually intimately associated with the platform jacket.

Young-of-the-year rockfish settlement (recruitment) to midwater habitats is also strongly influenced by oceanographic conditions. The density of these fishes varied greatly inter-annually by location and among platforms (Figure 3.9). Spatial and temporal differences in young-of-the-year rockfish densities often varied by a factor of 10 or even 100. In several instances, a species that was entirely absent from a platform midwater in one year would recruit in great numbers in the following year. Between 1996 and 1998, young-of-the-year rockfish recruitment was generally higher around the platforms north of Point Conception in the Santa Maria Basin (Irene, Hidalgo, Harvest, and Hermosa) than at the structures in the Santa Barbara Channel (Holly, Grace, and Gail) (Figure 3.9). In contrast, these three years were a period of low rockfish recruitment for many species south of Point Conception both at platforms (Holly, Grace, and Gail) and natural outcrops. The colder water conditions of 1999 brought with it widespread recruitment for a number of rockfish species in California compared to the previous decades. This was reflected at all of the platforms surveyed (Figure 3.9). We should note that the 2000 data at Platforms A, B, C, Hillhouse, Hogan, Houchin, and Henry (see sidebar) strongly suggest that recruitment for some rockfish species, particularly blue and widow rockfishes, had been very successful in 1999. In 2000 and 2001, recruitment of some rockfish at Platforms Gail and Grace remained higher than pre-1999 levels (Figure 3.9). We hypothesize that this represents a successful response to the oceanographic regime shift to cooler temperatures that may be occurring in southern California and the greater northeast Pacific.

The population dynamics of bocaccio exemplifies the annual and geographic variability that occurs in rockfish recruitment at both platforms (Figure 3.9) and natural

Figure 3.10. Patterns of young-of-the-year (YOY) bocaccio settlement in 1999, as observed from the Delta *submersible surveys.*

outcrops (Figure 3.10). Prior to 1999, young-of-the-year bocaccio were absent at the platforms we surveyed (except Irene in 1996 and 1997). During 1999, large densities of young-of-the-year bocaccio were observed at Platforms Irene and Grace; small numbers of at least a few individuals were observed at most other platforms. Platform Grace provided the most striking example of inter-annual variability. Almost no young-of-the-year bocaccio were observed at Platform Grace prior to 1999. In contrast, during 1999, the platform harbored the third highest densities (after 1996 and 1999 at Platform Irene) of young bocaccio we observed around either platforms or natural outcrops during the six years of research. It is important to realize that even in years of relatively high rockfish recruitment, the actual process of settlement may result in a patchy distribution of young-of-the-year benthic recruits. Such patchiness was observed in the bocaccio recruitment pattern in 1999 at Platforms Grace and Gail, which are located only 8 km (5 miles) apart. While Platform Grace harbored large numbers of young bocaccio, they were much less abundant at nearby Platform Gail. Furthermore, our research has shown that successful rockfish recruitment at platforms does not always translate to similar high densities of these species at nearby natural outcrops. Using the *Delta*, in 1999 we also surveyed 12 natural outcrops located in depths suitable for bocaccio recruitment and found little evidence of bocaccio recruitment over any of these structures (Figure 3.10).

In 2000, we studied the midwater habitats of Platforms C, B, A, Hillhouse, Henry, Houchin, Hogan, and Habitat. These platforms, located off Summerland east of Santa Barbara (Figure 1.1), were home to many typical midwater reef fishes, including juvenile blue, olive, and widow rockfishes (of the 1999 year class), blacksmith, kelp rockfish, kelp bass, painted greenling, halfmoon, and sharpnose seaperch. Unlike the species assemblage of the further offshore and the more northerly platforms, both garibaldi and California sheephead were common. In 1998, we surveyed Platform Edith and again found a typical mix of reef fishes, including blacksmith, halfmoon, opaleye, sheephead, and garibaldi. Complete species assemblages for all of these platforms are found in Appendix 3.

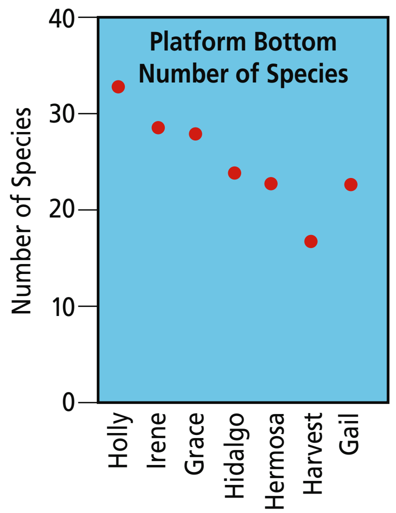

Figure 3.11. Number of species observed at the bottom of seven platforms, 1996–2001. Platforms are listed from left to right, from shallowest to deepest.

2c. Bottom Assemblages

Findings at a Glance

The bottom habitat of platforms is dominated by subadult and adult rockfishes. Young-of-the-year rockfishes were also abundant around some platform bottoms, occasionally in large numbers. In general, more than 90% of all the fishes found around platform bottoms were rockfishes. The numbers and estimated densities of all fishes in the bottom habitats are shown by platform in Appendix 3. Bottom depth strongly influenced the number of species, species diversity, and density of fishes living around platform bases. This is in direct contrast to the midwater habitat. The presence of young-of-the-year and older aged juveniles indicates that the bottom habitat of some platforms may be important nursery habitat for some species. The platform base appears to be important to many marine species, as it provides both refuge and prey.

Depth strongly influences fish assemblages in platform bottom habitat. Species richness varied widely from about 33 species at Platform Holly to 17 species at Platform Harvest. Generally, the shallower-water platforms harbored more species than platforms in deeper depths although this trend may have begun to reverse at Gail, the deepest platform (Figure 3.11). Species diversity was high at the shallowest and deepest platforms and lowest among the mid-depth structures (Figure 3.12). Conversely, overall fish densities were much higher at the mid-depth platforms than at the deepest platforms (Figure 3.13).

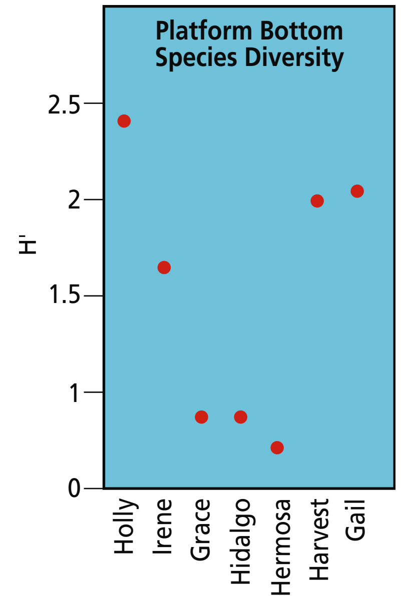

Figure 3.12. Diversity of fishes at the bottom of seven platforms, 1996–2001. Platforms are listed from left to right, from shallowest to deepest.

Diversity and abundance patterns were driven by the depth preferences of a suite of rockfishes that dominate the bottom habitats. For instance, brown, calico, copper, and vermilion rockfishes were most abundant around the shallower structures but were absent from the deepest platforms (Figure 3.13). Pile perch, painted greenling, and young-of-the-year lingcod displayed the same pattern. Juvenile lingcod were also abundant at the shallowest platforms, particularly at Platform Irene, but these were also occasional around even the deepest structures surveyed. Halfbanded rockfish and flag rockfish were typically found at the intermediate-depth platforms. Greenblotched, greenspotted, greenstriped, pinkrose, and stripetail rockfishes were most abundant around the deeper structures (Figure 3.13). The juveniles of many of these species were found in shallower water or on the shell mounds.

Platform structure in the bottom habitats may influence the distribution of fishes. This habitat encompasses that area where the platform jacket and conductors physically meet the seafloor. At all of the platforms surveyed, there is a crossbeam that rests on, or is close to, the bottom. Some portions of this crossbeam may be completely buried by sediment or undercut by currents. The platform jacket and, in particular, the undercut crossbeam, appears to provide many of the attributes of a natural outcrop, providing high relief and large crevices. Many species, such as canary, flag, vermilion, and widow rock-

fishes, bocaccio, pile perch, and painted greenling closely associate themselves with the platform jacket, particularly with the crossbeam. Similarly, larger copper, greenspotted, greenblotched, and pinkrose rockfishes and cowcod tend to shelter inside or immediately next to the platform. These fishes were particularly abundant where a space formed between the lowest crossbeam and the seafloor. Calico and greenstriped rockfishes and various life stages of lingcod were less closely associated with the structure. While most species rarely ascend more than a meter or two above the seafloor, bocaccio and halfbanded rockfish often rose as much as 5 m (17 ft.) above the bottom.

Most platform bottom species are either solitary or shelter in small groups. The exceptions are young-of-the-year rockfishes, juvenile and subadult brown, copper, halfbanded, and vermilion rockfishes, and bocaccio. On a number of occasions, we observed aggregations of tens and hundreds of brown, copper, and vermilion rockfishes and bocaccio and large schools of halfbanded rockfish comprised of thousands of individuals.

Compared to midwater habitats, the fish species compositions at platform bottoms were relatively stable over time (Figures 3.14a, b). The dominant species varied little between years at any platform. Thus a platform, such as Gail, that was dominated by adult greenspotted and greenblotched rockfishes, bocaccio, and cowcod in one year tended to be inhabited by these same species in all years in about the same abundances. Similar patterns were observed for such common species as painted greenling (Platforms Irene and Holly), greenspotted rockfish (Platforms Hidalgo and Hermosa), copper rockfish (Platforms Irene and Holly), and flag rockfish (Platform Hidalgo). It is likely that we were observing some of the same individuals each year. This constancy would be expected as these assemblages are at least partially composed of subadult and adult stages of relatively sedentary and long-lived rockfishes. Thus, the composition of the bottom assemblages is not determined by the year-to-year fluctuations in year-class success that is characteristic of the platform midwaters. However, the densities of a few important species, particularly halfbanded rockfish, varied annually. In some years halfbanded rockfish were essentially absent from a platform bottom, only to be extremely abundant the following year. Schools of this species are highly mobile and may have been present but not in the vicinity of the submersible when the survey was made.

Our observations indicate that the bottom habitat of some platforms may be particularly important for certain species. For example, young-of-the-year lingcod densities were much higher at Platform Irene and Hidalgo than at any natural outcrop during any year of the survey (Appendix 4).

Unlike most of the fishes living in the platform midwater, it is likely that the majority of the platform bottom-dwelling species feed on platform-associated prey. Many of these species, such as brown, copper, and flag rockfishes, eat a variety of crustaceans, molluscs, and small fishes, many of which live in and around the jacket, conductors, and shell mound. Other species, such as lingcod, cowcod, and bocaccio are opportunistic feeders, preying on a very wide range of organisms, including benthic and water column fishes, molluscs, and crustaceans (Love et al. 2002). Thus, for many benthic fishes, the platform base provides not only shelter but also an abundant source of food.

We conducted one survey, in 1998, around the base of Platform Edith. We found that California scorpionfish, sharpnose seaperch, blacksmith, and blackeye goby were the most abundant species. See Appendix 3 for a complete species list.

2d. Shell Mound Assemblages

Findings at a Glance

Shell mounds support a rich and diverse fish assemblage. As at other platform habitats, rockfishes comprise the vast majority of the fishes. The many small sheltering sites created by mussels, anemones, and other invertebrates on the shell mounds provided structure in a habitat dominated by small fishes. Many of these fishes are the young-of-the-year and older-aged juveniles of lingcod and copper, flag, greenblotched, and pinkrose rockfishes and cowcod. The adults of these species inhabit the platform bottom.

Depending on platform, we observed between 17 and 30 species living on this habitat. In the shell mound habitat, the patterns of species numbers, diversity, and fish densities were similar to those observed around the platform bottoms. Species numbers generally decreased with increasing depth (Figure 3.15) although it increased sharply at the Platform Gail, the deepest structure. This increase was due to the occurrence of a number of deeper water species (e. g., rex sole, blackgill rockfish, and California smoothtongue) that were absent from other platforms. As in the platform bottom habitat, species diversity was highest at the shallowest and deepest platforms compared to shell mounds in intermediate depths (Figure 3.16).

The shell mounds surrounding all platforms provided habitat and refuge for a diverse assemblage of fishes. Fish densities were highest on the intermediate-depth platform shell mounds (Figure 3.17). However, as in the platform midwater and bottom, a majority of these fishes are rockfishes; between 53% and 98% of all fishes living on the shell mounds are rockfishes (Appendix 3). Furthermore, when highly migratory and non-resident species, such as Pacific hake and Pacific sardine, are eliminated from the analysis, rockfishes comprise more than 80% of the shell mound fauna at each of the seven platforms surveyed. Those species most characteristic of the shell mounds exhibited distinct depth preferences (Figure 3.17) and the abundance of some of these fishes was responsible for the higher densities in the intermediate bottom depths. The dominant species of the shallow water shell mounds were vermilion, copper, and calico rockfishes, young-of-the-year and immature lingcod, and painted greenling. A few species, such as greenspotted and halfbanded rockfishes, were most common in the intermediate bottom depths. It was primarily the very high densities of halfbanded rockfish that were responsible for the overall high densities at intermediate-depth shell mounds. Greenstriped, pinkrose, and stripetail rockfishes

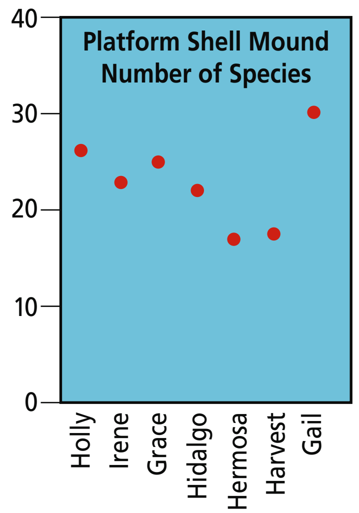

Figure 3.15. Number of fish species observed on the shell mounds of seven platforms, 1996–2001. Platforms listed left to right from shallowest to deepest.

were most abundant at the deepest platforms surveyed.

The mosaic of small refuge sites created by mussels, anemones, and other invertebrates are occupied by small fishes. Many of these fishes are the juveniles of such species as lingcod and copper, flag, greenblotched, and pinkrose rockfishes and cowcod, whose adults inhabit the adjacent platform bottom. Small sheltering sites are rarely found at the platform bottom. In part, this explains why fishes tend to be smaller on a shell mound than on the associated platform bottom (Table 2). This also explains why the shell mound assemblage so closely resembles its counterpart around the adjacent platform bottom. Painted greenling, calico, and halfbanded rockfishes, shortspine combfish, blackeye goby, and the poachers are among the dwarf species occupying the shell mound. Juveniles of the species characteristic of platform midwaters, such as blue and widow rockfishes, are rare over the shell mounds.

Most shell mound species are solitary fishes, living just above the seafloor or nestled among the shell debris or around anemones, seastars, and other large invertebrates. The only schooling species is the halfbanded rockfish that often forms highly mobile schools of 100 to 1,000 or more individuals.

It is likely that many of the fishes, including most of the rockfishes, combfishes, painted greenling, and other benthic species are resident to the shell mound habitat. Highly mobile and migratory species, such as northern anchovy, Pacific sardine, and juvenile Pacific hake, that were observed over the shell mounds probably spend only a relatively short period associated with this habitat.

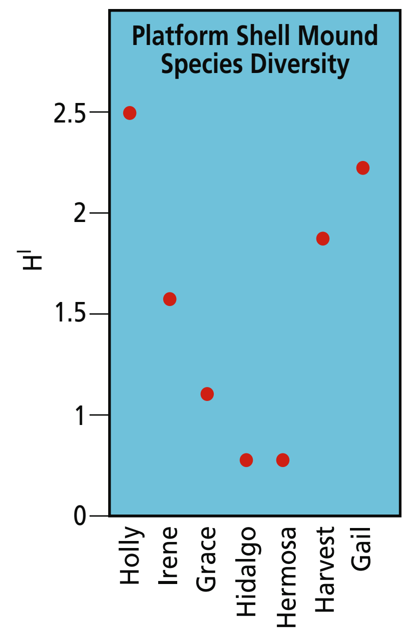

Figure 3.16. Diversity of all fishes observed on the shell mounds of seven platforms, 1996–2001. Platforms are listed left to right from shallowest to deepest.

Shell mound surveys were conducted around Platform Edith in 1998 and around Platform C in 2000. Young vermilion rockfish, as well as halfbanded and calico rockfish, were the most abundant species around Platform C. These species were also characteristic of the shell mound at Platform Holly, which lies in a similar depth. California scorpionfish and blackeye goby dominated the shell mound around platform Edith. Edith lies a few miles southeast of Long Beach and near a known California scorpionfish spawning grounds (Love et al. 1987). California scorpionfish are relatively uncommon in the Santa Barbara Channel and are rare north of Point Conception. This distribution explains the near absence of this species from other shell mounds we surveyed.

3. A Comparison of Fish Assemblages at a Deeper Platform and a Nearby Natural Outcrop: Hidalgo and North Reef

Findings at a Glance

The species composition at Platform Hidalgo and North Reef are quite similar as both structures are dominated by rockfishes. In general, the distinctions between the platform and reef assemblages were based on differences in species densities (rather than species presence or absence). Most species were more abundant at Platform Hidalgo than at North Reef. Halfbanded, greenspotted, flag, greenstriped, and canary rockfishes, all three life stages of lingcod (young-of-the-year, immature, adult), and painted greenling all had higher densities around the platform. Five species (i. e., pink seaperch, shortspine combfish, pygmy, squarespot, and yellowtail rockfishes) were more abundant at the reef. The dominance of small fishes at North Reef probably reflects fishing pressure that has cropped larger individuals. Young-of-the-year rockfishes were found at both Platform Hidalgo (primarily in the midwaters) and at North Reef. In each of five years, young-of-the-year rockfish density was higher at the platform than at the reef. In several years, densities of these young fishes were more than 100 times greater at Platform Hidalgo than at North Reef.

We surveyed the fish assemblages at Platform Hidalgo and a nearby natural outcrop, North Reef, for the period 1996–2001. North Reef was compared with Platform Hidalgo because it is close to the platform (about 1,000 m, 3,300 ft., north of the platform) (Figure 3.18), and its depth (112 m, 370 ft.) is comparable to the platform's 130 m (430 ft.). North Reef is a hard carbonate scarp, which is 1–4 m (3–13 ft.) high, 3,353 m^2 in area and contains numerous boulders, caves, and crevices.

The species composition at Platform Hidalgo and North Reef are very similar (Table 3). Both habitats are dominated by rockfishes; they comprised 98.3% and

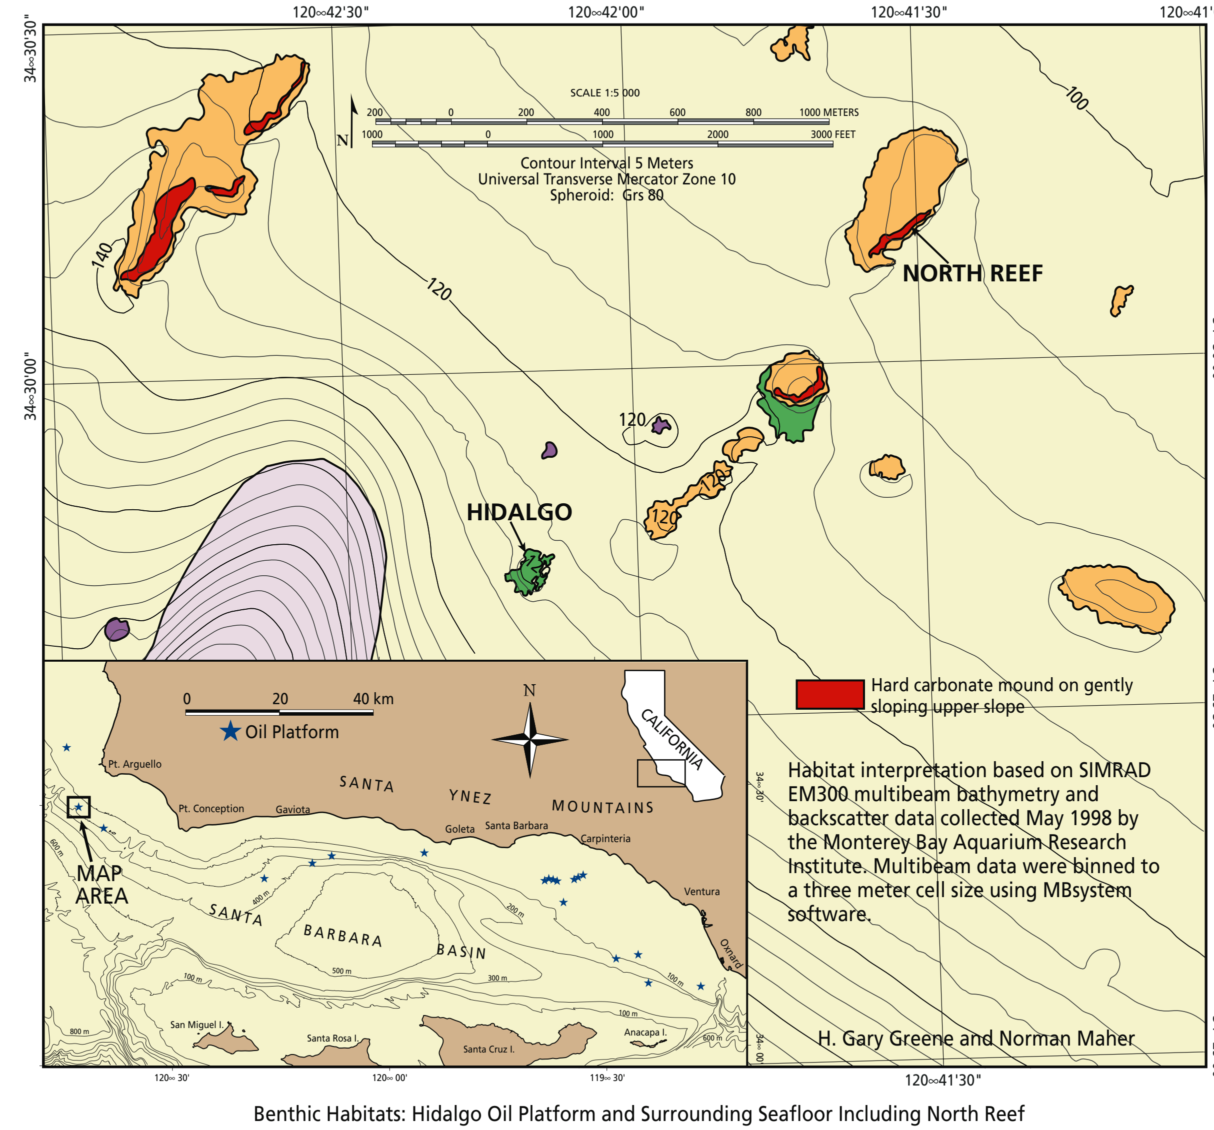

Figure 3.18. Locations of Platform Hidalgo and North Reef. Seafloor characterization by Gary Greene, Moss Landing Marine Laboratory.

96.6% of all fishes at Platform Hidalgo and North Reef, respectively. We observed a minimum of 34 fish species at each location. A few species were unique to each structure. Copper and stripetail rockfishes and California scorpionfish were found only at Platform Hidalgo, while blackeye goby, bluebarred prickleback, Pacific argentine, speckled sanddab, and an unidentified cuskeel were present only at North Reef. None of these species were major constituents of their respective fish communities.

However, when taking into consideration the fish assemblages of the three habitats (midwater, bottom, and shell mounds) at Platform Hidalgo, each was somewhat distinct from that of North Reef (Figure 3.19). To characterize and distinguish between the species assemblages at Platform Hidalgo and North Reef, we compared only the benthic assemblages of the platform bottom and shell mound and North Reef. Canonical discriminant analysis showed that species assemblages at the bottom of Platform Hidalgo and its shell mound were somewhat different from each other and from the North Reef assemblages (Figure 3.20a). The platform bottom assemblage was characterized by a suite of rockfishes, including bocaccio and cowcod, flag, vermilion, and widow rockfishes and lingcod. The shell mound assemblage was similar to and overlapped with the platform bottom, but was characterized by smaller fishes, such as swordspine,

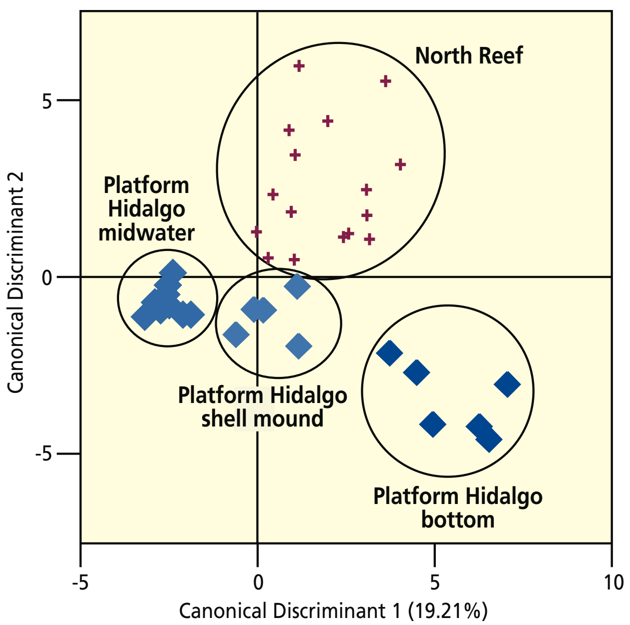

Figure 3.19. Canonical Discriminant Analysis of fish assemblages at Platform Hidalgo, midwater, bottom, and shell mound habitats and North Reef, 1996–2001.

greenstriped and halfbanded rockfishes, painted greenling, and juvenile lingcod (Figure 3.20b).

In general, the distinctions between the platform and reef assemblages were based on differences in species densities rather than species presence and absence. The densities of a range of species varied between the two sites (Figure 3.21) and most exhibited higher densities at Platform Hidalgo than at North Reef (Figure 3.21). Halfbanded, greenspotted, flag, greenstriped, canary rockfishes, all three life stages of lingcod (young-of-the-year, immature, adult), and painted greenling were among the species that were more abundant around the platform. Five species (pink seaperch, shortspine combfish, pygmy, squarespot, and yellowtail rockfishes) were more abundant at the reef.

Young-of-the-year rockfishes were common at both Platform Hidalgo (primarily in the midwaters) and at North Reef, although species differences were observed. From our submersible surveys, we identified at least seven species of young-of-the-year rockfishes at Hidalgo (e.g., blue, bocaccio, olive, pygmy, squarespot, widow, and yellowtail). Our scuba surveys around that platform also noted young-of-the-year of the "copper complex," composed of black-and-yellow, copper, gopher, and kelp rockfishes. Most of the young-of-the-year rockfishes at North Reef appeared to be pygmy, squarespot, and widow rockfishes.

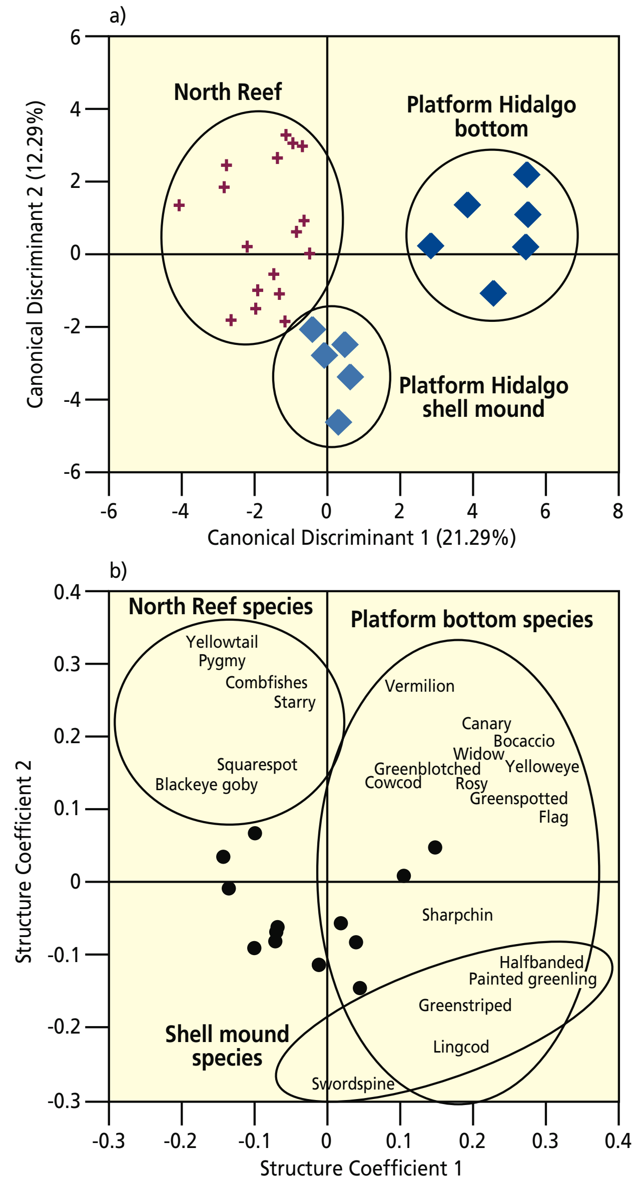

Figure 3.20. 3.20a. Canonical Discriminant Analysis of fish assemblages at Platform Hidalgo bottom and shell mound habitats and North Reef, 1996–2001. Each yearly survey at North Reef was comprised of 2–3 transects and thus each year's survey is represented by more than one cross. 3.20b. Canonical Discriminant Analysis of the species found around Platform Hidalgo, bottom and shell mound and North Reef, 1996–2001. Dots represent species that were not strongly associated with either axis.

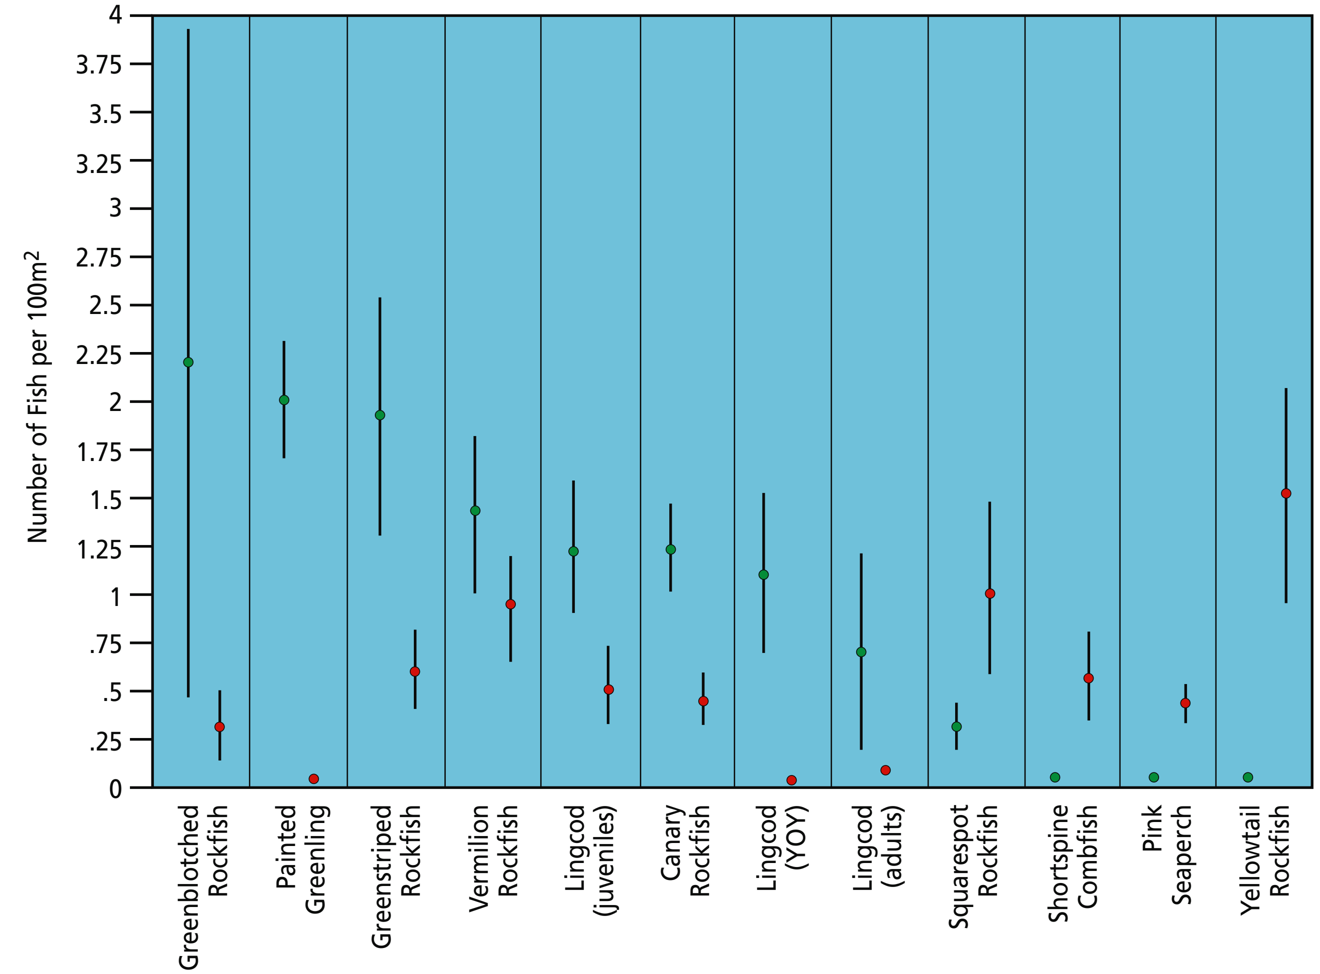
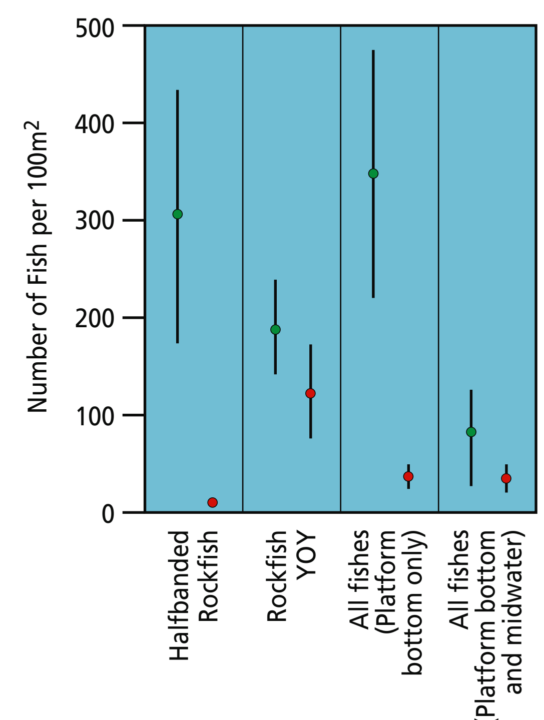
The mean density of young-of-the-year rockfishes in the midwater habitat of Platform Hidalgo was higher than at North Reef (Figure 3.21). This probably reflects greater rockfish recruitment to the platform. This has important implications with respect to platform habitat values regarding settlement and fish production around





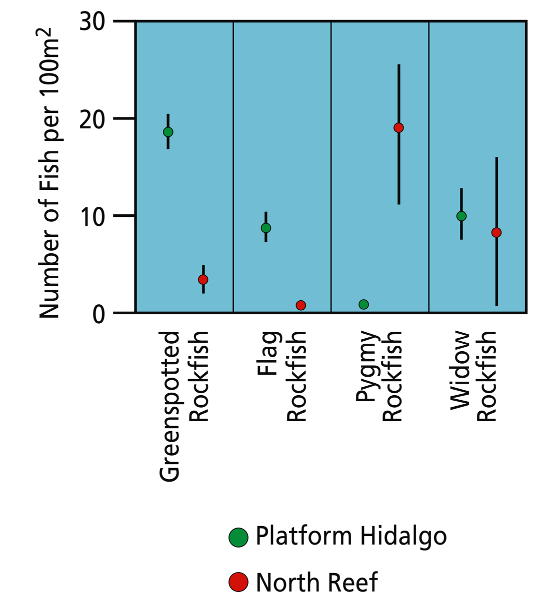


Figure 3.21. Mean densities (with standard error bars) of the common species or species assemblages at Platform Hidalgo and North Reef, 1996–2001. Species or species assemblages are grouped by abundance.

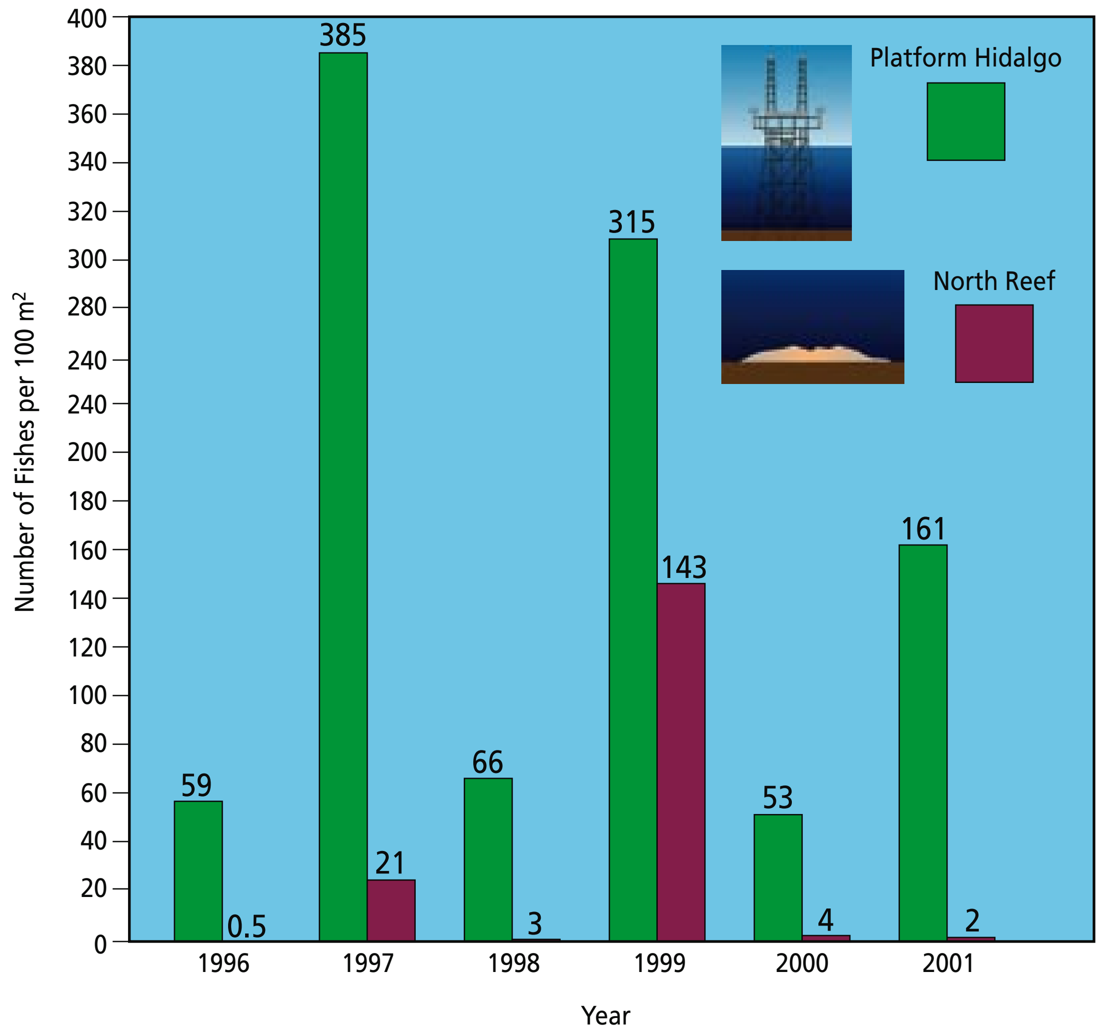

Figure 3.22. Mean densities of young-of-the-year rockfishes, all species combined, at Platform Hidalgo midwater and North Reef, 1996–2001.

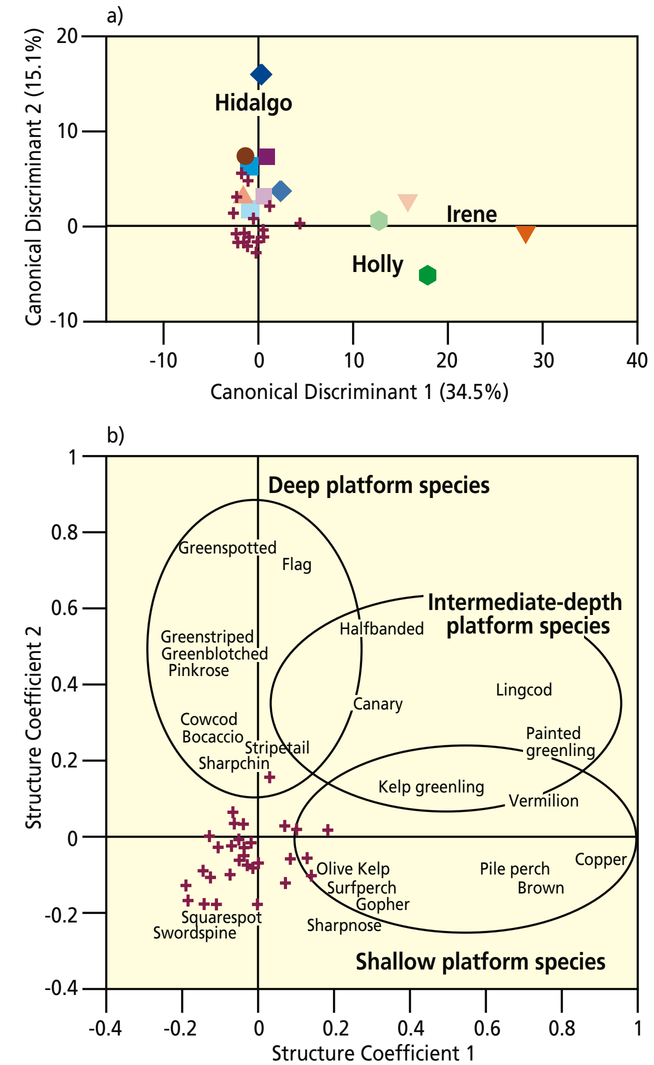
these structures. This recruitment pattern was repeated in each year of our surveys as young-of-the-year rockfish densities were always greater at the platform than at the outcrop (Figure 3.22). In some years, densities were more than 100 times greater at the platform.

4. A Comparison of Fish Assemblages of Platforms and Natural Outcrops off Central and Southern California

Findings at a Glance

Based on surveys of seven platforms and over 80 natural outcrops, rockfishes dominate almost all of the platform and hard seafloor habitats. A greater number of species was observed at the natural outcrops (94) than at the platforms (85). There is a high degree of overlap in species composition and differences are primarily due to generally higher densities for more species at platforms. In particular, widow rockfish young-of-the-year, canary, copper, flag, greenblotched, greenspotted, greenstriped, halfbanded, and vermilion rockfishes, bocaccio, painted greenling and all life history stages of lingcod were more abundant at platforms. Yellowtail rockfish and the dwarf species pygmy, squarespot, and swordspine rockfishes were more abundant on natural outcrops. Some of these differences can be explained by recruitment (settlement) processes and the greater chance for survival at the platform habitats. We believe that as fish size increases with age the platforms act as de facto marine reserves because fishing pressure is light or nonexistent. Platforms can be characterized as having higher densities of young-of-the-year rockfishes than natural outcrops.



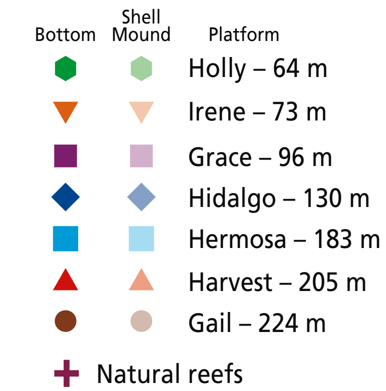


Figure 3.23. 3.23a. Canonical Discriminant Analysis of fish assemblages at seven platforms, bottom and shell mound, and all natural outcrops, 1996–2001. Each cross represents more than one natural outcrop. 3.23b. Canonical Discriminant Analysis of the species found at seven platforms, bottom and shell mounds, and all natural reefs, 1996–2001. Crosses represent species that were not strongly associated with either axis.

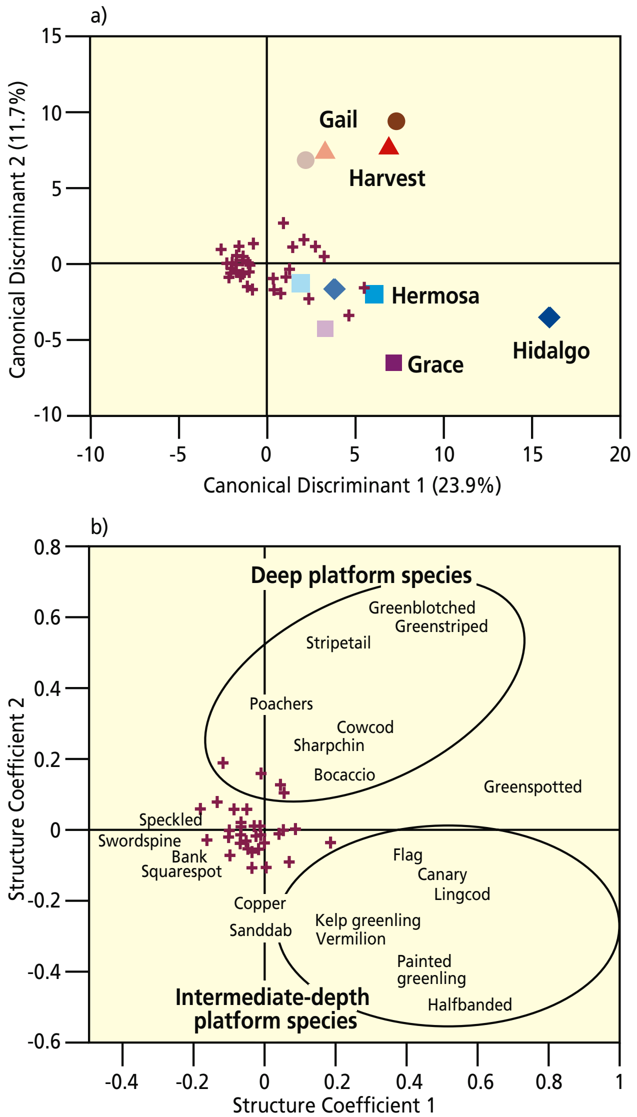
We compared the fish assemblages from the deeper parts of seven platforms (below about 30 m, 100 ft.) with those of similar depth natural outcrops. Analyses were based on platform surveys and on 133 dives at over 80 natural outcrops throughout southern California and off Point Conception and Point Arguello (Figure 1.5).

We observed at least 85 species at platforms and 94 species at outcrops (Table 4). Rockfishes dominated both habitats, comprising 89.7% of all fishes at platforms and 92.5% at outcrops. Platform fish assemblages were somewhat different from those of natural outcrops (Figures 3.23a, b). However, these differences were due almost entirely to the generally greater numbers, of more species, of fishes around platforms, rather than differences in species composition between platforms and outcrops.

There was a distinct assemblage of fishes at the two shallow platforms, Holly and Irene, and another composed of species occupying the deeper platforms. Differences among platform bottom assemblages were more extreme than differences among shell mounds. This, too, was largely a function of greater fish abundance around platform bottoms than over the shell mounds. Intermediate-depth and deepest platforms were less distinct from each other than from shallow platforms. With or without the two shallow platforms (Holly and Irene) in our comparative analysis, the fish assemblages at the platforms still tended to be different from those at the natural outcrops (Figures 3.24a, b). These differences were primarily due to most fish species being more abundant at platforms than at outcrops (Figure 3.25). Widow rockfish young-of-the-year, canary, copper, flag, greenblotched, greenspotted, greenstriped, halfbanded, and vermilion rockfishes, bocaccio, painted greenling, and all life history stages of lingcod were more abundant at platforms. Species that were more abundant at natural outcrops than platforms included pygmy, squarespot, swordspine, and yellowtail rockfishes.

Platforms tended to harbor higher densities of young-of-the-year rockfishes than did natural outcrops. Young-of-the-year rockfishes primarily occurred in the platform midwaters. Thirteen of the 20 highest young-of-the-year rockfish densities were observed at Platforms Grace, Harvest, Hermosa, Hidalgo, Holly, and Irene (Table 5). The highest young-of-the-year rockfish densities over natural outcrops were usually at high relief sites well away from the mainland. The California Current, which is centered



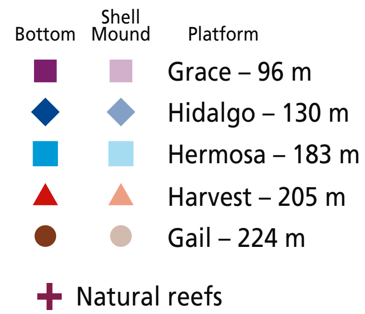


Figure 3.24. 3.24a. Canonical Discriminant Analysis of fish assemblages at five platforms (shallower platforms Holly and Irene deleted), bottom and shell mound, and all natural outcrops, 1996–2001. Each cross represents more than one natural outcrop. 3.24b. Canonical Discriminant Analysis of the species found at five platforms (shallower platforms Holly and Irene deleted), bottom and shell mound, and all natural outcrops, 1996–2001. Crosses represent species that were not strongly associated with either axis.

offshore of the coastal shelf, influences these locations (e.g., San Nicolas and San Miguel islands) more than the mainland sites we surveyed. Furthermore, our observations strongly imply that the midwaters of many platforms bear a striking resemblance to some of the relatively shallow and steep-sided outcrops (such as those on Hidden Reef) that dot the outer continental shelf of southern California. In both cases, the assemblages are dominated by young rockfishes and larger fish predators are relatively uncommon. Thus, survivorship of young fishes may be higher in both habitats due to lowered predation rates.

The role that some platforms play as defacto marine refuges is supported by evidence of greater densities of rockfishes, particularly the larger size classes, at platforms compared to natural outcrops. As an example, densities tended to be higher at some platforms than at natural outcrops for: (1) all rockfishes regardless of size, (2) all rockfishes greater than or equal to 30 cm (12 in.), (3) adult bocaccio, and (4) adult cowcod (Figures 3.26–3.29). Our experience is that rockfishes are most susceptible to being caught by both recreational and commercial gear when they reach about 30 cm (12 in.); thus, densities of fishes of this or larger sizes would be an indication of fishing pressure. Adult bocaccio and cowcod are overfished species with population sizes at levels less than 10% of unfished stock. These fishes at one time were abundant in southern California.

Rockfishes were observed at all of the platforms and outcrops we surveyed, with the exception of two sites on Piggy Bank (Figure 3.26). The highest rockfish densities (500 rockfishes or more per 100 m^2) occurred at four platforms and at five natural outcrops; all of these structures were nursery grounds for young-of-the-year rockfishes. The assemblages of most of the other platforms and outcrops that harbored relatively high rockfish densities also were primarily composed of small rockfishes, both immature individuals and dwarf species. This can be clearly seen when we focussed on rockfishes 30 cm (12 in.) or larger (Figure 3.27). The paucity of rockfishes 30 cm (12 in.) or larger is evident even at the most productive sites (Figure 3.27). Highest densities of large rockfishes (10 rockfishes or more per 100 m^2) occurred at three platforms and two natural outcrops. Many sites harbored no or only a few larger rockfishes.

Almost all of the natural outcrops we studied should have harbored large numbers of larger rockfishes. Their absence or rarity is almost certainly attributable at least

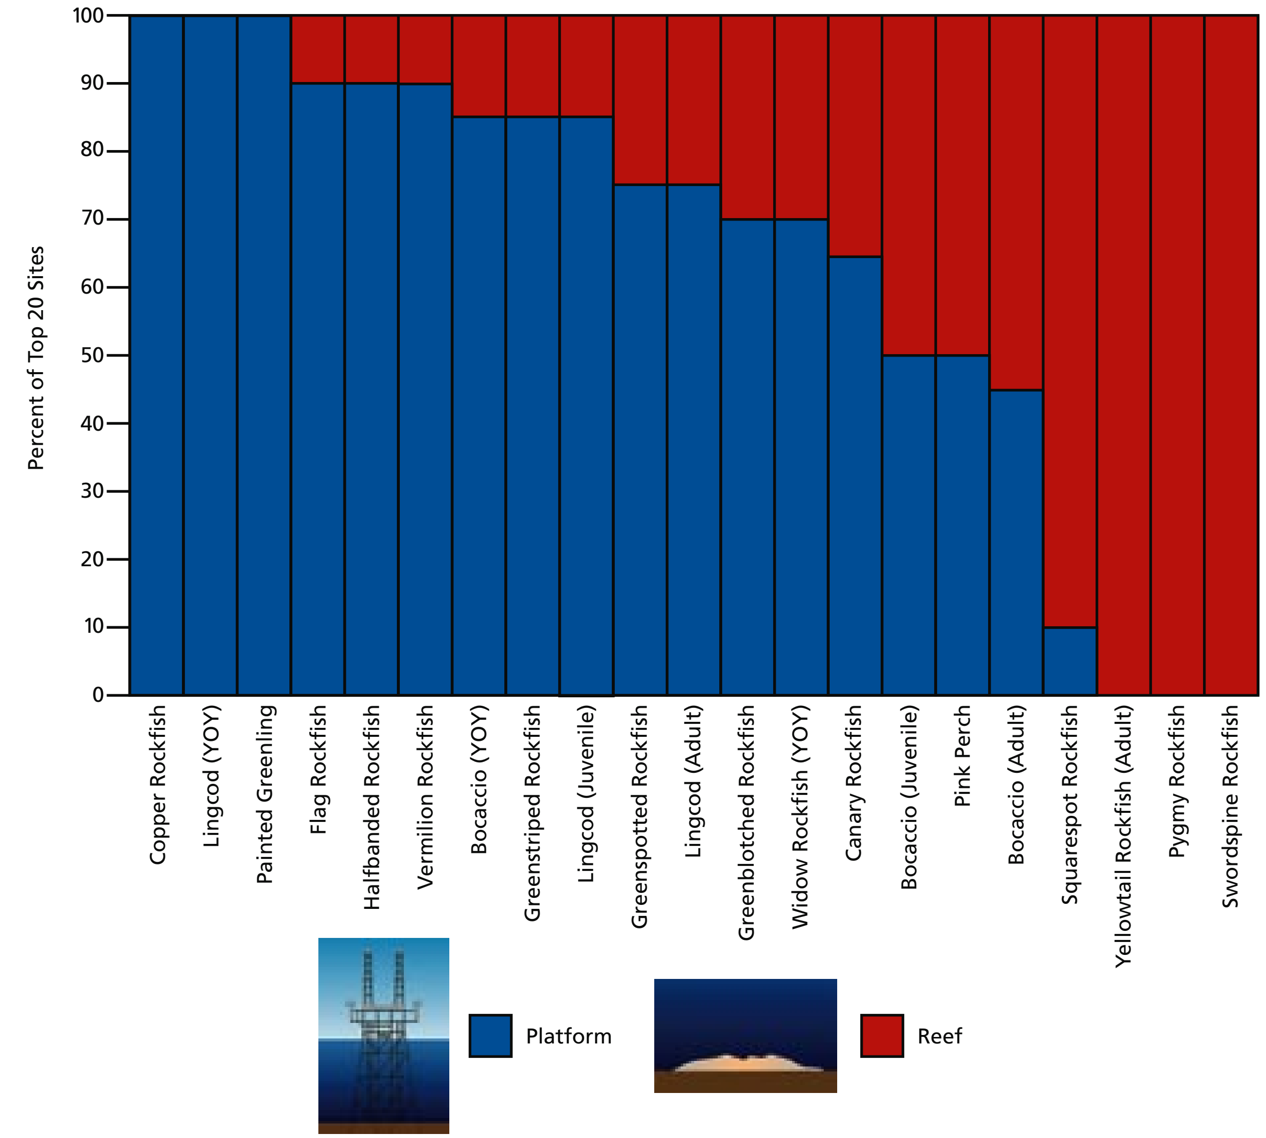

Figure 3.25. The relative importance of seven platforms (Irene, Hidalgo, Harvest, Hermosa, Holly, Grace, and Gail) and about 80 natural outcrops off central and southern California as habitat for common reef fish species. Densities of these species were computed for each year, at each location (platform midwater, bottom and shell mound, and natural outcrops) and ranked from highest to lowest. This figure displays the percentage that platforms or natural outcrops comprised of the top 20 densities for each species (or species' life history stage). For example, of all sites where copper rockfish were observed, the highest 20 densities were at various platforms, in a number of years. Similarly, the highest 20 densities of swordspine rockfish were all at natural outcrops. See Appendix 4 for underlying data.

in part to fishing pressure. These sites were comprised of boulders or other structures that were suitable shelter sites for larger sized rockfishes. A few outcrops, such as sites near the Potato and Osborn Banks, were composed of cobble, a habitat that is less likely to harbor large rockfishes. Adult bocaccio were only abundant around Platform Gail and were relatively common at Platform Hidalgo, Reef "D" near that platform and a few sites around the northern Channel Islands (Figure 3.28). Even at these natural outcrops, many shelter structures contained no or few adult bocaccio. Cowcod densities were also depressed (Figure 3.29). Relatively few rock outcrops surveyed contained adults, and platform Gail harbored the highest densities, although even here numbers were low. In general, the highest densities of adult bocaccio and cowcod occurred at platforms or at those outcrops that were protected from harvest by distance from ports or by being situated in areas susceptible to poor weather conditions.

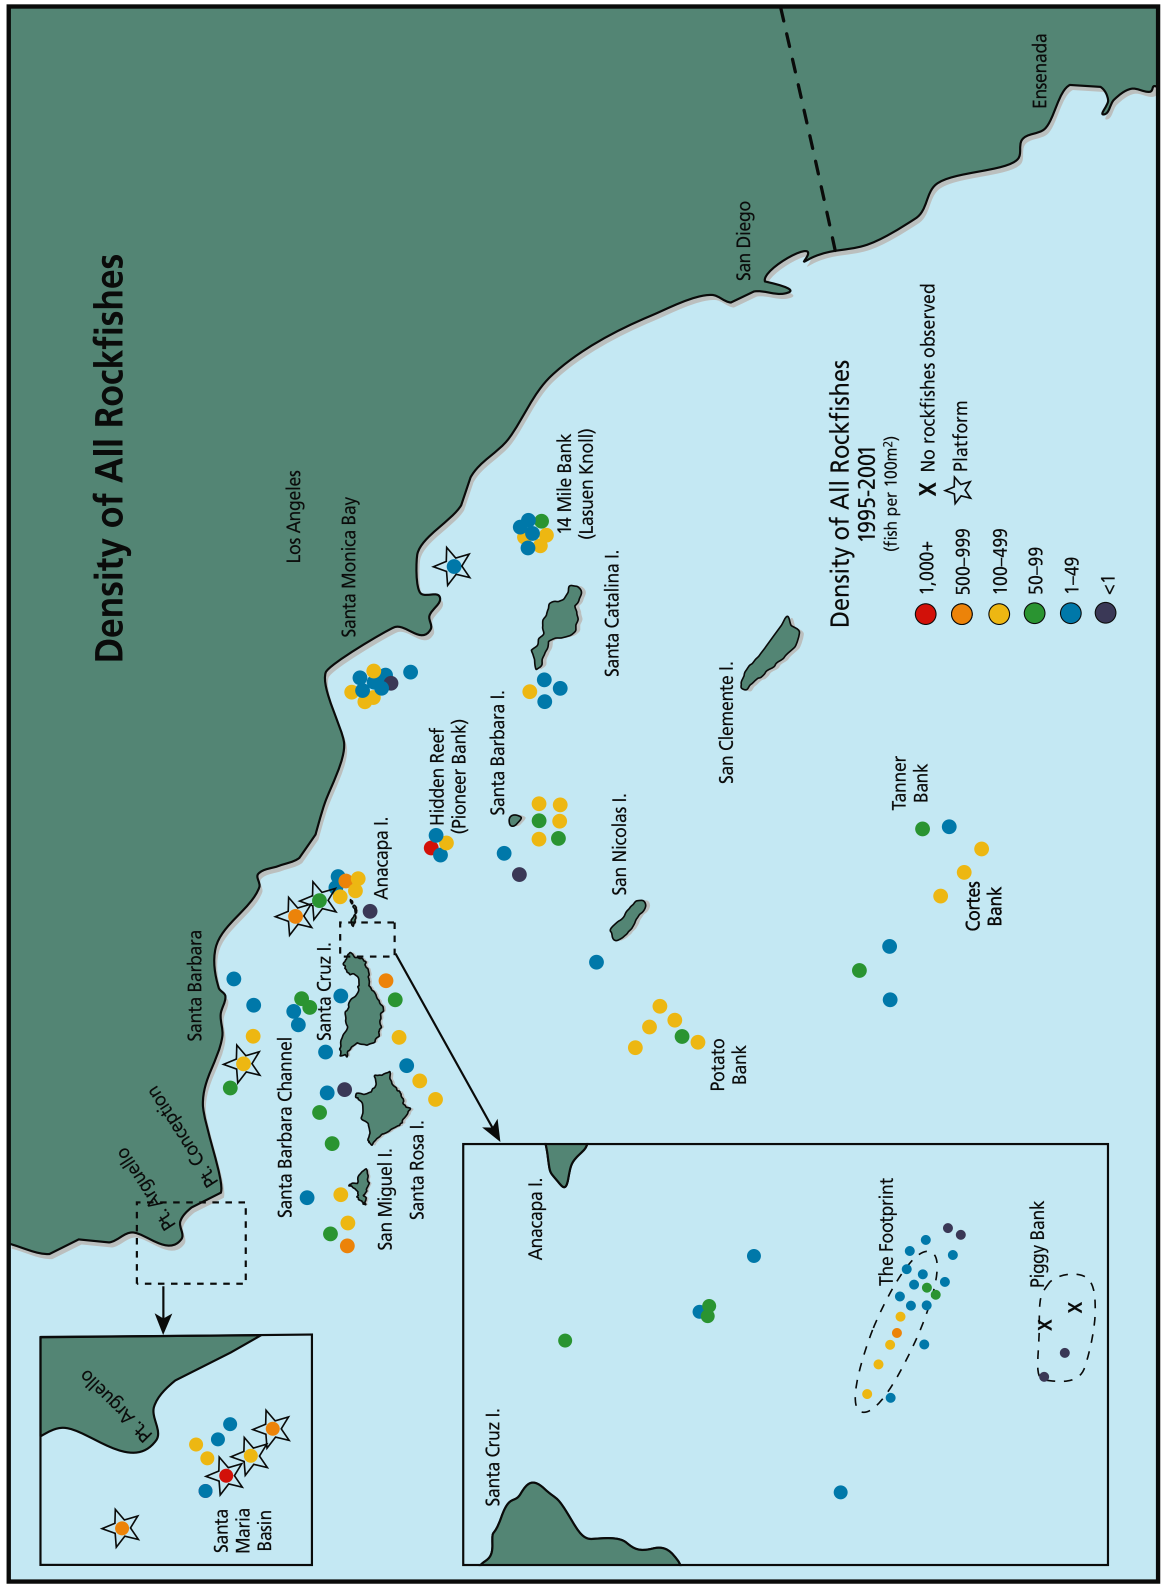

Figure 3.26. Density of all rockfishes, regardless of size, as observed from the Delta submersible on platforms and natural outcrops, 1995–2001. Fish densities for Platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Grace and Gail, North Reef and reefs "A", "B", "C" and "D" in the vicinity of Platform Hidalgo represent means of years.

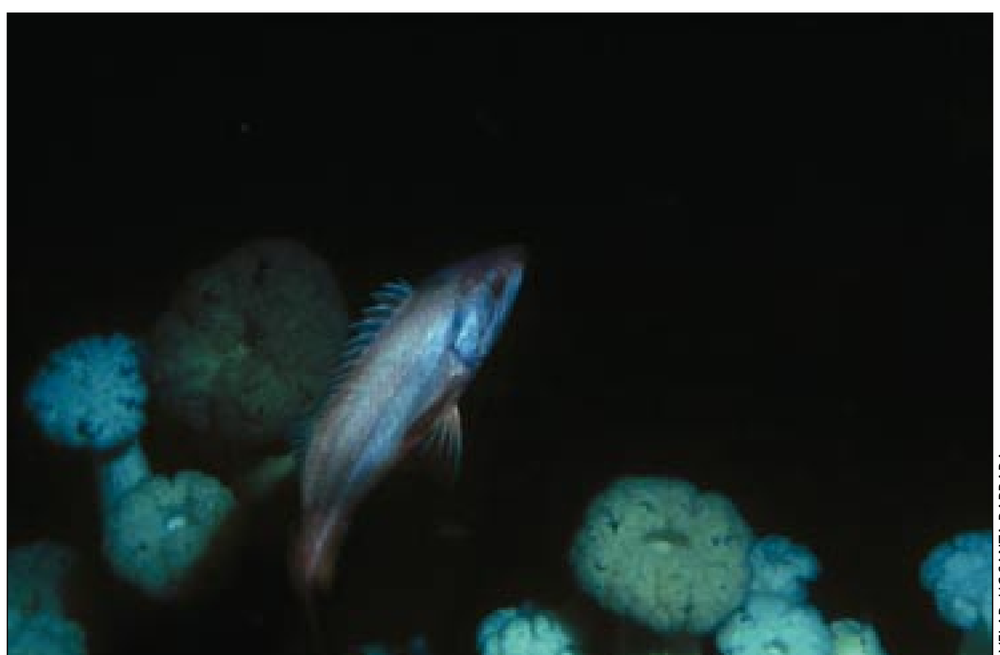
Platforms C, B, A, Hill-house, Hogan, Houchin, and Henry were not included because they were not completely surveyed.*

Why platforms support higher densities of young rockfishes than do nearby natural outcrops.

Platforms are important nursery habitat for many species of rockfishes. This research demonstrates that, in general, platforms may be more important nursery habitats than nearby natural outcrops or, indeed, most other outcrops surveyed in central and southern California. Why is this? First, platforms occupy more of the water column than do most natural outcrops. Presettlement juvenile rockfishes, swimming in the midwater, are much more likely to encounter these tall structures than the relatively low-lying natural rock outcrops. It is interesting to note that most of the natural outcrops we found that had high densities of young-of-the-year rockfishes (e.g., Hidden Reef and outcrops around islands) were very high relief features that thrust their way well into the water column.

In addition, there are also relatively fewer large predators in the platform midwaters. By comparison, even on heavily fished outcrops there tend to be at least a few larger fishes. Many of the major predators of young rockfishes are species that live close to the bottom, such as lingcod, copper and vermilion rockfishes, cowcod and large bocaccio. In general, these species do not ascend the platform jacket. Thus, even when they are abundant at the bottom of a platform, they are absent from the platform midwaters. In this respect, platforms are similar to some of the offshore pinnacles on the southern California continental shelf. Predatory species, such as cowcod, lingcod, and greenblotched rockfishes are also not abundant around the steep, smooth sides of offshore outcrops.

At most of the platforms, we observed both harbor seals and California sea lions, both resting on the platforms and swimming in the water column among the jackets and conductors. Based on the known food habits of these animals, it is likely that they feed on platform fishes, but their low numbers probably have little effect on the abundance of young rockfishes. We also observed both harbor seals and California sea lions swimming over natural outcrops and it likely that here, too, predation on young rockfishes occurs.



LOVELAB, UC SANTA BARBARA

Bocaccio.

Platforms as defacto marine refuges

The role that some platforms play as defacto marine refuges is supported by evidence of greater densities of rockfishes, particularly the larger size classes, at platforms than at natural outcrops. The role that platforms may play as de facto reserves should not be underestimated at a time when many fish populations are in decline on natural outcrops. A number of benthic fishes, including such economically important species as bocaccio, cowcod, copper, and vermilion rockfishes and lingcod find refuge within the platforms and this is probably a factor in their relatively high densities compared to most natural outcrops. Schroeder and Love (2002) compared the rockfish assemblages at three deeper-water areas subjected to variable fishing pressures. Two were natural outcrops, one outcrop open to all fishing and one open only to recreational fishing, and the third was Platform Gail, acting as a de facto marine refuge. The outcrop allowing open fishing had the highest densities of rockfishes (7,212 fish/ha); however, the assemblage was dominated by dwarf species. The recreational fishing area had the lowest rockfish density (423 fish/ha) and this assemblage was also dominated by small fishes. Platform Gail possessed a relatively high density (5,635 fish/ha), and the fishes tended to be larger than individuals at either of the fished sites. Two federally listed overfished species, cowcod and bocaccio, had 32- and 408-fold higher densities, respectively, at Platform Gail than the recreational site, and 8- and 18-fold higher densities, respectively, than the all-fishing area.

There is some fishing effort around most platforms in the Southern California Bight and Santa Maria Basin. The relative amount of fish pressure among platforms is dependent on ease of access and local ocean conditions. Platforms in the Santa Maria Basin are located in an area that is far from ports, usually windy, and unprotected from weather. It is difficult to fish around the bottom of platforms, especially the deeper ones, because of the threat to gear imposed by the large number of crossbeams, other platform structural elements, conductors, and strong currents. Many anglers also believe that operators do not welcome fishing near their platforms.

Some platforms are important fishing areas for recreational anglers. Historically, commercial passenger fishing vessels and small private vessels fished around some of the shallower platforms in the Santa Barbara Channel (Love and Westphal 1990). Platforms Hilda and Hazel were targeted for kelp bass. During years with strong rockfish recruitment, large numbers of juvenile bocaccio, blue, olive, and widow rockfishes were caught at Platforms Holly, A, B, C and Hillhouse. In all of these instances, fishing effort was directed at surface or midwaters, rather than at the platform bottom. The removal of Hilda and Hazel and the poor rockfish recruitment of the 1980s and much of the 1990s reduced the overall fishing effort at oil/gas platforms. Some recreational fishing continues around Platform Gina, and there is minimal effort around a few other structures in the Santa Barbara Channel.

Overfishing has drastically altered the species composition of many outcrops off central and southern California (Yoklavich et al. 2000; M. Love, unpublished data). Over most moderate-depth and deep outcrops in central and southern California, many, or sometimes all, of the larger predatory fishes, such as lingcod, cowcod, bocaccio, yelloweye, and canary rockfishes are gone. In contrast, surveys made over an unfished outcrop in central California showed very high densities of large predatory fishes, including lingcod, cowcod, bocaccio, and yelloweye rockfish (Yoklavich et al. 2000). At many natural outcrops, these larger individuals have been replaced by very large numbers of dwarf species, particularly pygmy, swordspine, and squarespot rockfishes. Fish assemblages at platforms, such as Gail, Hidalgo, and Irene, with relatively high densities of many economically important species and low numbers of dwarf species, may more closely resemble unfished assemblages than those at many natural outcrops.

5. The Origins of Platform Fishes: Production and Attraction

Finding at a Glance

Our research suggests that platforms, like natural outcrops, both produce and attract fishes, depending on species and location. Platform fish assemblages around the deeper and further offshore platforms may be generated primarily from the recruitment of larval and pelagic juvenile fishes, not from attraction of fishes from natural outcrops. Some fishes may live their entire lives around a single platform but their movement patterns are poorly known. A pilot study comparing growth rates showed that young-of-the-year blue rockfish grew faster at a platform than at a natural outcrop.

In recent years, public attention has been drawn to artificial reefs and their function in the marine environment. While a variety of issues have been raised, much of the discussion has centered around the question of whether artificial reefs are producers or attractors of marine life (Carr and Hixon 1997; Lindberg 1997). Some researchers suggest this question is biologically simplistic, because it "imposes an unrealistic either-or-dichotomy…" (Lindberg 1997). Nevertheless, this issue continues to arise in the context of the importance of platforms as fish habitat off California (Carr and Stephens 1998; Krop 1998).

Attraction suggests the net movement of juvenile and adult fishes away from natural outcrops to platforms. While there is not complete agreement on the definition of production, most researchers agree that it involves larval or pelagic juvenile settlement at a structure and the survival and growth of these organisms in this habitat (Carr and Hixon 1997).The attraction/production debate is framed around three questions (Carr and Stephens 1998; Krop 1998): (1) Do larval and juvenile fishes settle onto platforms from the plankton, or do fishes move from other structures to platforms as older juveniles or adults? (2) If a species does settle onto a platform, are growth and survivorship at least as good as on a natural outcrop? (3) If a species does grow and survive well around a platform, did the structure take away larvae or pelagic juveniles that would have settled onto natural outcrops?

5a. Do Fishes Settle from the Plankton onto Platforms or Do They Swim There from Other Structures as Juveniles or Adults?

A large number of fish species settled out of the plankton and took up residence around platforms. We observed young-of-the-year of about 46 fish species at these structures (Table 6) and, including species observed by other researchers (Carlisle et al. 1964), at least 50 fish settle on to platforms from the plankton. During some years, the midwaters of many platforms had very high densities of juvenile rockfishes. Young-of-the-year blacksmith, kelp and painted greenlings, and cabezon also were abundant in this habitat at times. Young-of-the-year rockfishes, lingcod, and other species were abundant around platform bottoms and shell mounds. With a few exceptions, species that settled on the bottom and shell mound were different from those found in the midwaters.

Juveniles of some species were rarely or never observed around platforms. For instance, young-of-the-year kelp bass were rarely seen around any platform, although adults were very abundant at one platform. Young seaperches also were rare or absent. In these cases, older juveniles or adults immigrated to the platforms or juveniles settled there at times other than our surveys.

5b. The Biological Influence of Oceanographic Conditions on Recruitment Success at Platforms and Natural Outcrops in the Santa Barbara Channel and Santa Maria Basin

Most coastal fishes and invertebrates, including those inhabiting platforms, are planktonic during early stages of their life histories. These life stages, which may last from weeks to months, can begin as fertilized eggs (e.g., lingcod, cabezon, and garibaldi) or larvae (e.g., rockfishes). Some fishes, including rockfishes, continue to develop in the pelagic environment until they transform to the juvenile stage (Figure 3.30).

Pelagic life stages are at risk from starvation and predation and transport away from the specific habitats required for their growth and survival. Therefore, the type of water mass an animal finds itself may have a profound effect on its survival. There are a number of water masses in our study area, including waters from the Southern California Bight, the central California coast, upwelling from Point Conception, and from more distant places such as Baja California. How these waters enter, circulate and mix in the Santa Barbara Channel and Santa Maria Basin affects marine populations and community diversity on both platforms and natural habitats.

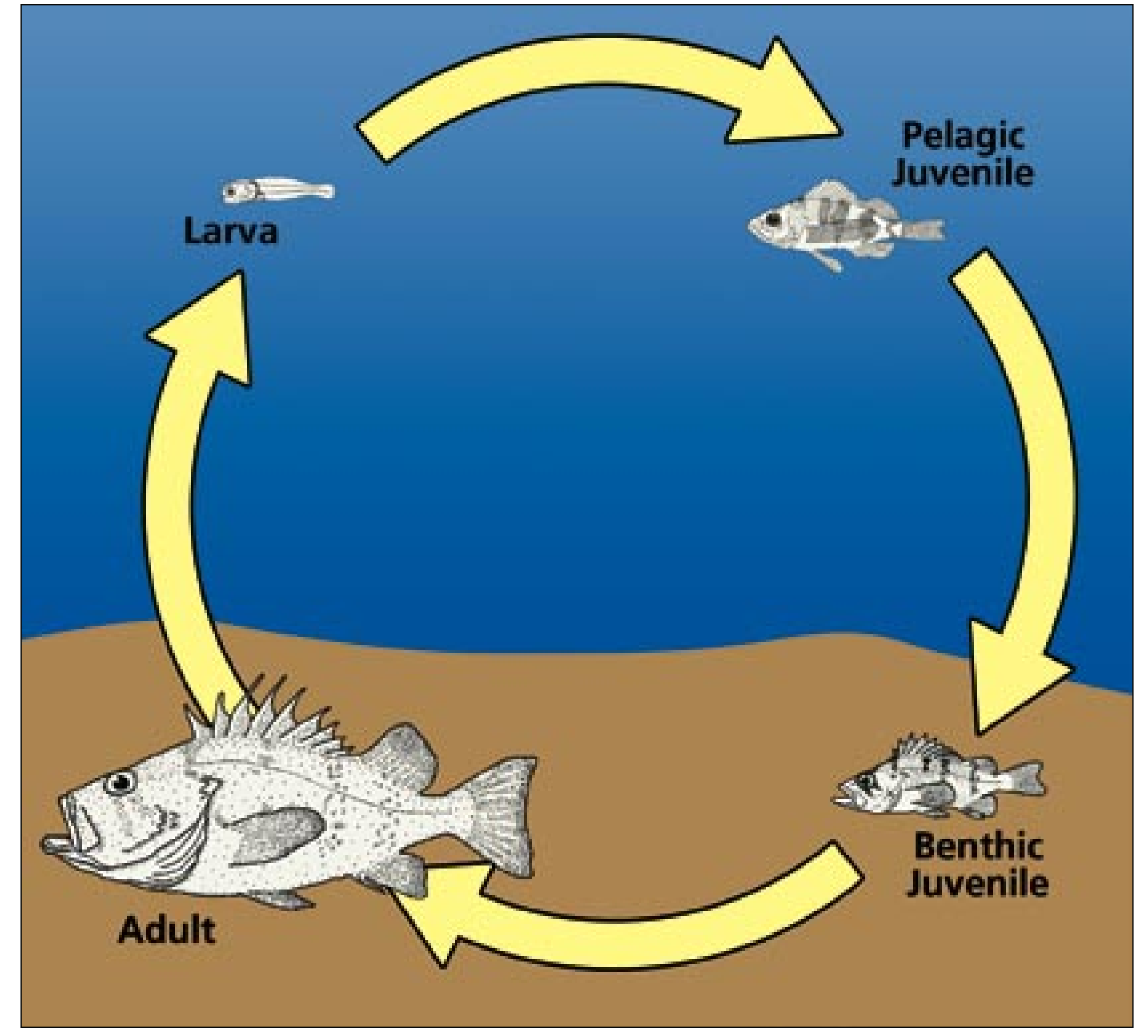


Figure 3.30. A typical rockfish life history cycle using the cowcod as an example.

Upwelling processes, the wind-induced pulling of deeper, colder water to the surface and displacement of warmer waters offshore, is a major factor in larval and pelagic juvenile survival. During years when upwelling coincides with larval fish production, fish survival may be enhanced. Because deep waters are nutrient-rich, upwelling increases reproduction of phytoplankton and encourages the growth of zooplankton, providing food for larval and pelagic juvenile fishes. Upwelling may also increase survivorship of some species by moving larvae and pelagic juveniles somewhat offshore, away from high densities of nearshore predators. Conversely, the offshore transport that accompanies upwelling can be detrimental to the survival of larvae and pelagic juveniles. Wind-induced turbulence in surface waters can make it difficult for larvae to come into contact with prey. Larvae risk being swept well offshore by strong upwelling and far removed from suitable habitat. Spatial and temporal variability in circulation, however, can provide some larvae and pelagic juveniles with conditions that enhance survivorship including delivery to optimum settlement.

The timing, location, intensity, and duration of upwelling events may have a large effect on rockfish settlement. For instance, recruitment may be hampered at sites constantly exposed to newly upwelled water. Through much of the late-spring and summer when presettlement-stage rockfishes are in the pelagic environment, upwelling from the mainland at Point Conception impacts the west channel. Our summer oceanographic data confirm that the upwelling plume can extend across the western portion of the Northern Channel Islands (Love et al. 1999). We found that pelagic juvenile rockfishes were relatively rare in this newly upwelled water (Figure 3.31) (Nishimoto 2000). As an example, when cool upwelled waters moved into an area off the south side

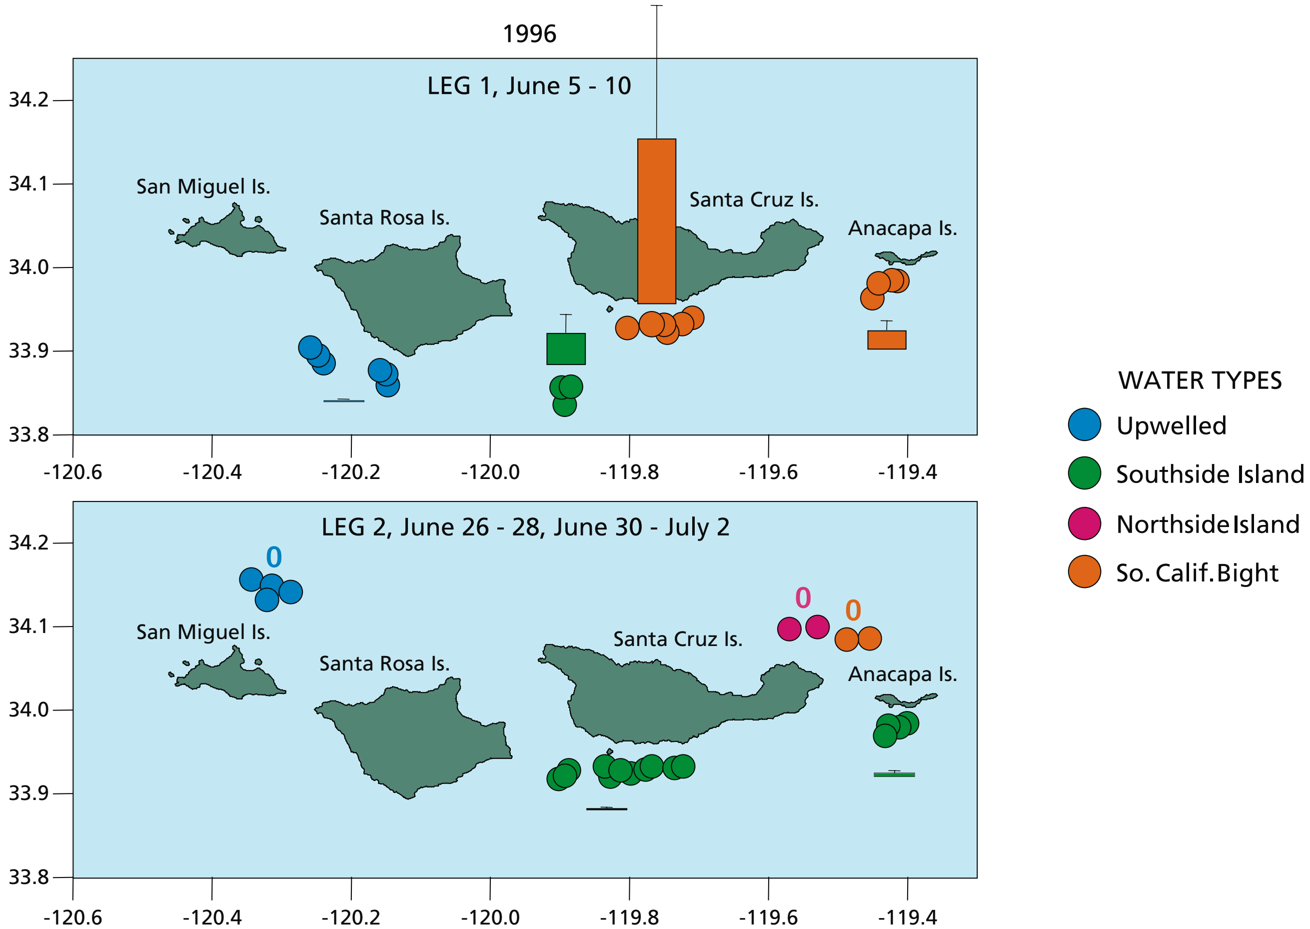

Figure 3.31. The abundance of late-larval stage and pelagic juvenile rockfishes decreases off the south side of Santa Cruz Island when one water mass replaced another between two sampling periods, June–July 1996. Temperature and salinity properties were used to identify four water masses: Upwelled water, Southside Island water, Northside Island water, and Southern California Bight water. Hauls are represented by colored circles. Fish abundance was estimated using the mean collected in midwater trawl hauls within a water mass. Bars illustrate the relative abundances among the water masses. Zeros indicate that no rockfishes were collected in the hauls within a water mass.

of Santa Cruz Island, the fish assemblage changed from one with relatively abundant pelagic juvenile rockfishes to one where these fishes were almost absent. We suspect that the upwelled water, the coldest and most saline water mass that we identified, was recently brought to the surface from depths where few larval and juvenile rockfishes reside**.**

Inter-annual oceanographic conditions, including the intensity of seasonal, coastal upwelling, are highly variable and this affects year class success and population variability. A shift from El Niño to La Niña conditions between 1998 and 1999 was marked by abrupt changes in the marine ecosystem off southern and central California. Our survey data of young-of-the-year rockfishes in 1999 indicates an increase in rockfish recruitment. The number of several juvenile rockfishes and other fish species observed on oil/gas production platforms and rocky outcrops in 1999 far exceeded those of 1998 and previous years. This increased recruitment coincided with intense coastal upwelling off Central California (among the strongest events in 50 years) in spring 1999 followed by high phyto- and zooplankton production (Lynn et al. 1998; Hayward et al. 1999). High productivity in the region likely contributed to the increased survivorship of the fishes including those that recruited to the platforms and natural outcrops.

Relatively transitory phenomena, such as fronts and eddies, may also play an important role in fish settlement and year-class success. Fronts, the zones where different water masses collide and mix, may prevent weak-swimming

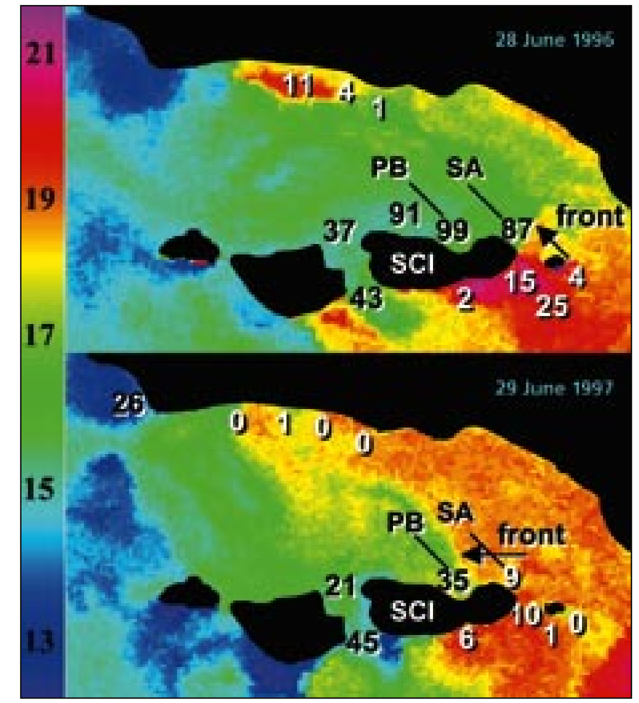

Figure 3.32. The strong correspondence between exposure to cool water and young-of-the-year rockfish density. A shift in position of the thermal front on the north shore of Santa Cruz Island (SCI) in 1996 and 1997 corresponded with a striking spatial shift in juvenile rockfish densities (see sampling sites, Pelican Bay (PB) and Scorpion Anchorage (SA)). Numbers overlaid on images represent mean densities of juvenile rockfishes (number/60 m²) that recruited to giant kelp canopy at sites within the survey area.

planktonic animals from swimming between these masses (Moser and Smith 1993; Wing et al. 1998). The strength of recruitment to a platform or outcrop may be determined in part by the habitat's exposure to those fronts carrying ready-to-settle fish larvae and juveniles. Our research at Santa Cruz and Anacapa islands indicates that the recruitment of nearshore rockfishes was sparse on outcrops separated from cool, fish-rich waters by a frontal boundary (Figure 3.32) (Love, Nishimoto, Schroeder, and Caselle 1999).

Eddies, cyclonic currents that can concentrate and retain plankton, may retain fishes and affect the dispersal of larval and juvenile fishes to outcrops and platforms. For instance, in summer 1998 we sampled a stationary and persistent cold-core cyclonic eddy in the western Santa Barbara Channel. In this feature, we found very high concentrations of small fishes, including late-stage larval and pelagic juvenile rockfishes (Figure 3.33). Eddies may also be very transitory. During the summer of 1999, we observed a much different circulation pattern of shorter-lived, propagating eddies and collected few young rockfishes.

We suspect that the high levels of recruitment of young-of-the-year rockfishes at some platforms were associated, in part, with eddies and fronts retaining larvae that had been locally produced at either platforms or natural outcrops. For instance, Platform Irene is located to the north of the frontal boundary of the upwelling plume that extends off Point Conception. The platform is also situated in an area where a semi-persistent eddy is frequently observed during spring and summer (L.Washburn, personal communication). Similarly, both fronts and eddies were observed at Platforms Gail and Grace in the eastern channel north of Anacapa. As noted previously, Platform Gail harbors important habitat for adult bocaccio in the Santa Barbara Channel. Local retention of bocaccio larvae produced at Platform Gail would explain the high levels of bocaccio settlement at nearby platform Grace and Gilda.

The variability of oceanographic conditions in the Santa Barbara Channel between 1995 and 2001 appears to have strongly influenced settlement as young-of-the-year recruitment to platforms and natural outcrops was highly variable both temporally and spatially. For instance, while the 1997–1998 El Niño corresponded with a large increase in juvenile recruitment of species that dominate the warm-temperate fish assemblage (such as blacksmith), the 1999 La Niña corresponded to a strong settlement of cool-temperate species, such as rockfishes. While settlement of many rockfish species to platforms was generally higher north of Point Conception than in

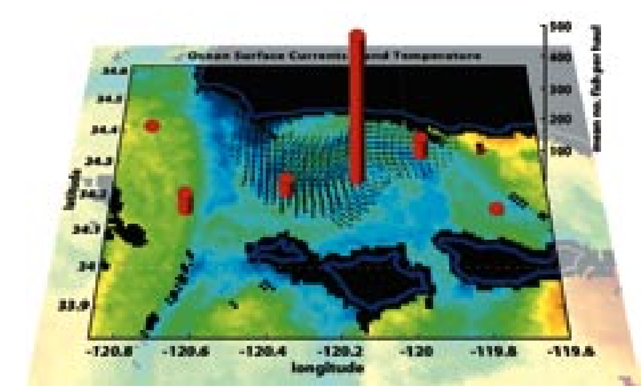

Figure 3.33. The strong link between eddy circulation and the distribution of pelagic young-of-year rockfishes. A persistent eddy about 30 km (19 mi.) wide was evident in satellite sea surface temperature imagery and in surface current mapping generated from coastal-based high frequency radar observations. The abundance of fishes were extraordinarily high in the center of the eddy (red bars represent the mean number of late-stage larval and pelagic juvenile rockfishes in midwater trawl samples from different areas).

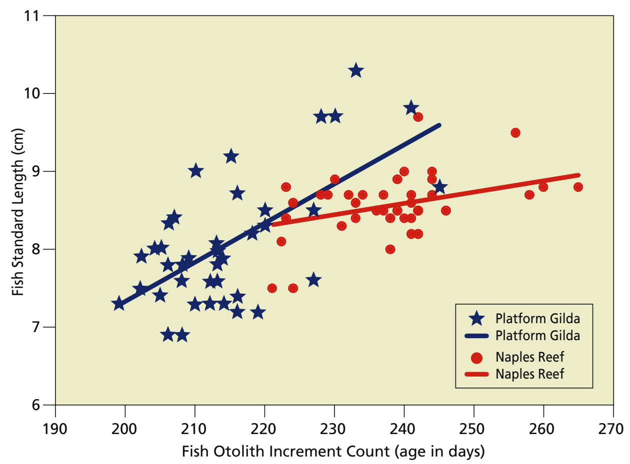

Figure 3.34. A comparison of daily growth rates of young-of-the-year blue rockfish collected at Platform Gilda and Naples Reef in 1999. Fish from Platform Gilda grew at a statistically faster rate than did those from the natural outcrop.

the Santa Barbara Channel during 1996 through 1998, the cooler waters of 1999 brought with it a relatively good year for cool-temperate rockfish recruitment throughout the channel.

The timing of this upsurge in young-of-the-year rockfish settlement in the Santa Barbara Channel also coincided with what may have been a Northeast Pacific oceanographic regime shift from warm to cool waters that overlaid the El Niño and La Niña events. This may have been reflected in the 2000 and 2001 rockfish recruitment at platforms in the eastern channel, which remained higher than pre-1999 levels. We should note that the last cold water regime off southern California occurred in the 1970s, a period that saw heavy settlement of young-of-the-year blue, olive, and widow rockfishes and bocaccio to some of the platforms near Santa Barbara (Love and Westphal 1990).

5c. If a Species Does Settle around a Platform, How Well Does It Grow and Survive, Particularly Compared to the Same Species on a Natural Outcrop?

While our studies in this area are preliminary, they are sufficiently compelling that we can begin to draw some conclusion regarding production of fishes at platforms. On many platforms, we believe that larval and pelagic juvenile recruitment is a major force in shaping platform fish assemblages. We have observed young-of-the-year of about 46 species at the platforms. Of these species, at least 35 were observed as adults at the same structures (Table 7). Adults of some species, such as pygmy, widow, and yellowtail rockfishes, are relatively uncommon around platforms suggesting different habitat requirements. Conversely, adults of many more species, including blacksmith, bocaccio, cabezon, cowcod, lingcod, painted greenling, shortspine and longspine combfishes, and calico, copper, flag, greenblotched, greenspotted, greenstriped, halfbanded, kelp, and pinkrose rockfishes are abundant at the platforms.

Pilot research suggests that at least some juvenile fishes may be growing as well or better at the platforms than at natural outcrops. In 1999, we collected young-of-the-year blue rockfish from Platform Gilda and from Naples Reef (Figure 1.1). Daily growth rates derived from these fishes from otoliths (ear bones) indicated that the platform fish grew at a statistically faster rate than did those from the natural outcrop (F-test, $F = 2.96$, $p = 0.0006$) (Figure 3.34).

Recruitment patterns of flag rockfish at Platform Grace and bocaccio at Platform Gail in 1999 and subsequent annual monitoring of year classes at these sites is providing important new information about the production value of platform habitats. In 2000, and again in 2001, we observed the 1999 year classes of these species at the bottoms of the platforms (Figures 3.35 and 3.36). Length-frequency data indicate substantial survival of the 1999 year classes at the platforms (Figure 3.36). Flag rockfish mature at about six years of age (M. Love and M. Yoklavich, unpublished data) and bocaccio at four or five years (A. MacCall, personal communication). Thus,

DONNA SCHROEDER

Figure 3.35. Flag rockfish at the bottom of Platform Grace, 2001. These fish recruited to the platform as pelagic juveniles in 1999 and moved to the bottom in 2000.

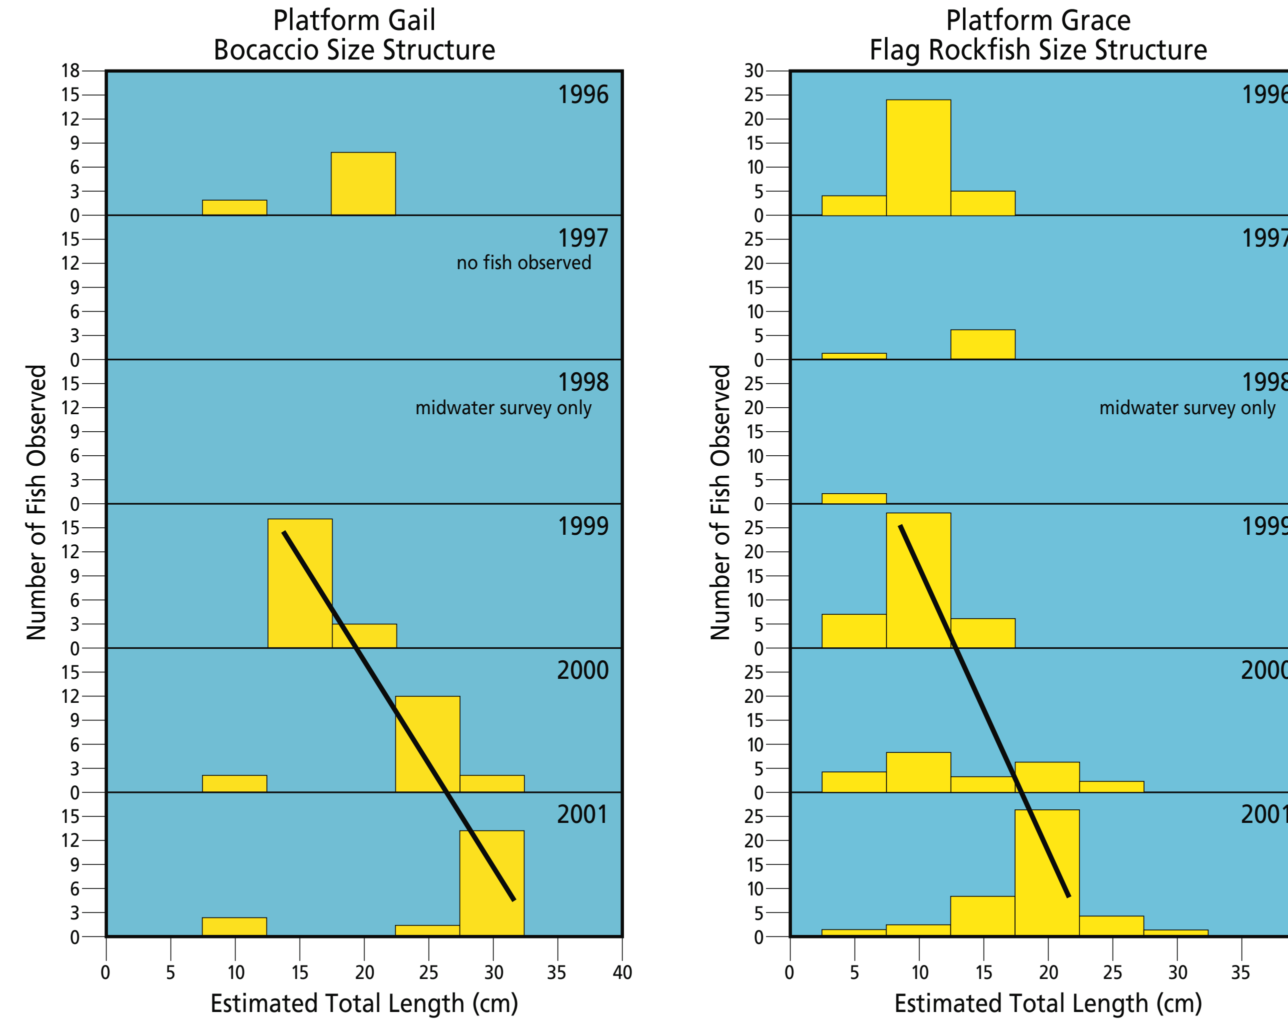

Figure 3.36. Size structure of young bocaccio observed at Platform Gail and flag rockfish observed at Platform Grace, 1996 to 2001. Black line denotes persistence of the successful 1999 year class.

it is conceivable that these fishes will mature at the platforms. This would be strong evidence of production at these structures. [Added in proof: We again observed these fishes during our 2002 surveys of Platforms Gail and Grace.]

5d. Both Attraction and Production Play Important Roles in Shaping Fish Assemblages at Platforms

Our research suggests that populations of fishes at platforms far removed from natural outcrops, as is true for Platforms Gail and Grace, are most likely dependent on larval and juvenile recruitment from the plankton. Our research is developing information about recruitment and residence of fishes at platforms and we have provided evidence of fishes not only settling out at platforms but also maturing there. Recruitment process is highly variable at all habitats from year to year. Adult abundance, at least for some species, is dependent on the strength of recruitment in previous years. Furthermore, recruitment variability may contribute to the year class success (i.e., demographics) of platform and outcrop species such as flag rockfish and bocaccio.

While the movement patterns of some deeper-water rockfishes are unknown, it is likely that many benthic species, such as greenspotted, greenblotched, pinkrose, and cowcod are residential (Starr et al. 2001; Love et al. 2002). Certainly many are restricted to hard substrata seafloors and probably rarely traverse large expanses of soft sediment (Love et al. 2002). Thus, it is likely that the high densities of many platform rockfishes, as well as such species as combfishes, painted greenling, and perhaps lingcod, are due to successful settlement from the plankton and subsequent survival.

The shallow-water species that do inhabit offshore platforms are further evidence that larval and juvenile recruitment play a dominant role in these structures' assemblages. Shallow species that do occur on Gail and/or Grace include kelp bass, garibaldi, and grass and kelp rockfishes. All of these fishes have pelagic larvae. Pile perch and rubberlip seaperch, species without a pelagic life stage, while found on the shallower platforms, are not present on Gail and Grace. This reflects the difficulty these species have in crossing deep waters along the seafloor.

Thus, there is growing evidence that individuals of a number of species, particularly those that are relatively resident and benthic, not only settle out at platforms but also mature there. Such species include, but are not limited to, blacksmith, bocaccio, cowcod, flag, grass, greenblotched, greenspotted, kelp, pinkrose rockfishes, painted greenling, and combfishes.

A dependence on pelagic juvenile recruitment, rather than attraction of older fishes from other structures, explains some of the differences in species composition we observed among the platforms. For instance, until 1999, we observed high densities of adult flag rockfish only at Platform Hidalgo. These densities were far higher than at other platforms or natural outcrops. In 1999, there was a strong recruitment of pelagic juvenile flag rockfish to Platform Grace, and as noted above, these fish remained there at least through 2001. [Added in proof: We observed these fish in 2002.] Annual recruitment of rockfish is highly variable. Thus, the large numbers of flag rockfish observed at Platform Hidalgo are almost certainly the result of a previous successful recruitment, similar to that at Platform Grace. Spatial variability is indicated by the paucity of this species at the other platforms. Similarly, the high densities of adult bocaccio at Platform Gail, and their absence at Platform Harvest (which is located in about the same depth), also suggests spatial variability in the recruitment process.

In contrast, the fish assemblages at platforms that are closer to shore, and in shallow waters, are probably derived both from larval/pelagic juvenile settlement and movements of juveniles and adults from other structures. Carlisle et al. (1964) clearly demonstrated that inshore reef species, such as kelp bass and sheephead, are very mobile and able to traverse shallow, soft seafloors from outcrop to artificial reef. Platform Gina, for instance, is a shallow water platform that seasonally harbors very large numbers of kelp bass, halfmoon, opaleye, pile perch, and other reef species. Fishes are abundant around that platform during summer and fall, but move elsewhere in late winter and spring.

CHAPTER 4

A GUIDE TO ECOLOGICAL AND POLITICAL ISSUES SURROUNDING OIL PLATFORM DECOMMISSIONING IN CALIFORNIA

Donna M. Schroeder and Milton S. Love

Decommissioning Alternatives

Within one year of an OCS lease termination, the Minerals Management Service (MMS) requires that the lessee remove the oil platform structure to a depth of fifteen feet below the mud line, and the leased area must be cleared of obstructions (*see generally*, 30 C.F.R. Part 250, subpart Q, § 250.1700 *et seq.*). However, the MMS may waive these requirements to accommodate conversion of a platform structure to an artificial reef provided that (1) the remaining structure does not inhibit future oil or other mineral development, (2) the resulting artificial reef complies with the Army Corps of Engineers permit requirements and procedures outlined in the National Artificial Reef Plan, and (3) a state fishing management agency accepts liability for the remaining structure (30 C.F.R. §§ 250.1703, 250.1730). In addition, the National Fishing Enhancement Act of 1984 (NFEA), which authorizes the Corps of Engineers' permit program and the National Artificial Reef Plan (33 U.S.C. § 2101 *et seq.*), allows other organizations or agencies (such as the operator) to assume liability for the artificial reef, although MMS policy to date has required a state agency to accept liability.

The timing of future decommissioning activities is not fixed. It depends on the length of the lease, the rate of reservoir depletion, the market value of oil or gas, and whether the platform might serve an extended use for the operator, such as a gathering system for the production of other platforms. There are three stages in the decommissioning process: planning, permitting, and implementation. Platform decommissioning alternatives fall into four general categories: complete removal (the default option), partial removal, toppling, and leave-in-place (Figure 4.1). The suite of decommissioning alternatives that proposes to leave part or all of the abandoned platform structure in the marine environment is often collectively referred to as "rigs-to-reefs".

Alternative 1: COMPLETE REMOVAL

A typical full-removal project begins with well abandonment in which the well bores are filled with cement. The conductors are then separated from below the seafloor by being pulled, cut-off, or removed using explosives. Next the topsides, which contain the crew quarters and the oil and gas processing equipment, are cut from the jacket and removed. Finally, the piles that hold the jacket to the seabed are severed with explosives and the jacket is removed. Other typical decommissioning requirements include the removal or abandonment of pipelines and electrical cables and the removal of any debris from the seafloor.

After deciding to totally remove a platform from the seafloor, operators have several options (O'Connor 1999; van Voorst 1999; Gibbs 2000; Terdre 2000). (1) The platform can be taken to shore, where it is disassembled and the components either recycled, sold as scrap, or discarded in landfills or other depositories. To date, managers have selected this option for most decommissioned platforms. (2) The structure can be reconditioned and reused. As an example, in 1997 a platform was removed from the North Sea, taken to shore and cleaned, refurbished, shortened by 10 m (33 ft.), and installed in another North Sea location. A few small platforms have also been reused in the Gulf of Mexico. (3) A platform can be towed to another site and reefed. This has occurred a number of times in the Gulf of Mexico, with the most zealous example towing structures of two Tenneco platforms over 1480 km (920 mi) from offshore Louisiana to a site 1.5 miles off Dade County, Florida (Wilson et al. 1987).

Alternative 2: PARTIAL REMOVAL

In this scenario, the wells are abandoned, the topsides are removed, and the remaining jacket and possibly the shell mound are left in place to continue to function as an artificial reef. Navigation aids are added.

Despite what has been implied in other reports, conductors need not be completely removed. Dauterive (2000) notes "Recognizing the preservation of environmental values associated with the method of partial removal of the platform, the MMS in 1997 established a policy to allow the industry the option to partially remove

DECOMMISSIONING OPTIONS AND ISSUES

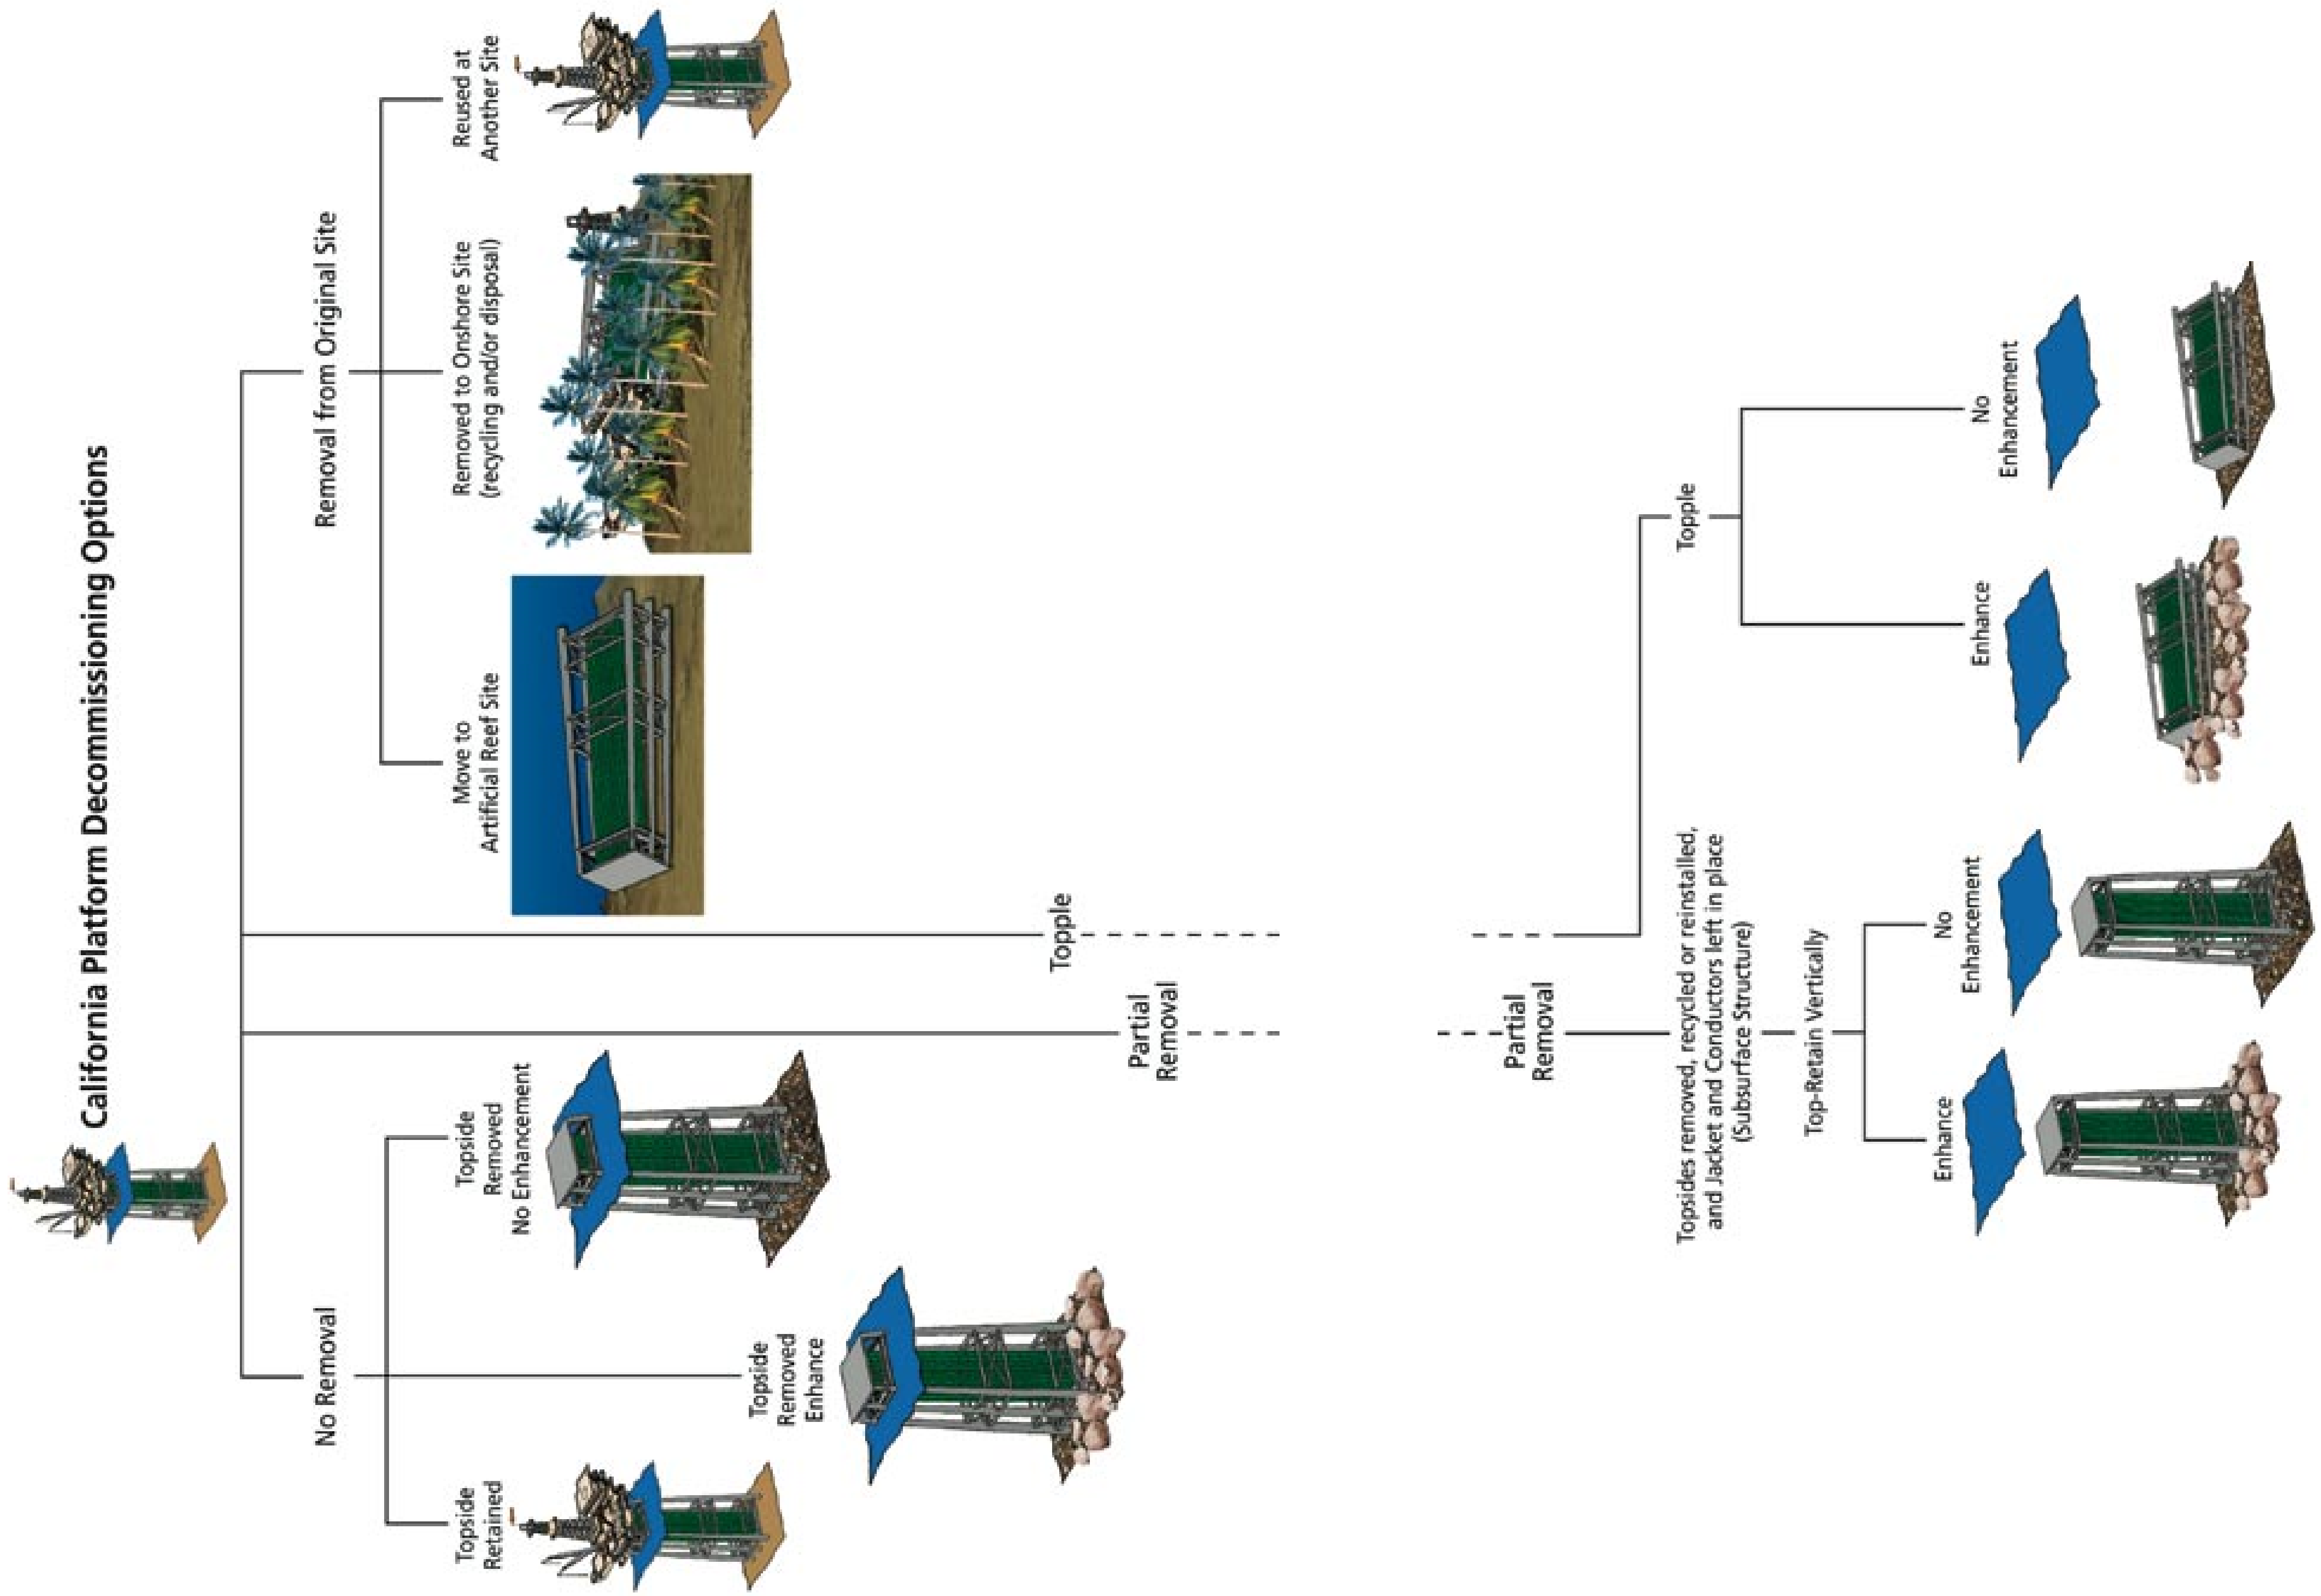

Figure 4.1. Platform decommissioning options.

the well conductors at the same depth below the water line (WL) at which the industry had proposed to remove the platform jacket." Retaining platform conductors has two consequences. First, it adds additional complexity to remaining structure. Second, explosives are usually used to remove the conductors and retaining these pipes eliminates the need for explosives (Dauterive 2000).

After cleaning, disposition of topsides may be handled in a couple of ways. It can be moved to a new platform and reinstalled, or it can be taken onshore, where the steel and other valuable components are recycled and other material sent to landfills. Certain parts of the topsides, such as the cleaned deck, have occasionally be used in forming artificial reefs.

Alternative 3: TOPPLING

As in partial removal, the wells are abandoned and the topsides are removed. The shell mounds may be either removed or left in place. The primary difference between partial removal and toppling is that, in toppling, explosives are used to sever the jacket from the seabed and then a derrick barge or pull barge drags the jacket over and it is allowed to settle to the seafloor (Twachtman 1997). Navigational aids, if necessary, are then put in place.

Alternative 4: NO REMOVAL (LEAVE-IN-PLACE)

A platform and its surrounding shell mound could be left in its original location at the time of decommissioning. The topside would be stripped and cleaned and navigational aids installed.

In the Gulf of Mexico this scenario has been discussed on a number of occasions, although it has not been attempted. For instance, a platform in the Flower Garden Banks National Marine Sanctuary was studied as a possible research laboratory. However, the cost of maintaining cathodic protection and navigational aids (together running to $300,000 per year) proved too high (L. Dauterive, personal communication). Other creative suggestions offered by stakeholders for decommissioned, left-in-place platforms include wind and aquaculture farms, meteorological stations, hospitals, hotels, gambling casinos, and penal institutions.

Agencies Responsible for the Decommissioning Process

By law, various coastal states and the federal government share the administration of submerged lands, subsoils and seabeds off the United States. Thus, depending on where platforms are positioned, responsibility for mineral extraction, including oil and gas development, is either under state or federal jurisdiction. Similarly, decisions regarding the decommissioning of platforms fall under either state or federal control, although the final decisions are based on consultation and mutual agreements among a number of agencies.

Responsibility for the fate of platforms in federal waters rests with the MMS (33 U.S.C. § 1331 *et seq.*) Federal agencies that are consulted in the decommissioning process include the Environmental Protection Agency (33 U.S.C. §§ 1311(a), 1342), Army Corps of Engineers (33 U.S.C. §§ 403,1344), National Oceanic and Atmospheric Administration (NOAA) Fisheries (16 U.S.C. § 1801 *et seq.*), and Coast Guard (14 U.S.C. § 85: 43 U.S.C. § 1333(d)). State agencies, such as the California Department of Fish and Game do not have jurisdiction in federal waters but may comment in the decision making process. Under the federal Coastal Zone Management Act (16 U.S.C. § 1451 *et seq.*), MMS decisions on platform decommissioning that will affect coastal resources are also reviewed by the appropriate state agency for consistency with the state's coastal zone management program. In California, the California Coastal Commission conducts review for consistency with the state program. In turn, state agency consistency decisions can be appealed to the U. S. Department of Commerce (16 U.S.C. § 1456(c)(3)(A), (c)(3)(B)(iii); 15 C.F.R. Part 930, subpart H).

Decisions regarding the decommissioning of platforms in California state waters are the province of the State Lands Commission (Cal. Pub. Res. Code § 6216), along with such agencies as the California Coastal Commission (Cal. Pub. Res. Code § 30330), Department of Fish and Game (Cal. Fish & Game Code § 1602), local Air Pollution Control Districts (Cal. Health & Safety Code 40000), U. S. Army Corps of Engineers (33 U.S.C. §§ 403, 1344), and the U. S. Coast Guard (14 U.S.C. § 85).

Jacket and conductor removal: the role of the U. S. Coast Guard in decommissioning

Local United States Coast Guard districts are responsible for the safety of vessel traffic in their respective geographic areas and have the authority to dictate aids to navigation for obstacles in the water (14 U.S.C. §85; 43 U.S.C. § 1333(d); 33 C.F.R. Part 67). Therefore, in instances where some part or all of a platform is to be reefed, the Coast Guard will specify the necessary navigational aids. Discussions regarding decommissioning of platforms off California have often erroneously assumed that the Coast Guard will require that the jacket be removed to about 26 m (85 ft.) below the surface. However, decommissioning experience in the Gulf of Mexico demonstrates that there is no set removal depth. Indeed, the Coast Guard decision-making process appears to be quite flexible; it reviews each decommissioning on a case-by-case basis. For instance, in the decommissioning of the mile-long Freeport-McMoRan sulfur mine platform and bridge off Louisiana, the Coast Guard required piles to be cut 9 m (30 ft.) beneath the surface (Kasprzak 1999).

Generally, the requirements for aids to navigation become more restrictive (and therefore more expensive) the closer to the surface the obstacle lies. As an example, here is a generic set of conditions for decommissioned platforms in the Gulf of Mexico based on recent Coast Guard decisions (G. Steinbach, personal communication):

- If the obstacle is greater than 61 m (200 ft.) in depth: no requirement for aids to navigation
- If the obstacle is from 61 m to 26 m (200 ft. to 85 ft.) in depth: unlighted buoys are required
- If the obstacle is 26 m to 11 m (85 ft. to 35 ft.) in depth: lighted buoys are required
- If the obstacle is from 11 m (35 ft.) to protruding through the surface: lights or lighted buoys and foghorns are required.

In the rigs-to-reefs programs in the Gulf of Mexico, the states are responsible for aids to navigation on reefed platforms. The costs of these aids are paid for from the funds created by the industry's donations. As a cost savings measure, these states generally have selected greater water clearances. The requirements for California waters may be different from those in the Gulf of Mexico. The local Coast Guard District will determine these requirements based on vessel traffic and other local conditions.

The question of liability for a reefed platform off California

Liability, who retains responsibility for a reefed platform, is a major issue in the decommissioning process. MMS policy states the "The MMS supports and encourages the reuse of obsolete offshore petroleum structures as artificial reefs in U. S. Waters." Current MMS regulations provide that a platform operator may be released from removal obligations in the federal lease instrument if a state agency responsible for managing fisheries resources will accept liability (30 C.F.R. § 250.1730). However, in situations where reefs are not managed by a state agency, another organization or agency must assume liability, as provided in the National Fishing Enhancement Act of 1984 (Stone 1985). In such cases, liability could possibly be retained by the oil company, transferred to a private entity, or handled in some other manner as long as MMS approval is received (G. Steinbach, personal communication).

An extensive body of policy and research outlines proper procedures for siting and deploying artificial reefs, and this information bears upon liability of such structures. The National Artificial Reef Plan (NARP) states "When a reef has been properly located, marked on navigation charts if necessary, and any required surface markers affixed, there should be very little potential for liability" (Stone 1985). Regarding accidents, which may occur during recreational activities near artificial reefs, the NARP further declares, "Diving accidents may occur with use by recreational divers. In this respect, an artificial reef is like a public park — there are dangers in those parks, guardrails and fences cannot be placed everywhere, and everyone who visits the park assumes some risk of injury. A warning could be placed on nautical charts and posted in local dive shops to warn of these dangers. However, each case would probably involve determination of comparative negligence" (Stone 1985). Parker (1999) notes that no lawsuits have ever been filed against the California Department of Fish and Game with respect to their artificial reef program.

Regardless of which decommissioning alternative is selected, the federal government cannot be held liable. Regarding State liability, the NARP notes, "If the permit holder is a State government, it may have sovereign immunity from liability. It is unclear whether the National Fishing Enhancement Act affects any State's claim of sovereign immunity." (Stone 1985)

National Artificial Reef Plan

Decommissioning options other than complete removal must be consistent with the National Artificial Reef Plan (33 U.S.C. § 2104(a)(4)). The National Fishing Enhancement Act of 1984 directed the development of a long-term National Artificial Reef Plan (NARP) to provide guidance and criteria on planning, construction, and evaluating artificial reef use, as well as introducing liability and mitigation issues (33 U.S.C. § 2103). Goals of the NARP seek to enhance fishing and fishery resources and minimize user conflicts and environmental risks without creating unreasonable obstruction to navigation (33 U.S.C. § 2102). In 1998, the NARP was supplemented by the Coastal Artificial Reef Planning Guide, which incorporates new language from relevant federal and state agencies, fishing interests, and the general public.

California Department of Fish and Game Rigs-to-Reef Guidelines

"These guidelines stipulate that the project must benefit living marine resources, habitat, and user groups; that disposal or use of contaminated materials is not permitted; that wherever possible the subsurface structure of the platform should remain in place; that where possible subsurface structure that must be removed could be relocated to the base of the rig or other appropriate sites; and that the remaining structure be augmented by rocks or other materials to assure that the site functions as a diverse and productive reef habitat. To replace the biotic productivity from that part of the platform removed for navigational purposes, rock or concrete reefs should be placed in nearshore locations. A rigs-to-reef project sponsor must provide sufficient funds to the Department to evaluate the benefits to biotic productivity, user groups, and the overall management of fishery resources." (Holbrook et al. 2000)

Social Values in Platform Decommissioning

Defining the social and ecological goals of decommissioned platforms as artificial reefs will be critical in evaluating the efficacy of any potential rigs-to-reef program and the current and future performance of any artificial reef. Therefore, it is likely that various stakeholder groups will vie in defining the goals (and therefore the usefulness) of decommissioned platforms as artificial reefs. In this report, we sort the multitude of stakeholder viewpoints regarding a rigs-to-reef program into three groups, each of which is primarily defined by one concern: community membership, resource accessibility and environmental (marine life) issues. Of course, an individual may be influenced by more than one social value, and others may use arguments from multiple categories to promote a desired decommissioning outcome.

The first group consists of stakeholders who are concerned about community membership, and either oppose or support local presence of the oil industry. Those that wish to promote a community without the oil industry often view reefing alternatives as bundled together with all oil industry activities (e.g., continued exploration and production), the whole of which should be locally opposed (although they may not be opposed to oil industry activities in the Gulf of Mexico). For example, Camozzi (1998a) states that complete removal should be the preferred alternative in decommissioning because, after decades of fighting oil development on the California Coast, it acts as a "catharsis" for the local community. Camozzi (1998b) reiterates this point by stating that, in regard to mussel mound removal, "Sending a message to oil companies that they must clean up our coast when they are done extracting their profits is the most vital issue in this case." Individuals who wish to encourage or maintain the presence of the oil industry in the local community, presumably for economic reasons, favor some sort of reefing option because reefing is less expensive than complete removal (Pulsipher et al. 2000). Further information regarding local community views on the oil industry in California can be found in Lima (1994) and Smith and Garcia (1995).

The second group of stakeholders is primarily concerned with resource accessibility. A heterogeneous group, these citizens will either favor or oppose decommissioning alternatives depending on how these alternatives aid or inhibit their ability to access a particular resource. For example, commercial trawlers in the Southern California Bight favor complete removal because fishing gear may snag on platform structure or shell mounds (Southern California Trawlers Association 1998; McCorkle 1999). Other commercial fishers benefit from oil industry activities. Shrimp trawlers in the Gulf of Mexico drag within 0.4 km (0.25 mi) of platform structures, reporting that these fishing grounds tend to be more productive (Wilson et al. 1987). The rocky habitat associated with Rincon Oil Island in California provides excellent lobster fishing grounds and trap fishers would oppose seeing this habitat removed (Miller 1999). Recreational fishers often dominate the debate surrounding platform decommissioning, and they have driven the formation of artificial reef policy at both state and federal levels (Stone 1985; Wilson et al. 1987). Many recreational fishers favor a reefing alternative in decommissioning because catch per unit effort is often high at offshore platforms for targeted fish species such as kelp bass (Love and Westphal 1990; McCrea 1998). In the Gulf of Mexico, Reggio (1987) estimates that 70% of fishing excursions target oil platform habitats. Citizens participating in non-consumptive activities also possess a variety of viewpoints regarding decommissioning alternatives. Many scuba divers find that underwater portions of oil platforms provide outstanding diving and underwater photographic opportunities, and favor decommissioning alternatives that preserve such opportunities, (Vallette 1999). Other members of the public may view the topside structure of platforms as denying them access to unobstructed, scenic ocean views, and consequently they oppose the leave-in-place decommissioning option (Wiseman 1999).

The third stakeholder group makes decisions regarding decommissioning based on their perception of how certain marine populations or environmental ideals fare under the various decommissioning alternatives. It is this last group that is most likely to use ecological information in making decisions regarding platform decommissioning. A decommissioning option that involves reefing may be supported if a substantial net benefit to the marine environment can be demonstrated (Chabot 1999). Others support complete removal because this option is the only one which promotes a wilderness ideal, that is, a marine environment which fails to retain a visible mark of human activities. If there is a lack of scientific evidence regarding ecological consequences, or if they are unaware of such consequences, these stakeholders may use another social value, such as community membership, in choosing a preferred decommissioning alternative (Chabot 1999).

Economic incentives interact and overlap with social values. In past rigs-to-reefs activities, industry and state entities have equally shared the cost-savings resulting from partial removal or toppling alternatives. Partial removal of deep water platforms will generate estimated savings of one to two orders of magnitude greater than the amount saved in decommissioning smaller platforms. The cost of maintaining navigational equipment (if any is needed) at these reefed platforms will not increase in the same proportion as the increase in cost-savings, and may actually decrease. These additional financial resources may be used to develop or enhance projects of interest to stakeholders, and may be a sufficient incentive to alter the preferred decommissioning option for some groups.

The Interaction of Science, Scale, and Social Values

State and federal regulatory agencies involved in the decommissioning process are required to protect the public interest when managing natural resources. In the face of strongly conflicting viewpoints among stakeholder groups, resource managers may try to convert a controversial issue into a technical one. For instance, they may give preference to the protection of marine life resources, thereby avoiding the appearance of favoring one group's economic concerns over another's. Additionally, legislation such as the Endangered Species Act and the Marine Mammal Protection Act, among others, often give environmental concerns priority over social and economic concerns. In combination, these issues give ecological information a prominent role in the decommissioning process.

Impacts to the environment may be measured at short or long time scales, or within a local or regional context. As time and space scales increase, so does scientific uncertainty about predicting consequences of various management alternatives (due to an increasing number of unknown variables and propagation of error associated with imprecise assumptions or model parameters). When there is greater scientific uncertainty, social values and political or economic factors often become more important in the decision-making process. This phenomenon may result in stakeholders advocating that ecological performance of reefed platforms be evaluated at scales which enhance the possibility of their preferred decommissioning alternative, even if ecological data are irrelevant to their concerns.

For example, proponents of regional ecological assessment at long time intervals may be individuals who oppose the local presence of the oil industry. Since regional assessment is difficult and expensive to accomplish, social values (e.g., antagonistic views of oil industry) will increase in importance. Significantly, these same individuals have not stipulated that other artificial reefs which are similar to reefed platforms, such as steel hulled ships, undergo the same rigorous ecological assessment. Further, the assured instantaneous and lethal effects of explosives are not considered in arguments about marine life effects.

Proponents of small scale ecological assessment tend to be recreational anglers, who often state their support for rigs-to-reef programs in terms of benefits to the environment. They maintain that the local presence of abundant marine life at a platform is sufficient evidence of satisfactory ecological performance. But this support for a rigs-to-reef alternative often evaporates if artificial reefs are designated no-take areas.

Ecological information greatly aids the decision-making process if explicit management goals are specified. The rebuilding of depleted fish stocks might be one goal, the preservation and expansion of marine wilderness might be another. Determination and ranking of ecological goals reflects cultural values. Thus, controversies surrounding platform decommissioning cannot easily be translated into technical issues by giving priority to ecological goals because we lack agreement on the space and time scales in which ecological impacts should be measured. Therefore, the scale at which ecological impacts are measured (local or regional) and considered (short or long term) becomes paramount in the decommissioning process. To date, such specific space and time scales have not been designated by any state or federal government agency.

Decommissioning Activities in the Gulf of Mexico

To date, almost all platform decommissioning and reefing in the world has occurred in the Gulf of Mexico. Because large-scale offshore drilling first took place in the Gulf of Mexico, it was in this region that the issue of what to do with unwanted platforms first arose. Below, we give a brief summary of the history of decommissioning in the Gulf of Mexico; additional details are found in Lukens (1997), Kasprzak (1998), and Dauterive (2000).

Kerr-McGee erected the first offshore oil and gas platform in the Gulf of Mexico off Louisiana in 1947. Despite its primitive structure and placement in waters only 6 m (18 ft.) deep, oil was struck 22 days after drilling began, presaging a veritable tidal wave of offshore drilling. In 2001, there were over 4,000 platforms in the Gulf of Mexico, the vast majority occurring off Louisiana, followed by Texas, Mississippi and Alabama (Lukens 1997; Moritis 1997; Kasprzak 1998, 1999; Dauterive 2000). Platforms provide a considerable amount of the hard substrate in the north-central Gulf of Mexico, and surveys indicate that 20%–50% more fish live around platforms than on surrounding soft seafloors (Gallaway and Lewbel 1982; Driesen 1985). Because recreational and commercial fishers target fish residing near these structures, they are of considerable economic value (Dimitroff 1982; Reggio 1987; Kasprzak 1998).

By the late 1970s, it was apparent that the economic life span of many of these structures was nearing an end. During that decade, about 150 platforms were removed to shore and scrapped. The first reefing of an oil and gas structure occurred in 1979 when a subsea production system was towed from Louisiana to an artificial reef site off the Panhandle of Florida. In 1982, an obsolete platform jacket was moved from Louisiana to a Dade County, Florida site and over the next few years several additional structures were moved to various artificial reef sites.

Responding to this new activity, Congress passed the National Fishing Enhancement Act (NFEA) in 1984 (33 U.S.C. § 2101 *et seq.*). The NFEA mandated the creation of a "long-term plan for siting, constructing, permitting, installing, monitoring, managing, and maintaining artificial reefs within and seaward of state jurisdictions" (Kasprzak 1998). This document, later called the National Artificial Reef Plan, was published in 1985. In response to NFEA, several Gulf of Mexico states have now passed laws to take advantage of platform decommissioning to help preserve complex habitat in the northern Gulf of Mexico, for example, the Louisiana Fishing Enhancement Act of 1986 (La. Rev. Stat. § 56:639.1 *et seq.*) [Act 100] and the Texas Artificial Reef Act of 1989 (Tex. Parks & Wildlife Code § 89.001 *et seq.*). As an example, Act 100 created a process by which ownership of and liability for uneconomical platforms could be transferred from operators to the state of Louisiana. As noted by Kasprzak (1998), "Act 100 established the State of Louisiana as the permittee for artificial reefs developed under the program's jurisdiction and appointed the Department of Wildlife and Fisheries as agent for the state. The state assumes responsibility for the reefs upon placement within the established reef permit area…Act 100 does not authorize state general funds for the artificial reef program but does establish the Louisiana Artificial Reef Trust Fund. Oil and gas companies that donate structures to the program are asked to contribute half of the disposal savings realized through program participation to the trust fund." A similar program exists in Texas (Texas Parks and Recreation 1999).

A significant amount of money has been collected in rigs-to-reef programs in both Louisiana and Texas. As of 2001, there was about $15 million in the Louisiana fund and at least $4 million in Texas. Contrary to what has been reported (McGinnis et al. 2001), major artificial reef programs of several states, including Louisiana and Texas, receive neither state nor federal funding, they are fully underwritten by the interest paid on their respective rigs-to-reef accounts (J. Culbertson, personal communication; R. Kasprzak, personal communication). The Louisiana Department of Wildlife and Fisheries and Texas Parks and Wildlife Department describe their rigs-to-reefs programs at http://www.wlf.state.la.us (under "Marine Fisheries") and http://www.tpwd.state.tx.us/fish/reef/artreef.htm, respectively.

Since 1942, over 188 Gulf of Mexico platforms have been reefed, primarily off Louisiana and Texas. This represents about 8.4% of all decommissioned platforms (L. Dauterive, personal communication). The reasons for this early low reefing rate were economic. Most of the platforms thus far decommissioned were in shallow water, and it was more cost effective to haul them onshore for salvage or reuse rather then tow them to reefing sites. In the future, it is likely that a higher proportion of platforms will be reefed as more offshore structures become obsolete. Of the platforms that have been reefed, about 60% have been removed from a site and towed to a new location. Contrary to what was stated by Krop (1998), some decommissioned platform structures have been left in place. Thus far, 30% have been toppled in place and the remainder have been partially removed and left standing (Dauterive 2000). As larger platforms in deeper waters are decommissioned, L. Dauterive (personal communication) has noted a trend towards partial removal, rather than towing or toppling. In all but a few instances, only the platform jacket has been used as reef material.

The Future: Ecological Consequences of Offshore Platform Decommissioning in California

Complete Removal (Total Removal) of Platform

The immediate impact of removing and hauling an entire platform to shore is that all attached animals die. If some of the platform structure is hauled to a reef area and replaced in the water, some of these animals may survive, depending on water depth and the length of time the structure is exposed to the air.

Using explosives to separate the jacket from the seafloor kills large numbers of fishes, although limited research makes it difficult to predict how many deaths will occur. Marine mammals and sea turtles may also be indirectly killed by damage to the auditory system. In a study in the Gulf of Mexico (Bull and Kendall 1994), explosives were placed 5 m (15 ft.) below the seafloor to sever the well conductors, platform anchor pilings and support legs, of a platform in about 30 m (100 ft.) of water. All of the fishes on or near the bottom and most of the adult fishes around the entire platform suffered lethal concussion.

Some shallow-water platforms can be removed without explosives. However, "The oil and gas industry has attempted to find alternatives to the use of explosives, such as cryogenic cutting, hydraulic abrasive cutting, mechanical cutting, and torch cutting. Most of these techniques either have proven to be ineffective or are successful only in limited situations. At present, the industry maintains that the use of explosives is by far the safest, most reliable, and most cost-effective method of platform removal" (Kasprzak 1998). A recent assessment of techniques for removing platforms (NRC 1996) found that it is unlikely that any techniques or devices now known will significantly reduce fish kills during removal operations that use explosives.

Shell Mounds at the Base of Platform

The jackets and conductors of all platforms off southern and central California are heavily encrusted with invertebrates, including mussels, barnacles, seastars, rock scallops, rock oysters and jingle shells, sea anemones, caprellid amphipods, rock crabs, limpets, gooseneck barnacles, and sessile tunicates. An extremely thick layer of mussels extends from the intertidal zone to depths of at least 30 m (100 ft.) (and deeper on some platforms). The seafloor surrounding the platforms is covered with mussel shells. This "shell mound" or "mussel mound" is created when mussels, and other invertebrates, are dislodged during platform cleaning or heavy swells. Our observations show that, depending on bottom depth, a number of species of invertebrates, including many species of seastars, brittle stars, and rock crabs, as well as king crabs, opisthobranchs, shrimps, octopi, and sea anemones are abundant on the shell mounds. Substantial number of fishes, primarily the juvenile stages of various rockfishes, adult stages of dwarf rockfish species, as well as lingcod, poachers, painted greenling, and other benthic species also inhabit shell mounds.

Around four platforms in shallow water locations (+/- about 33 m, 109 ft., water depth), the shell mounds were found to be many meters thick, and were found to cover accumulations of drilling muds and cuttings. Investigations of the shell mounds around deep-water platforms have not been completed. Nevertheless, because of the potential for environmental harm, this issue must be addressed for all platforms regardless of the decommissioning option pursued. The level of contamination, while localized, has been shown to vary from platform to platform. Therefore, any remedial actions taken during the decommissioning process will likely be determined on a case-by-case basis. Although the regulatory requirements are still evolving, the alternatives being discussed include leaving the shell mounds undisturbed, smoothing and shaping them to allow for trawling, capping the shell mounds with an impervious material, adding material to the mounds for enhancement, or completely removing the shell mounds.

The removal of shell mounds may have a number of consequences to marine life by (1) removing habitat and (2) the potential for releasing toxins into the water column during the removal process. The biological consequences of either removing, altering, or leaving the shell mounds in-place must be given appropriate attention in the decommissioning process.

Partial Removal of Platform

Since partial removal reduces or eliminates shallow water habitat from the platform structure, this alternative would likely result in lower species composition and diversity than at the start of decommissioning process. Response of biotic communities will depend upon how much of the upper portion is removed. Depending on the platform, fewer nearshore reef fishes, such as surfperches, basses, and damselfishes may occur. Invertebrates that only reside or recruit to shallow water habitat would also be absent. Since the majority of mussels are located at shallow depths, shell mound replenishment will be reduced or absent, and affect the persistence of that community.

Since partial removal does not require the use of explosives, there is relatively little marine mammal, sea turtle, fish and invertebrate mortality compared to complete removal. Vertebrate and invertebrate assemblages associated with the remaining platform structure are assumed to be minimally affected.

A number of misunderstandings surround predictions regarding the potential ecological consequences of partial removal.

(1) Some stakeholders and policy analysts have erroneously assumed that Coast Guard regulations require a minimum depth below the ocean surface to which a reefed platform must be reduced. However, as noted earlier, the decision on how much of the jacket and conductors is left in place is based on both a Coast Guard assessment and the willingness of the liability holder to pay for the requisite navigational aids. As mussels become rare below 30 m (100 ft.) on most platforms, the mistaken assumption that all topped platforms must be cut to 24–30 m (80–100 ft.) below the surface has led some to conclude that partial removal will inevitably lead to a severe reduction in the amount of mussels that fall to the bottom and, thus, to a change in or end to the shell mound community. This is not necessarily the case.

(2) Some reports suggest that partial removal will lead to a large decrease in juvenile rockfish densities; our research does not support this supposition. On the offshore platforms in the Santa Barbara Channel region, the juveniles of most rockfish species (particularly blue, bocaccio, halfbanded, olive, pygmy, squarespot, starry, widow, and yellowtail) are uncommon in waters shallower than 26 m (85 ft.). Partial removal could reduce fish densities if pelagic juvenile stages of these rockfishes first encounter a platform in shallow surface waters, then swim downwards below the 26 m range, causing pelagic juveniles to "miss" a platform. However, young-of-the-year rockfishes of many of these species recruit from the plankton in large numbers both to natural outcrops in nearshore waters and to those coming out of deeper waters that have crests in about 30 m (100 ft.) of water. This indicates that emergent structure is not necessary for these juveniles to locate suitable habitat.

On the other hand, the pelagic stage of a few rockfish species, particularly copper, gopher, black-and-yellow, and kelp may prefer to recruit shallower portions of the platform than other rockfish species (Holbrook et al. 2000; this report). These species recruit to nearshore rocky outcrops and kelp beds and do not appear to settle in deeper waters (Larson 2002a,b). For these species, partial removal of a platform would probably decrease juvenile recruitment, depending on the uppermost depth of the remaining structure.

(3) Errors regarding factors affecting juvenile fish mortality have also lead to confusion. McGinnis et al. (2001), in describing the history of artificial reef research in California, states that "Research has shown that high relief, open structures serve best to attract fish, and better enable fishery exploitation, while low relief, complex structured reefs provide better nurseries and afford more diverse assemblages of fish and other organisms". McGinnis et al. (2001) also cite an anonymous California Department of Fish and Game biologist who notes that "a drawback to rigs as reefs is that they are high relief, which works against survival of young-of-the-year fish, suggesting they may not be a source of production but rather simply an attraction site."

We know of no research that can support the above claims, and the authors do not cite any specific studies. Predators are the main source of juvenile fish mortality in marine systems; death due to starvation or exposure is rare. Thus, variation in habitat structure would modify juvenile fish survivorship by modifying the success rate of predators. Presently, no studies have assessed comparative performance in survivorship rates between platforms and natural habitats. Alternatively, we may begin to infer potential predator vulnerability between habitats by examining the ratio of juvenile fishes to piscivorous fishes. In the shallow portion of Platform Irene, the ratio of juvenile rockfishes to piscivorous fish is about 25:1 and at nearby Tarantula Reef it is 3:1 (Appendix 2; Schroeder, unpublished data). Conversely, in the east Santa Barbara Channel, at Platform Gina the ratio is 1:5, and at Portuguese Rock, Anacapa Island it is 1:1.4.

Toppling of Platform

Toppling would produce reefs with somewhat different fish assemblages than what has been observed around intact platforms. Consequences of removal of shallow water habitat would be similar to that of partial removal. In California, because most platforms reside in fairly deep water, toppled platforms would also harbor fewer young-of-the-year rockfishes, just as the reefs adjacent to Platform Hidalgo harbor fewer of these animals. Depending on the characteristics of the platform, a toppled structure, with twisted and deformed pilings and beams, might have more complexity than an upright one. This might increase the number of such crevice dwelling fishes as pygmy rockfishes.

No Removal (Leave-in-Place) of Platform

The no-removal option would allow the platform and shell mound to continue to function as they had when the structure was occupied. Decommissioning activities would result in small mortality impacts to resident marine populations.

What is the Life Span of a Reefed Platform?

How long can a decommissioned steel platform survive in the marine environment before rusting away? Operating steel platforms are protected by sacrificial anodes, often made of aluminum or zinc, which preferentially corrode before steel, thus preserving the jackets' integrity. This cathodic protection lasts as long as the anodes are intact, usually for a number of decades. It is assumed that, once a platform is reefed, there will be no additional replacement of the sacrificial anodes, although the issue has yet to be addressed for platforms off California. While corrosion rates vary in seawater, depending on water temperature, biofouling and other factors, it is estimated that the life span of a cathodically unprotected platform will range from a minimum of 100 to more than 300 years (Quigle and Thorton 1989; Mishael 1997; Voskanian and Byrd 1998).

Pipelines Associated with Platforms

Pipelines run from all platforms either to shore or to other platforms that collect the oil or gas and then ship it to shore. McGinnis et al. (2001), note that "Both Federal and California regulations allow decommissioned OCS pipelines to be abandoned in place so long as they do not constitute a hazard to navigation, commercial fishing or unduly interfere with other uses of the OCS." (See also 30 C.F.R. § 250.1750; Ca. Pub. Res. Code § 6873.) In the Gulf of Mexico, few pipelines have been completely removed in the course of decommissioning (Breaux et al. 1997).

In 2001, using the research submersible *Delta*, we conducted pilot surveys of a pipeline between Platforms Gail and Grace. We found this pipe to be heavily encrusted with such invertebrates as anemones, crinoids, basket stars, and seastars. We also noted relatively large numbers of fishes, particularly juvenile or dwarf fishes, including cowcod, flag, blackgill, striped, and vermilion rockfishes, along with poachers and flatfishes. Both fish and invertebrate densities were much higher than found on the surrounding mud bottom.

Resource Management Issues Associated with Decommissioning

Habitat Enhancement of Reefed Platform Structure

The California Department of Fish and Game has issued guidelines for rigs-to-reef projects that call for enhancing the remaining structure using quarry rocks or other material (Parker 1998). Adding such material would increase the number of crevices and hiding places suitable for smaller sized fish. Thus, species which are rare or absent from observed platform fish assemblages, such as pygmy rockfish, may then occur. The ecological community response may depend on the type of habitat enhancement and has not been examined.

Marine Protected Areas

To a certain extent, the platforms in the Santa Barbara Channel and Santa Maria Basin currently act as de facto marine protected areas (Schroeder and Love 2002). Fishing pressure around many of these platforms is relatively low because (1) some platforms are relatively far from harbors and thus from fishing vessels, (2) four platforms (Irene, Hidalgo, Harvest, and Hermosa) are located near Point Conception in waters that are extremely rough for much of the year, and (3) it is difficult to fish close to operating platforms because tying up to these structures is discouraged by platform operators.

Clearly, many reefed platforms would be a target for recreational anglers or commercial fishermen because platforms often host sizable local populations of sought-after fish species. Off Florida, Shinn and Wicklund (1989) suggest that patterns of large fish at Tenneco platforms may be in part determined by fishing activities. Thus, in California, it has been proposed that reefed structures be designated as no-take areas (California senate bill introduced by D. Alpert). In addition, it may be possible to modify the architecture of reefed platforms to make them difficult to fish. For instance, because most of the target species are found inside the bottom of platform any structure above the bottom would prevent gear from reaching the seafloor, thus inhibiting the capture of many fishes.

Decommissioning Alternatives in Relation to National Marine Fishery Service's Fishery Rebuilding Plans

The use of explosives to remove or topple a platform may compromise fishery-rebuilding programs. Cowcod provide one example. This species has been declared overfished by NOAA Fisheries (formerly known as the National Marine Fisheries Service) and is the subject of a federal rebuilding plan. The Pacific Fisheries Management Council has approved a cowcod rebuilding plan that limits fishery impacts to 1% per year (about 2.4 metric tons for 2001), as part of a 95-year rebuilding period, and the use of spatial closures south of Point Conception to reduce bycatch mortality. As noted earlier, our observations around Platform Gail indicate it has the highest density of adult cowcod and bocaccio of any natural or artificial structure surveyed. We can make an estimate of the number of cowcod at the bottom of Gail by multiplying the density of cowcod observed by the area of the platform's footprint (the area underneath the platform). For instance, in the last two years of the survey, 1999 and 2000, observed cowcod densities were 0.015 and 0.0183 fish per m^2, respectively. As Gail's footprint is 5,327 m^2 (Holbrook et al. 2000), extrapolation for 1999 and 2000 gives estimates of 79 and 97 individuals respectively. This conservative estimate does not include juveniles we have observed living on the shell mound or on the adjacent pipeline. The current rebuilding plan calls for both a quota on commercial and recreational fisheries combined of 2.4 metric tons, equal to about 600 fish (T. Barnes, personal communication). Assuming that Platform Gail has 75 or more cowcod living under it, and if, as seems likely from all known research, explosives used to remove or topple a platform will kill all of them, that loss may be sufficiently large to complicate the rebuilding plan (T. Barnes, personal communication).

LOVELAB, UC SANTA BARBARA

Spotted ratfish on shell mound at Platform Gail.

CHAPTER 5
RESEARCH AND MONITORING RECOMMENDATIONS

When Governor Davis vetoed SB 1, a bill that would have allotted some of the savings derived from reefing platforms to California, he wrote, " There is no conclusive evidence that converted platforms enhance marine species or produce net benefits to the environment…it is premature to establish this program until the environmental benefits of such conversions are widely accepted by the scientific and environmental communities." And, with respect to assessing the effect of different decommissioning options on marine populations, Holbrook et al. (2000) state that the key marine ecological question is, "What is the effect of each decommissioning alternative on regional stocks of reef-associated species in general, or of particular targeted species?" Clearly, in the decommissioning process, there is a need for additional information.

Below we list examples of research that would be useful in addressing these issues. Many of these examples have been suggested by various resource managers. The first two tasks are necessary to resolve issues regarding attraction or production of platform and natural habitats as well as helping to define essential fish habitat. In addition to aiding in the platform decommissioning process, these three tasks will also aid in future coastal zoning and mapping that would occur in any future boundary expansion of the Channel Islands Marine Sanctuary.

Compare ecological performance between oil platforms and natural outcrops and determine if any oil platforms serve as Essential Fish Habitat for focal species.

What fishes live around platforms and nearby natural reefs?

In order to assess the relative importance of a platform to its region, it is essential to conduct basic surveys not only around the platform, but also at nearby reefs. A majority of platforms have not been well surveyed or have not been surveyed at all. Both scuba and submersible surveys must be conducted.

How does fish production around platforms compare to that at natural outcrops?

Fish production can be assessed and compared between habitats by examining a number of ecological yardsticks. These include (1) fish growth rates, (2) mortality rates, and (3) reproductive output. As an example, we conducted a pilot study comparing the growth rates of young-of-the-year blue rockfish at Platform Gilda and Naples Reef. More research needs to be conducted in all of these areas. For instance, mortality rates can be estimated by sequential surveys of the densities of young fishes at a specific platform or natural outcrop. Reproductive output (larval production in the case of rockfishes) can be quantified by first estimating the size frequency and density of a species at a platform or natural outcrop. Then, using size-fecundity relationships from the literature, the potential annual larval production for that species can be calculated.

How does trophic structure around platforms compare to that at natural outcrops?

How do platforms and natural outcrops compare in terms of habitat value?

A relatively new measure called Habitat Value (HV) allows comparisons between habitats, incorporating fish density, fish length, and fish regularity of occurrence. In Stephens et al. (1999), we presented a preliminary analysis of nine platforms and found that platform HVs tended to be much higher than those for open coastal soft substrate, higher than low relief deep rock outcrop and in the same range as wetlands and kelp/rock natural outcrops. An analysis of all of the platforms and as many outcrops as possible should be conducted.

Can we identify areas that are Essential Fish Habitat?

All of the above studies contribute to answering this question.

Define the spatial distribution of economically important species (all life history stages) within the region of interest and define connectivity of habitats within this region.

What is the relative contribution of platforms in supplying hard substrate and fishes to the region?

This research would put in perspective the relative contribution of platforms in supplying hard substrate and reef fishes to their environment.

First, this requires an assessment of the rocky outcrops in the vicinity of each platform; this is derived from seafloor mapping. Much of the seafloor in the vicinity of platforms remains to be characterized. Once the mapping is complete, visual surveys of the outcrops, using a research submersible, will determine the fish assemblages and species densities in these habitats. Knowing the areal extent of both natural and platforms habitats and the densities of each species in both of these habitats, it is then possible to assess the total contribution of each platform to the fish populations and hard substrate in that region.

How long do fishes reside at platforms?

It remains unclear how long fishes are resident around a platform. For instance, do the large numbers of fishes, such as the overfished bocaccio and cowcod, remain around the platforms for extended periods? One settled on a platform, how long do young-of-the-year fishes remain there? A knowledge of the residence time of these species would allow for a more accurate determination if platforms form optimal habitat for these species and if they are indeed acting as long-term marine reserves. Residence time can be determined through the use of both tagging studies and observations of a year class through time.

Acoustic tags are one way to determine fish residency. In a pilot study, Dr. Christopher Lowe, at California State University, Long Beach, captured and acoustically tagged rockfishes at Platform Gail and, after one year has determined that all have remained around the platform. Broader studies, covering additional platforms, outcrops, and species are needed.

What are the effects of platform retention or removal on fish populations within a region?

As an example, what effect would platform retention or removal have on fish recruitment? For instance, would the young rockfishes that settle out at a platform survive in the absence of that platform? Our surveys demonstrate that planktonic juvenile fishes, particularly rockfishes, often settle out of the plankton to a platform in substantial numbers. If that platform did not exist, would these young fishes have found, and settled upon, natural outcrops? In a pilot project, we are using radar-derived (CODAR) current data to estimate where the young rockfishes that settled at Platform Irene would have gone if Irene had not existed. We identify the direction and distance of pathways from the platform to natural outcrops. A directional histogram of radar-derived trajectories will show the degree to which surface currents potentially carry larvae in any given direction from the platform site. Knowing how long it would take rockfish larvae to reach suitable natural outcrops, and what percent of these larvae would likely die before reaching these outcrops, will give a sense of the importance of a platform as a nursery ground. Similarly, using a synthesis of oceanographic information, it is possible to model the drift direction of larvae produced by fishes living at a platform.

It would be useful to understand the natal origins of fishes residing at platforms and natural outcrops. Both genetic and otolith microchemistry techniques might aid in determining the degree of dispersal of fishes produced at platforms and natural outcrops.

Understand how habitat modification of platform environment (e.g., removal of upper portion or addition of bottom structure) changes associated assemblages of marine life at offshore platforms.

All decommissioning options except leave-in-place involve modification of the current physical structure of offshore platforms. Is it possible to increase fish diversity and density by altering the seafloor or the platform itself? For instance, it would be useful to add complexity, in the form of quarry rock or other structure, to the shell mound around a platform, and follow the changes in fish assemblages.

Descriptive information such as depth distribution and life history information is also useful in determining how decommissioning options affect the environment. Experimental research, using a BACI design or similar approach, can aid in predicting how the biotic community will respond to such structural changes.

ACKNOWLEDGEMENTS

This research was funded by the Biological Resources Division, U. S. Geological Survey (National Offshore Environmental Studies Program 1445-CA-0995-0386) based on an information need identified by the Minerals Management Service's Pacific OCS Region, as well as by the Minerals Management Service and the California Artificial Reef Enhancement Program (CARE). We would like to thank Lyman Thorsteinson for his unflagging support for this research. Ann Bull and Lyman Thorsteinson carefully reviewed the first draft and we wish to express our sincerest thanks. George Steinbach reviewed our discussion of the platform decommissioning process and options and made very constructive comments.

We greatly appreciate the efforts of Roberta Bloom, UCSB Artworks, who was responsible for the layout and many of the graphics. Also, we would like to thank the following companies for granting us permission to survey their platforms: Arguello Associates, Chevron Texaco, Nuevo Energy Company, Pacific Operators Offshore, Torch Operating Company, and Venoco Incorporated.

We thank the pilots of the submersible *Delta*, Chris Ijames and Dave Slater, for their very professional handling of the technical aspects of that survey, as well as the crews of the R/V *Cavalier*, R/V *McGaw* and R/V *Valero*. Linda Snook managed the deep-water survey data. We thank Craig Syms for his masterful analyses of the deep-water survey data. Frank Donohue, skipper of the F/V *Gus D*, was an essential part of our pelagic fish surveys. Dr. Edward Brothers compared daily growth rates of blue rockfish. Dr. Mark Carr provided advice and field assistance early in the research program. Dr. Libe Washburn assisted us in planning the biological oceanographic surveys and in subsequently interpreting data from those surveys. Many thanks to the scuba divers who helped us collect data, including Arnold Ammann, Scott Clark, Becky Frodsham, Lise Goddard, William Golden, Jeff Harding, Eric Hessell, Janine Kido, Laird MacDonald, Scott Mau, Melissa Meeker, Michelle Paddack, Chris Thompson, and Jordan Watson. We thank Edwin Beckenbach, Christy Herren, Matt Knope, Elan Love, Kurt McClure, Karina Mendiola, Martin Moreti, Dawn Outram, Maria Petueli, Toni Ross, David Salazar, Clara Svedlund, Melinda Simmons, Eric Simons and others for all manners of assistance in the field and laboratory. Frank Manago and Fred Piltz were always very supportive of our research. We received much useful information about platforms and platform decommissioning from Lee Bafalon, Rob Campbell-Taylor, John Deacon, Tom Dunoway, Rod Eason, Mike Edwards, Jim Galloway, David Gebauer, Jeff Goddard, Rick Kasprzak, Herb Leidy, Jim Lima, Michael Mitchell, Greg Pelka, Karen Robertson-Fall, David Rose, George Steinbach, and Marina Voskanian. Glenn Shackell provided the ROV platform inspection tapes. Linda Nelson drew one of the cowcod images for one of the figures. The California Department of Fish and Game provided the net for the midwater trawling surveys. Finally, we offer apologies to anyone we may have inadvertently forgotten to acknowledge.

PERSONAL COMMUNICATIONS

Tom Barnes, California Department of Fish and Game, La Jolla, California.

Jan Culbertson, Texas Department of Park and Wildlife, Houston, Texas.

Lester Dauterive, Minerals Management Service, New Orleans, Louisiana.

Jennifer Dugan, Marine Science Institute, University of California, Santa Barbara.

Rick Kasprzak, Louisiana Department of Wildlife and Fisheries, Baton Rouge, Louisiana.

Alec MacCall, National Marine Fisheries Service, Santa Cruz, California.

George Steinbach, Ojai, California.

Libe Washburn, Department of Geography, University of California, Santa Barbara.

TABLES

TABLE 1. Common and scientific names of fishes observed in these studies.

Common Name	Scientific Name
Bank rockfish	*Sebastes rufus*
Barred sand bass	*Paralabrax nebulifer*
Barred surfperch	*Amphistichus argenteus*
Bat ray	*Myliobatis californica*
Bearded eelpout	*Lyconema barbatum*
Big skate	*Raja binoculata*
Black-and-yellow rockfish	*Sebastes chrysomelas*
Blackeye goby	*Rhinogobius nicholsi*
Blackgill rockfish	*Sebastes melanostomus*
Black rockfish	*Sebastes melanops*
Blacksmith	*Chromis punctipinnis*
Black perch	*Embiotoca jacksoni*
Bluebanded goby	*Lythrypnus dalli*
Bluebarred prickleback	*Plectobranchus evides*
Blue rockfish	*Sebastes mystinus*
Bluntnose sixgill shark	*Hexanchus griseus*
Bocaccio	*Sebastes paucispinis*
Brown rockfish	*Sebastes auriculatus*
Bull sculpin	*Enophrys taurina*
Cabezon	*Scorpaenichthys marmoratus*
Calico rockfish	*Sebastes dalli*
California halibut	*Paralichthys californicus*
California lizardfish	*Synodus lucioceps*
California scorpionfish	*Scorpaena guttata*
California sheephead	*Semicossyphus pulcher*
California smoothtongue	*Leuroglossus stilbius*
California tonguefish	*Symphurus atricauda*
Canary rockfish	*Sebastes pinniger*
Chilipepper	*Sebastes goodei*
C-O turbot	*Pleuronichthys coenosus*
Copper rockfish	*Sebastes caurinus*
Cowcod	*Sebastes levis*
Darkblotched rockfish	*Sebastes crameri*
Dover sole	*Microstomus pacificus*
Dwarf perch	*Micrometrus minimus*
Embiotoca sp.	Black perch, *Embiotoca jacksoni* or striped perch, *E. lateralis*
Fantail sole	*Xystreurys liolepis*
Flag rockfish	*Sebastes rubrivinctus*
Freckled rockfish	*Sebastes lentiginosus*
Garibaldi	*Hypsypops rubicunda*
Giant kelpfish	*Heterostichus rostratus*
Gopher rockfish	*Sebastes carnatus*
Grass rockfish	*Sebastes rastrelliger*
Gray smoothhound	*Mustelus californicus*
Greenblotched rockfish	*Sebastes rosenblatti*
Greenspotted rockfish	*Sebastes chlorostictus*
Greenstriped rockfish	*Sebastes elongatus*
Halfbanded rockfish	*Sebastes semicinctus*
Halfblind goby	*Lethops connectens*
Halfmoon	*Medialuna californiensis*
Honeycomb rockfish	*Sebastes umbrosus*
Hornshark	*Heterodontus francisci*
Hornyhead turbot	*Pleuronicthys verticalis*
Island kelpfish	*Alloclinus holderi*
Jack mackerel	*Trachurus symmetricus*
Kelp bass	*Paralabrax clathratus*
Kelp goby	*Lethops connectens*
Kelp greenling	*Hexagrammos decagrammus*
Kelp gunnel	*Ulvicola sanctaerosae*
Kelp rockfish	*Sebastes atrovirens*
Kelp perch	*Brachyistius frenatus*
Lavender sculpin	*Leiocottus hirundo*
Leopard shark	*Triakis semifasciata*
Lingcod	*Ophiodon elongatus*
Longnose skate	*Raja rhina*
Mexican rockfish	*Sebastes macdonaldi*
Mola	*Mola mola*
Mussel blenny	*Hypsoblennius jenkinsi*
Northern anchovy	*Engraulis mordax*
Ocean sunfish	*Mola mola*
Ocean whitefish	*Caulolatilus princeps*
Olive rockfish	*Sebastes serranoides*
Opaleye	*Girella nigricans*
Pacific argentine	*Argentina sialis*
Pacific barracuda	*Sphyraena argentea*
Pacific electric ray	*Torpedo californica*
Pacific hagfish	*Eptatretus stouti*
Pacific hake	*Merluccius productus*
Pacific mackerel	*Scomber japonicus*
Pacific pompano	*Peprilus simillimus*
Pacific sanddab	*Citharichthys pacificus*
Pacific sardine	*Sardinops sagax*
Painted greenling	*Oxylebius pictus*
Phanerodon sp.	White seaperch, *Phanerodon furcatus* or sharpnose seaperch, *P. atripes*
Pile perch	*Rhacochilus vaca*
Pink rockfish	*Sebastes eos*
Pink seaperch	*Zalembius rosaceus*
Pinkrose rockfish	*Sebastes simulator*
Plainfin midshipman	*Porichthys notatus*
Pygmy rockfish	*Sebastes wilsoni*

TABLE 1. (cont.) Common and scientific names of fishes observed in these studies.

Common Name	Scientific Name
Rainbow surfperch	*Hypsurus caryi*
Rathbunella sp.	Unidentified ronquil
Redbanded rockfish	*Sebastes babcocki*
Rex sole	*Glyptocephalus zachirus*
Rock wrasse	*Halichoeres semicinctus*
Rosy rockfish	*Sebastes rosaceus*
Roughback sculpin	*Chitonotus pugetensis*
Rubberlip seaperch	*Rhacochilus toxotes*
Sarcastic fringehead	*Neoclinus blanchardi*
Sargo	*Anisotremus davidsoni*
Sebastomus sp.	Unidentified member of rockfish subgenus *Sebastomus*
Senorita	*Oxyjulis californica*
Sharpchin rockfish	*Sebastes zacentrus*
Sharpnose seaperch	*Phanerodon atripes*
Shiner perch	*Cymatogaster aggregata*
Shortbelly rockfish	*Sebastes jordani*
Shortspine combfish	*Zaniolepis frenata*
Shortspine thornyhead	*Sebastolobus alascanus*
Silver surfperch	*Hyperprosopon ellipticum*
Slender sole	*Eopsetta exilis*
Speckled sanddab	*Citharichthys stigmaeus*
Spotted cuskeel	*Chilara taylori*
Spotted ratfish	*Hydrolagus colliei*
Spotted sand bass	*Paralabrax maculatofasciatus*
Squarespot rockfish	*Sebastes hopkinsi*
Starry rockfish	*Sebastes constellatus*
Striped seaperch	*Embiotoca lateralis*
Stripetail rockfish	*Sebastes saxicola*
Swell shark	*Cephaloscyllium ventriosum*
Swordspine rockfish	*Sebastes ensifer*
Thornback	*Platyrhinoidis triseriata*
Threadfin bass	*Pronotogrammus multifasciatus*
Treefish	*Sebastes serriceps*
Tube-snout	*Aulorhynchus flavidus*
Vermilion rockfish	*Sebastes miniatus*
Walleye surfperch	*Hyperprosopon argenteum*
White seabass	*Atractoscion nobilis*
White surfperch	*Phanerodon furcatus*
Whitespeckled rockfish	*Sebastes moseri*
Widow rockfish	*Sebastes entomelas*
Wolf-eel	*Anarrhichthys ocellatus*
Yelloweye rockfish	*Sebastes ruberrimus*
Yellowtail	*Seriola lalandi*
Yellowtail rockfish	*Sebastes flavidus*
Zebra goby	*Lythrypnus zebra*
Zebraperch	*Hermosilla azurea*
Unidentified blennies	Family Blenniidae
Unidentified gunnel	Family Pholidae
Unidentified kelpfishes	Family Clinidae
Unidentified pipefishes	*Syngnathus* spp.
Unidentified poachers	Family Agonidae
Unidentified rockfish juveniles	*Sebastes* spp.
Unidentified ronquils	Family Bathymasteridae
Unidentified sanddabs	*Citharichthys* spp.
Unidentified sculpins	Family Cottidae
Unidentified silversides	Family Atherinidae
Unidentified fish species

GRAND TOTAL 298,379
Minimum number of species 94
Total rockfishes 276,034
All rockfishes comprised 92.5% of all fishes surveyed.

TABLE 5. Twenty highest densities of rockfish young-of-the-year juveniles, 1996–2001 as observed from the *Delta* submersible. Platforms are listed in blue, natural outcrops in red.

Site	Year	Habitat Type	Density of Rockfish YOY (fish per 100m^2)
Hidden Reef	1999	Natural	1249.2
Platform Hermosa	1999	Midwater	993. 6
Platform Irene	1998	Midwater	935.4
Platform Harvest	1999	Midwater	555.1
Platform Irene	1999	Midwater	524.3
San Miguel Island	1995	Natural	520.5
Platform Grace	2001	Midwater	486.5
Platform Hidalgo	1997	Midwater	385.2
Potato Bank	1996	Natural	367.7
Platform Irene	1997	Bottom	363.8
Platform Grace	2000	Midwater	346.2
Platform Irene	1997	Midwater	344.1
North Reef	1995	Natural	338.7
Platform Holly	1999	Bottom	326.1
Platform Hidalgo	1999	Midwater	314.6
Platform Irene	2001	Midwater	306.2
San Nicolas Island	1996	Natural	302.9
San Miguel Island	1995	Natural	262.1
Santa Rosa Island	1995	Natural	227.1
Platform Harvest	1997	Midwater	225.6

TABLE 6. Fish species observed as young-of-the-year juveniles at California oil/gas platforms.

Common Name	Common Name
Bank rockfish	Kelp bass*
Black rockfish	Kelp greenling*
Blackeye goby*	Kelp rockfish*
Blackgill rockfish	Lingcod*
Blacksmith*	Olive rockfish
Blue rockfish*	Pacific hake
Bluebanded goby*	Painted greenling*
Bocaccio*	Pinkrose rockfish*
Brown rockfish*	Pygmy rockfish*
Cabezon*	Rosy rockfish*
Calico rockfish*	Sharpchin rockfish
Canary rockfish*	Shortbelly rockfish*
Copper rockfish*	Splitnose rockfish
Cowcod*	Squarespot rockfish*
Flag rockfish*	Starry rockfish*
Garibaldi*	Stripetail rockfish*
Gopher/Black-and-Yellow rockfish*	Treefish
Greenblotched rockfish*	Vermilion rockfish*
Greenspotted rockfish*	Widow rockfish*
Greenstriped rockfish*	Yelloweye rockfish*
Halfbanded rockfish*	Yellowtail rockfish
Halfmoon*	Unidentified combfishes (*Zaniolepis* spp.)*

We also observed adult sarcastic fringehead, as well as unidentified blennies (*Hypsoblennius* spp.) and sculpins. Given the cryptic and sedentary nature of these species, we believe they arrived at platforms via larval recruitment.

In addition, Carlisle et al. (1964) observed young-of-the-year black perch, pile perch, rubberlip seaperch, and white surfperch at Platform Hazel (removed in 1996).

*These species were observed as both newly settled juveniles and adults at platforms.

APPENDICES

APPENDIX 1. Platform Synopses

In this section, we give a brief summary of each of the California platforms. The platforms are listed from the most northwest, Irene, off Point Arguello, to Emmy in the southeast off Long Beach.

Wherever possible, we have included the following information on each platform: (1) the original operator; (2) the current operator of record; (3) the date the platform was installed; (4) the first production date; (5) the platform's distance from shore (including whether it is in state or outer continental shelf [OCS] waters); (6) the bottom depth of the platform; (7) the number of wells; (8) what the platform produces (oil and/or gas); (9) the platform jacket dimensions (generally at the seafloor [bottom]); (10) the size of the shell mound surrounding the platform; (11) the size of the platform's footprint. This data was taken from California Resources Agency (1971), Manago and Williamson (1998), Holbrook et al. (2000), and Sea Surveyor Inc. (2001). We have also included a photograph of most of the platforms and their locations including latitude and longitude.

We follow this with a synopsis of the fish assemblages around each platform. When these summaries are based on our scuba and submersible surveys we include the years these surveys were conducted. Scuba surveys are midwater surveys except at the shallow water Platform Gina. Because of funding limitations, a number of platforms were surveyed only once and in a number of instances poor water visibility prevented complete coverage. Neither ExxonMobil nor Aera gave us permission to survey their platforms. In some instances, we were able to review videos that were taken during mandatory platform inspections. From these, we made a qualitative estimate of platform bottom fish assemblages for those platforms we were unable to survey.

IRENE

Original operator: Union; current operator of record: Nuevo Energy; date installed: 1985; first production: 1987; distance from shore (miles): 4.7 (OCS); water depth: 73 m (242 ft.); number of well slots 72; produces: oil and gas; platform jacket dimensions: 47 x 56 m (155 x 185 ft.) (bottom); platform footprint (m²): 2,633; location: 120°43.45'N, 34°36.37'W.

Dates and types of surveys:

Scuba: 1995–2000

Submersible:

	Midwater	Bottom	Shell Mound
1995	x		
1996	x	x	x
1997	x	x	x
1998	x	x	x
1999	x	x	x
2000	x	x	x
2001	x	x	x

Platform Irene's midwaters consistently harbored large numbers of YOY (young-of-the-year) and older juvenile rockfishes. Bocaccio, blue, shortbelly, squarespot, treefish, and widow rockfishes, and the complex comprised of young black-and-yellow, copper, gopher, and kelp rockfishes, were abundant. Densities of these fishes were usually among the highest we observed around either platforms or natural outcrops. Young painted greenling, living on the jacket, were also quite abundant. During the 1998 El Niño, YOY blacksmith settled on the platform in large numbers. However, they were gone by the following year. Kelp greenling recruited as young-of-the-year in 1999; they swam to the platform bottom during the next year and were there through 2001. Two pelagic species, jack mackerel and Pacific sardine, were also occasionally seen in high numbers. The platform bottom had particularly high densities of halfbanded rockfish and YOY rockfishes, as well as subadult and adult copper, vermilion, calico, and brown rockfishes. Juvenile lingcod, pile perch and painted greenling were also very abundant and Pacific sanddab, canary and yellowtail rockfishes were frequently seen. On the shell mound, halfbanded and copper rockfish, as well as young lingcod were very common. Platform Irene is particularly noteworthy as it harbored far higher densities of young lingcod than did any other site (platform or natural outcrop) that we surveyed.

Opposite: Vermilion rockfish and assorted invertebrates at the bottom of Platform Grace. (Photograph by Donna Schroeder)

HIDALGO

Original operator: Chevron; current operator of record: Arguello Inc.; date installed: 1986; first production: 1991; distance from shore (miles): 5.9 (OCS); water depth: 130 m (430 ft.); number of well slots: 56; produces: oil and gas; platform jacket dimensions: 78 x 53 m (257 x 176 ft.) (bottom); platform footprint (m^2): 4,154; location: 34°29'N, 120°42'W.

Dates and types of surveys:
Scuba: 1996–2000
Submersible:

	Midwater	Bottom	Shell Mound
1996	x	x	x
1997	x	x	x
1998	x	x	x
1999	x	x	x
2000	x	x	x
2001	x	x	x

We observed high densities of YOY and older juvenile rockfishes in the midwaters of Platform Hidalgo. A number of rockfishes, including blue, copper, gopher, kelp, olive, rosy, squarespot, and widow rockfishes and bocaccio were abundant. Halfmoon and young painted greenling were also common. Large numbers of YOY blacksmith recruited to the platform during 1998 and remained there through 2001. Similarly, kelp greenling young settled during 1999, and some remained through 2001. Jack mackerel and northern anchovy were occasional visitors. The bottom of this platform was dominated by halfbanded, greenspotted, and flag rockfishes, YOY rockfishes, and lingcod. Flag rockfish density was higher than at any natural outcrop or other platform. Other important species included canary, greenstriped, vermilion, and widow rockfishes and painted greenling. On the shell mounds, we noted extremely large numbers of halfbanded rockfish. Both juvenile and adult lingcod were also abundant.

HARVEST

Original operator: Texaco; current operator of record: Arguello Inc.; date installed: 1985; first production: 1991; distance from shore (miles): 6.7 (OCS); water depth: 205 m (675 ft.); number of well slots: 50; produces: oil and gas; platform jacket dimensions: 61 x 97 m (200 x 319 ft.) (bottom); platform footprint (m^2): 5,859; location: 34°28'N, 120°40'W.

Dates and types of surveys:
Scuba: 1996–2000
Submersible:

	Midwater	Bottom	Shell Mound
1996	x		
1997	x	x	x
1998	x	x	x
1999	x	x	x
2000	x	x	x
2001			

As on most of the other platforms we surveyed, YOY and somewhat older rockfishes characterized the midwaters of Platform Harvest. Of these, bocaccio, as well as blue, olive, squarespot, and widow rockfishes were most abundant. Young painted greenling , as well as halfmoon, also were seen frequently. Blacksmith were abundant, they had recruited in 1998 as YOY and remained at the platform through 2001. Large numbers of kelp greenling settled from the plankton in 1999. Pelagic species, such as northern anchovy and Pacific sardine, were occasional visitors. In the deeper midwaters, we saw many sharpchin and whitespeckled rockfishes. Stripetail, greenstriped, greenspotted, and greenblotched rockfishes and lingcod were commonly seen on the bottom. Stripetail, greenstriped and sharpchin rockfishes were most abundant on the shell mounds.

HERMOSA

Original operator: Chevron; current operator of record: Arguello Inc.; date installed: 1985; first production: 1991; distance from shore (miles): 6.8 (OCS); water depth: 183 m (603 ft.); number of well slots: 48; produces: oil and gas; platform jacket dimensions: 61 x 85 m (200 x 280 ft.) (bottom); platform footprint (m^2): 5,142; location: 34°27'N, 120°38'W.

Dates and types of surveys:
Scuba: 1996–2000
Submersible:

	Midwater	Bottom	Shell Mound
1996	x	x	
1997	x	x	x
1998	x	x	x
1999	x	x	x
2000	x	x	x
2001			

Platform Hermosa's midwaters are noteworthy as rockfish nursery grounds. They harbored the second highest densities of YOY rockfishes of any site we surveyed (second only to Hidden Reef) (Table 5). Bocaccio, blue, olive, squarespot, widow, and whitespeckled rockfishes, as well as painted greenling were very abundant. Blacksmith and halfmoon were also typical species. As at many other platforms, in 1999 kelp greenling settled out of the plankton at Platform Hermosa. Jack mackerel and northern anchovy were also common. While halfbanded rockfish dominated the bottom assemblage, greenspotted rockfish were also abundant. Halfbanded rockfish also were the most abundant species on the shell mound.

HONDO

Original operator: Exxon; current operator of record: ExxonMobil; date installed: 1976; first production: 1981; distance from shore (miles): 5.1 (OCS); water depth: 255 m (842 ft.); number of well slots: 28; produces: oil and gas; platform jacket dimensions: 68 x 68 m (225 x 225 ft.) (bottom); platform footprint (m^2): 4,649; location: 34°23'N, 120°07'W.

Exxon and ExxonMobil did not allow us to survey this platform. However, we were able to review part of an inspection tape made at and near the bottom of Platform Hondo (Divecon International, 3 August 2002). Based on this, a number of rockfishes, including bank, darkblotched, pinkrose, widow and probably blackgill, live around the bottom of Platform Hondo. Darkblotched rockfish appeared to be particularly abundant.

HARMONY

Original operator: Exxon; current operator of record: ExxonMobil; date installed: 1989; first production: 1993; distance from shore (miles): 6.4 (OCS); water depth: 363 m (1,198 ft.); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 91 x 117 m (300 x 385 ft.) (bottom); platform footprint (m^2): 10,606; location: 34°22'N, 120°10'W.

Exxon and ExxonMobil did not allow us to survey this platform.

HERITAGE

Original operator: Exxon; current operator of record: ExxonMobil; distance from shore (miles): 8.2 (OCS); water depth: 326 m (1,075 ft.); number of well slots: 60; produces: oil and gas; location: 34°21'N, 120°16'W.

Exxon and ExxonMobil did not allow us to survey this platform. We reviewed part of an ROV inspection of this platform (Divecon International, 2 August 2002) and noted blackgill, darkblotch, pinkrose, and widow rockfish at or near the bottom.

HOLLY

Original operator: Atlantic Richfield, current operator of record: Venoco, date installed: 1966; first production: 1966; distance from shore (miles): 1.8 (state); water depth: 64 m (211 ft.); number of well slots: 30; produces: oil and gas; platform jacket dimensions: 18 x 30 m (60 by 100 ft.) (surface), 36 x 48 m (119 by 158 ft.) (bottom); location: 34°22'N, 119° 52'W.

Dates and types of surveys:
Scuba: 1995–2000
Submersible:

	Midwater	Bottom	Shell Mound
1995	x		
1996	x	x	
1997	x	x	x
1998	x	x	x
1999		x	
2000			
2001	x	x	x

The midwaters around Platform Holly were populated by large numbers of blue, copper, kelp, olive, squarespot, and widow rockfishes and bocaccio. With the exception of kelp rockfishes, most of these fishes were juveniles. Blacksmith, halfmoon, kelp bass, painted greenling, pile perch, and sharpnose seaperch were also abundant. Schools of jack mackerel and Pacific sardines were also noted. The platform bottom fish assemblage was characterized by YOY widow rockfish, calico, vermilion, halfbanded, and copper rockfishes, sharpnose seaperch and blackeye goby. Most of the vermilion and copper rockfishes were juveniles and subadults. Calico, vermilion, and copper rockfishes were the most abundant species on the shell mound.

C

Original operator: Union Oil; current operator of record: Nuevo Energy; date installed: 1977; first production: 1977; distance from shore (miles): 5.7 (OCS); water depth: 58 m (192 ft); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 40 x 48 m (133 x 158 ft.) (bottom); platform footprint (m^2): 1,930; location: 34°19'N, 119°37'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
2000	x (partial)		x

Only part of the platform midwater was surveyed and olive rockfish were most abundant. On the shell mound, vermilion, halfbanded, and calico rockfishes were most common, and blackeye goby, copper rockfish and painted greenling were also frequently encountered. A platform inspection video made on 23 September 1999 (Stolt Comex Seaway) around the platform bottom showed large numbers of juvenile blue, brown, copper, olive, vermilion, and widow rockfishes and lingcod. Both juvenile and adult calico, gopher, halfbanded and kelp rockfishes and painted greenling were also present.

B

Original operator: Union Oil; current operator of record: Nuevo Energy; date installed: 1968; first production: 1969; distance from shore (miles): 5.7 (OCS); water depth: 58 m (190 ft.); number of well slots: 63; produces: oil and gas; platform jacket dimensions: 40 x 48 m (133 x 158 ft.) (bottom); platform footprint (m^2): 1,930; location: 34°19'N, 119°37'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Juvenile widow rockfish, which had probably settled from the plankton in 1999, were abundant in the platform midwaters in 2000. Blacksmith, young blue, olive and kelp rockfishes, senorita and painted greenling were also common. We reviewed a video of a platform inspection (Stolt Comex Seaway, 21 September 1999) and noted large numbers of juvenile lingcod, blue, flag, and vermilion rockfishes as well as many juvenile and adult calico, gopher, halfbanded, kelp and rosy rockfishes and painted greenling.

A

Original operator: Union Oil; current operator of record: Nuevo Energy; date installed: 1968; first production: 1969; distance from shore (miles): 5.8 (OCS); water depth: 57 m (188 ft.); number of well slots: 57; produces: oil and gas; platform jacket dimensions: 40 x 48 m (133 x 158 ft.) (bottom); platform footprint (m^2): 1,930; location: 34°19'N, 119°36'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Blacksmith, blue and olive rockfishes were most abundant in the platform midwaters during 2000. Halfmoon, kelp bass and painted greenling were also common. Due to poor visibility, we were unable to survey the bottom and shell mound of Platform A during 2000. However, we reviewed a 2001 platform inspection video tape (Divecon International 2001) conducted with a remotely operated vehicle. That tape showed that there were large numbers of fishes, primarily rockfishes, around the platform bottom. These included many subadult vermilion and copper rockfishes, as well as blue, calico, gopher, kelp, and juvenile widow rockfishes, lingcod and painted greenling.

HILLHOUSE

Original operator: Sun Oil; current operator of record: Nuevo Energy; date installed: 1969; first production: 1970; distance from shore (miles): 5.5 (OCS); water depth: 58 m (190 ft.); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 49 x 40 m (163 x 133 ft.) (bottom); location: 34°19'N, 119°36'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Blacksmith and painted greenling were the most abundant species in the platform midwaters. Poor water visibility prevented us from surveying the platform bottom and shell mound. We reviewed a videotape made during an ROV platform inspection survey (Divecon International, 26 August 2001) and, although this too was conducted during poor visibility, noted juvenile copper, flag, and vermilion rockfishes, as well as painted greenling and pile perch.

HENRY

Current operator of record: Nuevo Energy; date installed: 1979; first production: 1980; distance from shore (miles): 4.3 (OCS); water depth: 52 m (173 ft.); number of well slots: 24; produces: oil and gas; platform jacket dimensions: 45 x 33 m (149 x 110 ft.) (bottom); size of shell mound: 9 m (19 ft) high, circular and 76 m (250 ft.) in diameter; platform footprint (m^2): 1,505; location: 34°19'N, 119°33'W.

Dates and types of surveys:

Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Halfmoon, blacksmith and kelp bass were common in the midwaters of Platform Henry.

HOUCHIN

Original operator: Phillips Petroleum/Continental Oil/Cities Services Oil; current operator of record: Pacific Operators Offshore; date installed: 1968; first production: 1969; distance from shore (miles): 4.1 (OCS); water depth: 49 m (163 ft.); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 38 x 38 m (125 x 125 ft.) (bottom); size of shell mound: 6 m (21 ft.) high, circular and 85 m (280 ft.) in diameter; 1,435; location: 34°20'N, 119°33'W.

Dates and types of surveys:

Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Painted greenling and halfmoon were the most abundant species in the platform midwaters.

HOGAN

Original operator: Phillips Petroleum/Continental Oil/Cities Services Oil; current operator of record: Pacific Operators Offshore; date installed: 1967; first production: 1968; distance from shore (miles): 3.7 (OCS); water depth: 47 m (154 ft.); number of well slots: 66; produces: oil and gas; platform jacket dimensions: 38 x 38 m (125 x 125 ft.) (bottom); platform footprint (m^2): 1,435; location: 34°20'N, 119°32'W.

Dates and types of surveys:

Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

The midwaters around Platform Hogan were important habitat for a diverse fish assemblage. Blacksmith, blue and olive rockfishes, painted greenling, sharpnose seaperch, pile perch and California sheephead were all common species.

HABITAT

Original operator: Texaco; current operator of record: Nuevo Energy; date installed: 1981; first production: 1993; distance from shore (miles): 7.8 (OCS); water depth: 88 m (290 ft.); number of well slots: 24; produces: gas; platform jacket dimensions: 60 x 38 m (199 x 125 ft.) (bottom); platform footprint (m^2): 2,284; location: 34°17'N, 119°35'W.

Dates and types of surveys:

Submersible:

	Midwater	Bottom	Shell Mound
1995	x (partial)		
2000	x		

YOY widow rockfish, blacksmith, and one-year-old widow rockfish dominated the midwater at Platform Habitat. Blue and kelp rockfishes and painted greenling were also common species.

GRACE

Original operator: Standard Oil; current operator of record: Venoco; date installed: 1979; first production: 1980; distance from shore (miles): 10.5 (OCS); water depth: 96 m (318 ft.); number of well slots: 48; produces: Grace is a non-producing platform; platform jacket dimensions (at surface and at bottom): 27 x 44 m (90 by 145 ft.) (surface), 48 x 65 m (158 x 213 ft.) (bottom); size of shell mound: 4 m (13 ft.) high, oval, 61 x 118 m (200 x 390 ft.), oriented in a northwest-southeast direction; platform footprint (m^2): 3,090; location: 34°10'N, 119°28'W.

Dates and types of surveys:

Scuba: 1996–2000

Submersible:

	Midwater	Bottom	Shell Mound
1996	x	x	
1997	x	x	x
1998	x		x
1999	x	x	x
2000	x	x	x
2001	x	x	x

The midwaters around Platform Grace contained very large numbers of young rockfishes. Most of these rockfishes recruited between 1999 and 2001. YOY widow rockfish and bocaccio, juvenile squarespot, blue and widow rockfishes, bocaccio and juvenile and adult blacksmith were very common. Painted greenling, sharpnose seaperch, jack mackerel and young flag rockfish were also frequently encountered. Halfbanded rockfish were the most abundant species around the platform bottom. Juvenile widow, vermilion, and flag rockfishes and bocaccio were also abundant. Many of these individuals had settled out of the plankton at the platform in 1999 and had remained there. Squarespot and greenspotted rockfishes, young lingcod, and sanddabs were also common. Over the shell mounds, halfbanded rockfish and shiner perch were the most abundant species. Pink seaperch, sanddabs, YOY bocaccio, young lingcod, juvenile greenspotted, flag and vermilion rockfishes were also characteristic species.

GILDA

Original operator: Union Oil; Current operator of record: Nuevo Energy; date installed: 1981; first production: 1981; distance from shore (miles): 8.8 (OCS); water depth: 62 m (205 ft.); number of well slots: 96; produces: oil and gas; platform jacket dimensions: 45 x 52 m (150 x 170 ft.) (bottom); platform footprint (m²): 2,342.location: 34°10'N, 119°25'W.

Dates and types of surveys:
Scuba: 1995–2000
Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Blacksmith, halfmoon, kelp bass, opaleye, senorita, as well as YOY and juvenile blue, olive, squarespot and widow rockfishes and bocaccio were abundant in the midwater of this platform. Many of these rockfishes recruited from the plankton as YOYs during 1999. Due to poor visibility, we were unable to survey the bottom and shell mound of Platform Gilda during 2000. However, we reviewed a 2001 platform inspection video tape (Divecon International 2001) conducted with a remotely operated vehicle. That tape showed high densities of calico and juvenile vermilion rockfishes, as well as blue, brown, copper, halfbanded, olive, and widow rockfishes. Kelp greenling, lingcod, Pacific sanddab, and painted greenling were also noted.

GAIL

Original operator: Standard Oil; current operator of record: Venoco; date installed: 1987; first production: 1988; distance from shore (miles): 9.9 (OCS); water depth: 224 m (739 ft.); number of well slots: 36; produces: oil and gas; platform jacket dimensions: 21 x 52 m (70 x 170 ft.) (surface), 60 x 90 m (197 x 297 ft.) (bottom); platform footprint (m²): 5,327; location: 34°07'N, 119°24'W.

Dates and types of surveys:
Scuba: 1996–2000
Submersible:

	Midwater	Bottom	Shell Mound
1996	x	x	
1997	x	x	x
1998	x		
1999	x	x	x
2000	x	x	x
2001	x	x	x

Blacksmith, halfmoon, kelp bass and a variety of young rockfishes, including bocaccio, blue, flag, olive, and widow, characterized the midwaters of this platform. Most of the young rockfishes settled from the plankton in 1999. The platform bottom fish assemblage was dominated by adult bocaccio, greenblotched, greenspotted, stripetail and pinkrose rockfishes. Of particular interest, we observed higher densities of both adult cowcod and bocaccio at the bottom of Platform Gail than at any natural outcrop or other platform. The shell mound at Platform Gail was characterized by stripetail, pinkrose, greenblotched and greenstriped rockfishes. On one occasion, large numbers of juvenile hake were observed, on another northern anchovies were abundant.

GINA

Original operator: Union Oil; current operator of record: Nuevo Energy; date installed:1980; first production: 1982; distance from shore (miles): 3.7 (OCS); water depth: 29 m (95 ft.); number of well slots: 15; produces: oil and gas; platform jacket dimensions: 28 x 20 m (94 x 65 ft.) (bottom); shell mound: 4 m (13 ft.) high, oval, 45 x 64 m (150 x 210 ft.), oriented in a northwest-southeast direction; platform footprint (m²): 561; location: 34°07'N, 119°16'W.

Dates and types of surveys:
Scuba: 1995–2000

Platform Gina had the highest species richness (47) of any platform surveyed using scuba. Blacksmith dominated the assemblage, comprising 38% of all fishes observed. A close second was kelp bass, which counted for 31% of all fishes observed. Platform Gina had the highest number and density of surfperches of any platform, and was the only site where rubberlip surfperch formed part of the assemblage. The shell mound habitat at this platform provided excellent habitat for many species of recruiting rockfishes, where 13 species were observed. However, despite being present at every other surveyed platform, no widow or bocaccio juveniles were observed at Platform Gina. Pelagic species that characterized this assemblage include yellowtail, barracuda, and jackmackerel.

EDITH

Original operator: Standard Oil; current operator of record: Nuevo Energy; date installed: 1983; first production: 1984; distance from shore (miles): 8.5 (OCS); water depth: 49 m (161 ft.); number of well slots: 72; produces: oil and gas; platform jacket dimensions: 58 x 50 m (190 x 165 ft.) (bottom); platform footprint (m²): 2,879; location: 33°35'N, 118°08'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
1998	x	x	x

Blacksmith, halfmoon, opaleye, sheephead and garibaldi characterized the midwater fish assemblage at Platform Edith. Very high densities of California scorpionfish, along with sharpnose seaperch, blacksmith and blackeye goby were found at the platform bottom. California scorpionfish were also extremely abundant on the shell mound.

ELLEN

Original operator: Shell Oil; current operator of record: Aera Energy; date installed: 1980; first production: 1981; distance from shore (miles): 8.6 (OCS); water depth: 80 m (265 ft.); number of well slots: 80; produces: oil and gas; platform jacket dimensions: 45 x 56 m (147 x 186 ft.) (bottom); platform footprint (m²): 2,511; location: 33°34'N, 118°07'W.

Aera did not allow us to survey this platform. We reviewed a tape of a platform inspection carried out with a remotely operated vehicle (Divecon International, 7 September 2001) and observed very high densities of flag, halfbanded, squarespot and honeycomb rockfishes. We also saw a number of young vermilion rockfish. In the platform midwater, from about 61 m (200 ft) and deeper, there were very large numbers of young rockfishes, including both squarespots and widows.

ELLY

Original operator: Shell Oil; current operator of record: Aera Energy; date installed: 1980; first production: n/a; distance from shore (miles): 8.6 (OCS); water depth: 77 m (255 ft.); number of well slots: n/a; produces: Elly is a processing facility for Ellen and Eureka; platform jacket dimensions: 48 x 61 m (159 x 202 ft.) (bottom); platform footprint (m^2): 2,949; location: 33°35'N, 118°07'W.

Aera did not allow us to survey this platform. We reviewed a tape of a platform inspection carried out with a remotely operated vehicle (Divecon International, 9 September 2001) and observed high densities of young vermilion and young widow rockfishes, as well as many flag, honeycomb, olive, and squarespot rockfishes, and lingcod.

EUREKA

Original operator: Shell Oil; current operator of record: Aera Energy; date installed: 1984; first production: 1985; distance from shore (miles): 9.0 (OCS); water depth: 212 m (700 ft.); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 54 x 85 m (179 x 282 ft.) (bottom); platform footprint (m^2): 4,635; location: 33°33'N, 118°06'W.

Aera did not allow us to survey this platform. We reviewed a tape of a platform inspection carried out with a remotely operated vehicle (Divecon International, 5 September 2001) and observed large numbers of pinkrose and juvenile darkblotched rockfishes, as well as juvenile and subadult bocaccio and widow rockfish. Also present were flag, greenblotched and greenspotted, and perhaps speckled, rockfishes and lingcod.

EVA

Original operator: Union Oil Company; current operator of record: Nuevo Energy; date installed: 1964; first production: 1966; distance from shore (miles): 1.8 (state); water depth: 17 m (57 ft.); number of well slots: 39; produces: oil and gas; location: 33°39'N, 118°03'W.

EMMY

Original operator: Signal Oil and Gas Company; current operator of record: Aera Energy; date installed: 1963; first production: 1963; distance from shore (miles): 1.2 (state); water depth: 14 m (47 ft.); number of well slots: 53; produces: oil and gas; location: 33°39N, 118°02'W.

Aera did not allow us to survey this platform.

APPENDIX 2

Density of fishes observed during the oil/gas platform scuba surveys off central and southern California. Platforms are listed from northwest to southeast. Density is in fish per 100 m^2, "<" means "less than."

DAN DUGAN

Cabezon in the midwater of Platform Holly.

APPENDIX 3

Number and density of fishes observed in the midwaters, bottoms and shell mounds of oil/gas platforms off central and southern California. Platforms are listed geographically, from northwest to southeast. Species are ranked by number observed. YOY means "young-of-the-year", those are fish that are less than one year old. Density is in fish per 100 m^2, "<" means "less than".

PLATFORM MIDWATERS

Because we could not estimate the lengths of the transects around Platforms Habitat and Gilda, no fish densities are presented.

PLATFORM IRENE (Surveyed 1995–2001)

Species	Number	Density
Shortbelly rockfish YOY	7,300	378
Unidentified rockfish YOY	4,133	214
Widow rockfish YOY	2,310	120
Pacific sardine	1,600	83

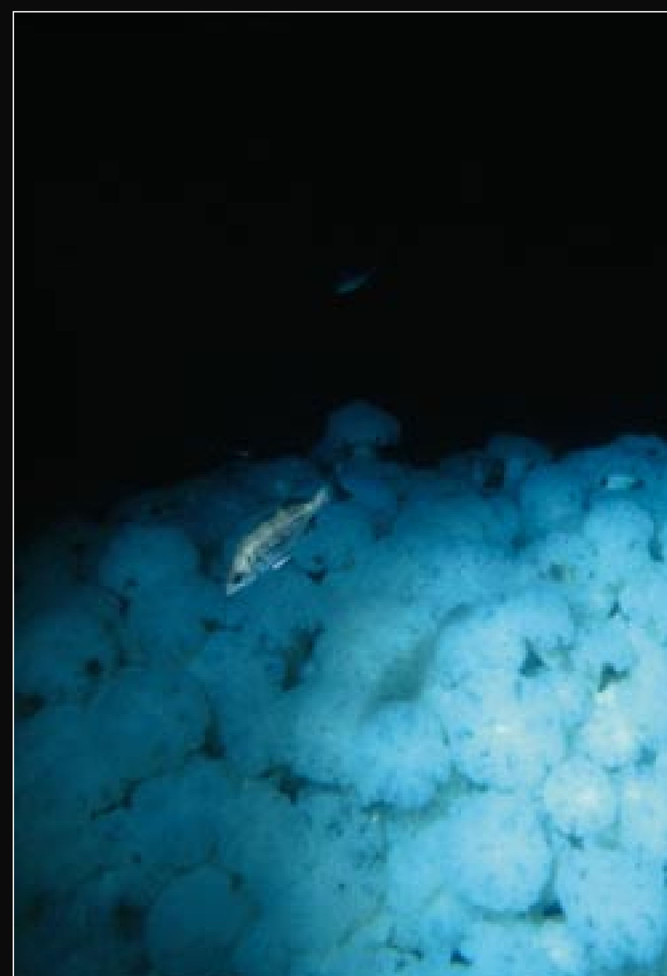
Mexican rockfish at bottom of Platform Gail.



EXECUTIVE SUMMARY

Information Needed

Production of oil and gas from offshore platforms has been a continual activity along the California coast since 1958. There are 26 oil and gas platforms off California, 23 in federal waters (greater than 3 miles from shore) and 3 in state waters. The platforms are located between 1.2 to 10.5 miles from shore and at depths ranging from 11 to 363 m (35–1,198 ft.). Crossbeams and diagonal beams occur about every 30 m (100 ft.), from near the surface to the seafloor. The beams extend both around the perimeter of the jacket and reach inside and across the platform. The beams and vertical pilings (forming the jacket) and the conductors on all platforms are very heavily encrusted with invertebrates and provide important habitat for fishes. The seafloor surrounding a platform is littered with mussel shells. This "shell mound" (also called "mussel mound" or "shell hash") is created when living mussels, and other invertebrates, are dislodged and fall to the seafloor during platform cleaning or storms.

Once an industrial decision is made to cease oil and gas production, managers must decide what to do with the structure, a process known as *decommissioning*. Platform decommissioning can take a number of forms, from leaving much, or all, of the structure in place to complete removal. Along with the platform operator, many federal and state agencies are involved in the decommissioning process. All oil and gas platforms have finite economic lives and by the beginning of the twenty-first century, seven platforms in southern California had been decommissioned and a number of others appeared to be nearing the end of their economic lives.

Management decisions regarding the decommissioning of an oil and gas platform are based on both biological and socioeconomic information. This study addressed the need for resource information and better understanding of how offshore oil/gas platforms contributed to the fish populations and fishery productivity in the Santa Maria Basin and Santa Barbara Channel. Prior to our studies, there was almost no biological information on Pacific Coast platform fish assemblages. This necessary research involved broad scale sampling at numerous oil/gas platforms and natural reefs. Research objectives included 1) characterizing the fish assemblages around platforms and natural reefs, 2) examining how oceanography affects patterns of recruitment and community structure of reef fishes, and 3) describing the spatial and temporal patterns of fish diversity, abundance and size distribution among habitat types (e. g., platforms and natural outcrops).

Research Summary

Between 1995 and 2001, we studied oil and gas platforms sited over a wide range of bottom depths, ranging between 29 and 224 m (95 and 739 ft.) and sited from north of Point Arguello, central California to off Long Beach, southern California. However, most of the platform research occurred in the Santa Barbara Channel and Santa Maria Basin. The Santa Barbara Channel and Santa Maria Basin are situated in a dynamic marine transition zone between the regional flow patterns of central and southern California. The Santa Barbara Channel is about 100 km long by about 50 km wide (60 x 20 miles) and is bordered on the south by the Northern Channel Islands (San Miguel, Santa Rosa, Santa Cruz, and Anacapa). This area is bathed in a complex hydrographic system of currents and water masses. Generally, cool coastal waters from the California Current enter the Santa Barbara Channel through its west entrance at Point Conception. Warm waters from the Southern California Bight flow in the opposite direction into the channel through its eastern entrance. Surface waters are substantially warmer in the Bight than north of Point Conception due to less wind-induced vertical mixing, the solar heating of surface waters, and currents of subtropical waters entering from the south. The convergence of different water masses in the Santa Barbara Channel results in relatively large scale differences in physical parameters (e.g., temperature, salinity, oxygen, and nutrient concentrations) and biotic assemblages (e. g., flora and fauna).

Scuba surveys were conducted at shallow depths and submersible surveys, using the research submarine *Delta*, at greater depths. We also surveyed shallow-water and deeper-water rock outcrops, many in the vicinity of platforms. Nine nearshore, shallow-water rock outcrops, seven on the mainland and two at Anacapa Island, were monitored annually from 1995 to 2000. These natural outcrops are geographically distributed across the Santa Barbara Channel providing opportunities for spatial comparisons. In addition, we surveyed over 80 deeper-water outcrops, in waters between 30 and 360 m (100

Opposite: Juvenile widow rockfish in platform midwater. (Photograph by Lovelab, UC Santa Barbara) and 1,180 ft.) deep, located throughout the Southern California Bight and off Points Conception and Arguello. These sites included a wide range of such habitats as banks, ridges, and carbonate reefs, ranging in size from a few kilometers in length to less than a hectare in area. On these features, we focussed on hard bottom macrohabitats, including kelp beds, boulder and cobble fields, and bedrock outcrops. Most of these deeper-water sites were visited once, a few were surveyed during as many as four years and one outcrop, North Reef, near Platform Hidalgo, was sampled annually.

Most of our oil and gas platform surveys were conducted at nine structures (Platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Gilda, Grace, Gina, and Gail) located in the Santa Barbara Channel and Santa Maria Basin. Between 1995 and 2000, we conducted annual surveys on the shallow portions of these nine platforms. The shallowest of the nine platforms, Gina, was surveyed from surface to bottom depths using scuba techniques. Deep-water surveys conducted between 1995 and 2001, using the research submersible, *Delta*, studied the same platforms excluding the bottom of Gilda and all of Gina. In 1998, one submersible survey was conducted around Platform Edith, located off Long Beach. In 2000 partial submersible surveys were completed around Platforms C, B, A, Hillhouse, Henry, Houchin, Hogan, and Habitat.

Patterns in Shallow-Water Habitats

Regional and local processes influenced patterns of outcrop fish assemblages in shallow waters. At regional spatial scales, outcrop fish abundance patterns often shifted abruptly as oceanographic patterns changed, roughly defining a cool-temperate assemblage in the western Santa Barbara Channel, and a warm-temperate assemblage in the eastern Santa Barbara Channel. This distinctive spatial pattern was observed in both oil and gas platform and natural outcrop habitats. In shallow waters, there was greater variability in platform species assemblages and population dynamics compared to natural outcrop assemblages, and this was most likely caused by the greater sensitivity of platform habitats to changing oceanographic conditions. Local processes that affected fish distribution and abundance were related to habitat features, where depth, relief height, and presence of giant kelp all played important roles. On platform habitat, we found that the majority of newly settled rockfish juveniles resided at depths greater than 26 m (86 ft.), although there were differences among species.

Characterization of the Deepwater Platform Fish Assemblages

With the exception of the shallow-water Platform Gina, all of the platforms we surveyed were characterized by three distinct fish assemblages: midwater, bottom, and shell mound. Rockfishes, totaling 42 species, dominated these habitats. Fish densities at most platforms were highest in the midwater habitat reflecting the depth preferences of young-of-the-year rockfishes. Young-of-the-year rockfishes represented the most abundant size classes in platform midwaters. Platform midwaters were nursery grounds for rockfishes as well as for a few other species, including cabezon and painted greenling. The young-of-the-year of at least 16 rockfish species inhabited these waters. Settlement success was affected by oceanographic conditions. Densities of young-of-the-year varied greatly between years and platforms. Young-of-the-year rockfish densities often varied by an order of magnitude or greater among survey years and platforms. From 1996 through 1998, rockfish settlement was generally higher around the platforms north of Point Conception as compared to platforms in the Santa Barbara Channel. This finding is reflective of the generally colder, more biologically productive waters in central California during the 1980s and much of the 1990s. Colder waters in 1999 were associated with relatively high levels of rockfish recruitment at all platforms surveyed. In 2000 and 2001, juvenile rockfish recruitment at platforms in the Santa Barbara Channel remained higher than pre-1999 levels, possibly reflecting the oceanographic regime shift to cooler temperatures that may be occurring in southern California.

Subadult and adult rockfishes and several other species dominated the bottom habitats of platforms. The bottom habitat of some platforms is also important nursery habitat as, in some instances, young-of-the-year rockfishes were observed in very large numbers. In general, more than 90% of all the fishes around platform bottoms were rockfishes. Bottom depth strongly influenced the number of species, species diversity, and density of fishes living around platform bases. This is distinctly different than the pattern observed in platform midwaters. The platform base provides habitat for not only fishes but also their prey and predators.

Shell mounds supported a rich and diverse fish assemblage. As at other platform habitats, rockfishes comprised the vast majority of the fishes. The many small sheltering sites created by mussels, anemones, and other invertebrates on the shell mounds created a habitat occupied by small fishes. Many of these fishes were the young-of-the-year and older juveniles of such species as lingcod and copper, flag, greenblotched, and pinkrose rockfishes and cowcod. The adults of these species also inhabited the platform bottom.

Platform versus Reef Fish Assemblages

We compared the species composition of the fish assemblages at Platform Hidalgo and at North Reef, an outcrop located about 1,000 m (3,300 ft.) from the platform. The assemblages were quite similar, both were dominated by rockfishes. In general, the distinctions between the platform and outcrop assemblages were based on differences in species densities, rather than species' presence or absence. Most species were more abundant at Platform Hidalgo. Halfbanded, greenspotted, flag, greenstriped, and canary rockfishes, and all three life stages of lingcod (young-of-the-year, immature, adult) and painted greenling had higher densities around the platform. Five species (pink seaperch, shortspine combfish, pygmy, squarespot, and yellowtail rockfishes) were more abundant at the outcrop. Young-of-the-year rockfishes were found at both Platform Hidalgo (primarily in the midwaters) and at North Reef. Young-of-the-year rockfish densities were higher at the platform than at the outcrop in each of the five years studied. In several years, their densities were more than 100 times greater at Platform Hidalgo compared to North Reef.

Rockfishes numerically dominated the fish assemblages at almost all of the platform and hard seafloor habitats in our study. Overall species richness was greater at the natural outcrops (94) than at the platforms (85). There was a high degree of overlap in species between platforms and outcrops and differences were primarily due to generally higher densities, of more species, at platforms. In general, canary, copper, flag, greenblotched, greenspotted, greenstriped, halfbanded, vermilion rockfishes, bocaccio, cowcod, and widow rockfish young-of-the-year, painted greenling and all life history stages of lingcod were more abundant at platforms than at all or most of the outcrops studied. Yellowtail rockfish and the dwarf species pygmy, squarespot, and swordspine rockfishes were more abundant on natural outcrops.

Findings

Our research demonstrates that some platforms may be important to regional fish production. The higher densities of rockfishes and lingcod at platforms compared to natural outcrops, particularly of larger fishes, support the hypothesis that platforms act as de facto marine refuges. High fishing pressure on most rocky outcrops in central and southern California has led to many habitats almost devoid of large fishes. Fishing pressure around most platforms has been minimal. In some locations, platforms may provide much or all of the adult fishes of some heavily fished species and thus contribute disproportionately to those species' larval production.

Platforms usually harbored higher densities of young-of-the-year rockfishes than natural outcrops and thus may be functionally more important as nurseries. Platforms may be more optimal habitat for juvenile fishes for several reasons. First, because as structure they physically occupy more of the water column than do most natural outcrops; presettlement juvenile or larval fishes, transported in the midwater, are more likely to encounter these tall structures than the relatively low-lying natural rock outcrops. Second, because there are few large fishes in the midwater habitat, predation on young fishes is probably lower. Third, the offshore position and extreme height of platforms may provide greater delivery rates of planktonic food for young fishes. Most of the natural outcrops we found that had high densities of young-of-the-year rockfishes were similar to platforms as they were very high relief structures that thrust their way well into the water column.

Our research, and reviews of existing literature, strongly implies that platforms, like natural outcrops, both produce and attract fishes, depending on species, site, season, and ocean conditions. Platform fish assemblages around many of the deeper and more offshore platforms probably reflect recruitment of larval and pelagic juvenile fishes from both near and distant maternal sources, not from attraction of juvenile or adult fishes from natural outcrops. Annual tracking observations of strong year classes of both flag rockfish and bocaccio imply that fishes may live their entire benthic lives around a single platform. A pilot study showed that young-of-the-year blue rockfish grew faster at a platform than at a natural outcrop indicating that juvenile fishes at platforms are at least as healthy as those around natural outcrops.

Management Applications

In this report, we discuss the ecological and political issues that surround platform decommissioning in California, including the ecological consequences of the four platform decommissioning alternatives: (1) Complete Removal, (2) Partial Removal and Toppling, and (3) Leave-in-Place.

Complete Removal: In complete removal, operators may haul the platform to shore (for recycling, reuse, or disposal) or it can be towed to another site and reefed.

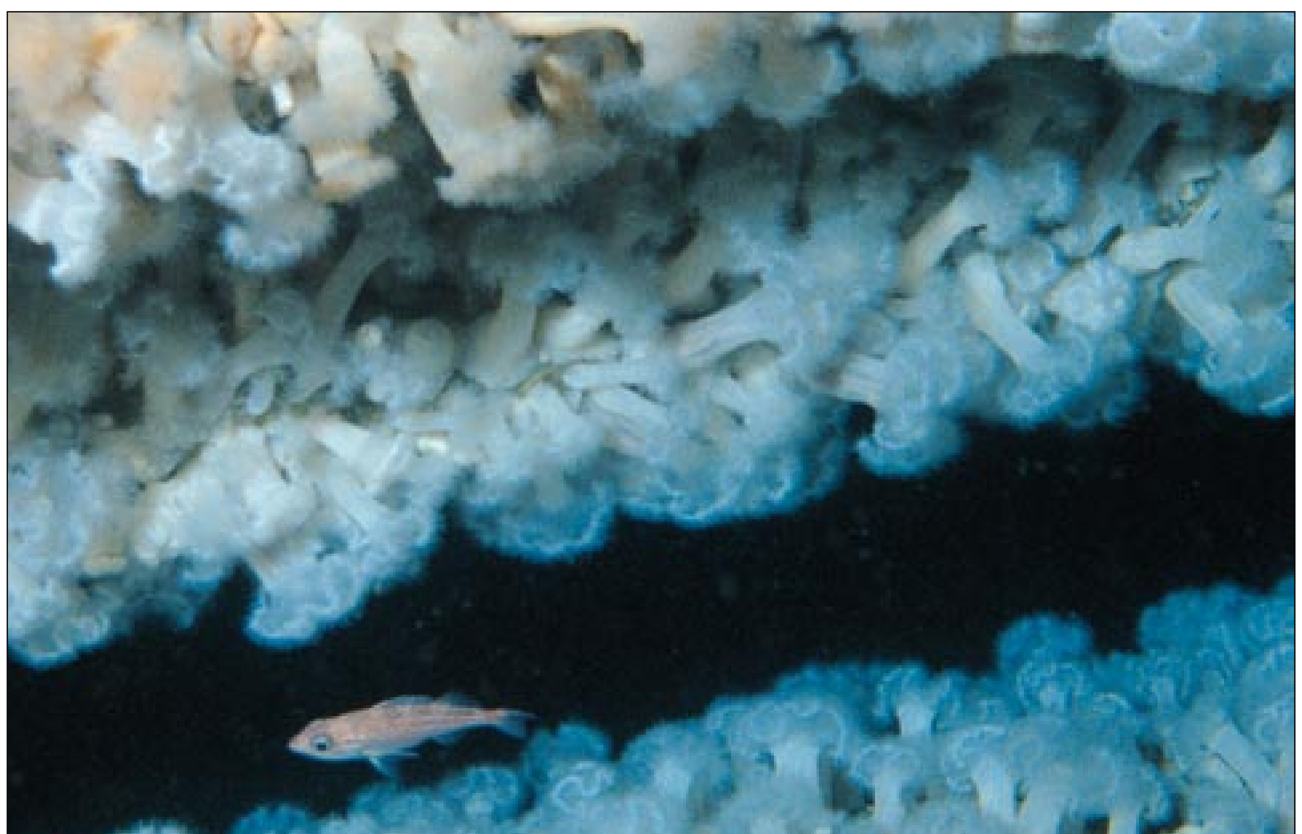
A typical full-removal project begins with well abandonment in which the well bores are filled with cement. The topsides, which contain the crew quarters and the oil and gas processing equipment, are cut from the jacket and removed and the conductors are removed with explosives. Finally, the piles that hold the jacket to the seabed are severed with explosives and the jacket is removed.

Completely removing a platform for disposal on land will kill all attached invertebrates. If some of the platform structure is hauled to a reef area and replaced in the water, some of these animals may survive, depending on water depth and the length of time the structure is exposed to the air. The explosives used to separate the conductor and jacket from the seafloor kill large numbers of fishes. In a study in the Gulf of Mexico, explosives were placed 5 m (15 ft.) below the seafloor to sever the well conductors, platform anchor pilings and support legs, of a platform in about 30 m (100 ft.) of water. All of the fishes on or near the bottom and most of the adult fishes around the entire platform suffered lethal concussions. Marine mammals and sea turtles may also be indirectly killed by damage to the auditory system.

The use of explosives to remove or topple a platform may also complicate fishery-rebuilding programs. Cowcod, a species declared overfished by NOAA Fisheries, provides an example. This species is the subject of a federal rebuilding plan that severely limits catches. In 2001, this was 2.4 metric tons or about 600 fish. Based on our research, there are at least 75 adult cowcod on Platform Gail. If explosives are used to remove Gail, all of these fish will be killed. The loss of at least 75 adult cowcod may be sufficiently large to complicate the rebuilding plan.

Partial Removal and Toppling: Under both partial removal and toppling the topsides are removed. In partial removal, the jacket is severed to a predetermined depth below the surface and the remaining subsurface structure is left standing. In toppling, the conductors and piles are severed with explosives and the jacket is pulled over and allowed to settle to the seafloor. In both partial removal and toppling, conductors need not be completely removed. Retaining conductors would add habitat complexity to a reefed platform.

While the immediate mortality impact to attached invertebrates of partial removal is greater than leaving the platform structure in place, mortality risks to both fishes and invertebrates are much lower than in both toppling and total removal. Partial removal causes fewer deaths than does toppling for two reasons. First, because partial removal does not require explosives (as does toppling), there is relatively little fish, marine mammal, sea turtle, and motile invertebrate (such as crab) mortality. In addition, when a platform is partially removed, vertebrate and invertebrate assemblages associated with the remaining structure are likely to be minimally affected. In contrast, when a platform is toppled, the jacket falls to the seafloor, and, depending on bottom depth, many, if not most of the attached invertebrates die.



MARY NISHIMOTO

*Whitespeckled rockfish and white anemones (*Metridium *sp.).*

Both partial removal and toppling would produce reefs with somewhat different fish assemblages than those around intact platforms. With the shallower parts of the platform gone, it is likely that partial removal would result in fewer nearshore reef fishes, such as seaperches, basses, and damselfishes. However, young-of-the-year rockfishes of many species recruit in large numbers to natural outcrops that have crests in about 30 m (100 ft.) of water or deeper. Thus, it is possible that partial removal would result in little or no reduction in young-of-the-year recruitment for many rockfish species. The pelagic stage of some rockfish species, particularly copper, gopher, black-and-yellow and kelp, may recruit only to the shallowest portions of the platform. For these species, both partial removal and toppling would probably decrease juvenile recruitment, depending on the uppermost depth of the remaining structure. Young-of-the-year rockfishes, which make up the bulk of the fish populations in the platform midwater habitat, would probably be less abundant around a toppled platform compared to a partially removed one. Because most California platforms reside in fairly deep water, toppled platforms might reside at depths below much rockfish juvenile settlement. Thus, toppling might result in lowered species composition and fish density. However, depending on the characteristics of the platform, a toppled structure, with twisted and deformed pilings and beams, might have more benthic complexity than one that is partially removed. This might increase the number of such crevice dwelling fishes as pygmy rockfishes.

It is difficult to catch fishes that live inside the vertically standing platform jacket. Our observations demonstrate that many of the rockfishes living at the platform bottom, such as cowcod, bocaccio, flag, greenspotted, and greenblotched rockfishes, dwell in the crevices formed by the bottom-most crossbeam and the seafloor. To a certain extent, these fishes are protected from fishing gear by the vertical mass of the platform, a safeguard that would persist if the platform were partially removed, particularly if the conductors remained in place. It would be much easier to fish over a toppled platform, as more of the substrate would be exposed to fishing gear.

Coast Guard regulations do not require a minimum depth below the ocean surface to which a decommissioned platform must be reduced. The decision on how much of the jacket and conductors is left in place is based on both a Coast Guard assessment and the willingness of the liability holder to pay for the navigational aids required by the Coast Guard. As mussels become rare below about 30 m (100 ft.) on most platforms, the mistaken assumption that all partially removed platforms must be cut to 24–30 m (80–100 ft.) below the surface has led some to conclude that this will inevitably lead to a severe reduction in the amount of mussels that fall to the bottom and, thus, to a change in or end to, the shell mound community. This is not necessarily the case.

Leave-in-Place: A platform could be left in its original location at the time of decommissioning. The topsides would be stripped of oil and gas processing equipment, cleaned, and navigational aids installed. If a platform were left in place, the effect on platform sea life would be minimal.

Pacific Coast Platforms

In this report we have also included a brief summary of information on all of the Pacific Coast platforms (Appendix 1), densities of all fishes observed at each platform during scuba and submersible surveys (Appendix 2 and Appendix 3, respectively), and a list of the 20 most important sites, both platforms and natural outcrops, for the most abundant species in our deepwater study (Appendix 4).

Research Needs

Our research demonstrates that additional biological information is needed in the decommissioning process. These information needs fall into three categories: (1) A comparison of the ecological performance of fishes living at oil platforms and on natural outcrops, (2) A definition of the spatial distribution of economically important species (of all life history stages) within the region of interest and a definition of the connectivity of habitats within this region, and (3) An understanding of how habitat modification of the platform environment (e.g., removal of upper portion or addition of bottom structure) changes associated assemblages of marine life at offshore platforms.

Major questions remaining to be addressed include:

What Fishes Live Around Platforms and Nearby Natural Reefs?

In order to assess the relative importance of a platform to its region, it is essential to conduct basic surveys not only around the platform, but also at nearby reefs. A majority of platforms have not been surveyed.

How Does Fish Production around Platforms Compare to that at Natural Outcrops?

It is possible to compare fish production between habitats by examining (1) fish growth rates, (2) mortality rates, and (3) reproductive output. A pilot study compared the growth rates of young-of-the-year blue rockfish at Platform Gilda and Naples Reef and another examining young-of-the-year mortality rates is planned. Additional work is needed to determine larval dispersal patterns and differences in densities at various study sites. For example, we now have enough data to study the relative larval production per hectare of cowcod and bocaccio at Platform Gail versus that on natural outcrops.

What Is the Relative Contribution of Platforms in Supplying Hard Substrate and Fishes to the Region?

This research would put in perspective the relative contribution of platforms in supplying hard substrate and reef fishes to their environment.

First, this requires knowledge of the rocky outcrops in the vicinity of each platform; this is derived from seafloor mapping. Once the mapping is complete, visual surveys of the outcrops, using a research submersible, will determine the fish assemblages and species densities in these habitats. Knowing the areal extent of both natural and platforms habitats and the densities of each species in both of these habitats, it is then possible to assess the total contribution of each platform to the fish populations and hard substrate in that region.

How Long Do Fishes Reside at Oil/Gas Offshore Platforms?

It is unclear how long fishes are resident to platforms. For instance, does the large number of fishes, particularly such species as the overfished bocaccio and cowcod, remain around the platforms for extended periods? Knowledge of the residence time of these species would allow us to more accurately determine if platforms form optimal habitat for these species.

What are the Effects of Platform Retention or Removal on Fish Populations within a Region?

As an example, what effect would platform retention or removal have on young-of-the-year fish recruitment? Would the young rockfishes that settle out at a platform survive in the absence of that platform? Our surveys demonstrate that planktonic juvenile fishes, particularly rockfishes, often settle to platforms in substantial numbers. If that platform did not exist, would these young fishes have been transported to natural outcrops? Knowing how long it would take rockfish larvae to reach suitable natural outcrops, and what percent of these larvae would likely die before reaching these outcrops, will give a sense of the importance of a platform as a nursery ground.

Similarly, using a synthesis of oceanographic information, it is possible to model the fate of larvae produced by fishes living at a platform.

How Does Habitat Modification of the Platform Environment (e.g., Removal of Upper Portion or Addition of Bottom Structure) Change Associated Assemblages of Marine Life?

All decommissioning options except leave-in-place involve modification of the current physical structure of offshore platforms. Is it possible to increase fish diversity and density by altering the seafloor or the platform itself? For instance, it would be useful to add complexity, in the form of quarry rock or other structure, to the shell mound around a platform, and follow the changes in fish assemblages.

Descriptive information such as depth distribution and life history information is also useful in determining how decommissioning options affect the environment. Experimental research, using a BACI design or similar approach, can aid in predicting how the biotic community will respond to such structural changes.

Chapter 1

INTRODUCTION

Milton S. Love, Donna M. Schroeder, and Mary M. Nishimoto

Goals and Objectives

Production of oil and gas from offshore platforms has been a continual activity along the California coast since 1958. All oil and gas platforms have finite economic lives and at the beginning of the twenty-first century, seven platforms in southern California have been decommissioned and a number of others appear to be nearing the end of their economic lives.

Once an industrial decision is made to cease oil and gas production, managers must decide what to do with the structure, a process known as *decommissioning*. Platform decommissioning can take a number of forms, from leaving much, or all, of the structure in place to complete removal (see Chapter 4, page 4-1). Along with the corporation that owns the platform, federal agencies that are involved in the decommissioning process include the Minerals Management Service (for Outer Continental Shelf platforms), U. S. Coast Guard, U. S. Army Corps of Engineers, National Marine Fisheries Service, U. S. Environmental Protection Agency, U. S. Occupational Safety & Health Administration. California State agencies include the California State Lands Commission (for platforms in State waters), California Regional Water Quality Control Districts (for platforms in State waters), California Coastal Commission, and California Fish and Game Commission. At the local level the County Air Pollution Control Districts and agencies such as the County Energy Division would also play a role.

Off California, three platforms, Harry (in 1974), Helen (in 1978), and Herman (in 1978) were decommissioned through complete removal without a great deal of controversy. Public debate arose over decommissioning of platforms Hilda, Hazel, Hope, and Heidi when a recreational angler's group, desiring to continue fishing on these structures, began to lobby for their retention. Ultimately, the four platforms were removed in 1996. It appears certain that future decommissioning of California platforms will be controversial because of conflicting desires regarding the fate of platforms on the part of various marine stakeholders (see Chapter 4, page 4-1).

Since 1995, our group, first funded by the Biological Resources Division of the U. S. Geological Survey, the Minerals Management Service and most recently by the California Artificial Reef Enhancement Program, has conducted research on the fishes that live around the platforms and on natural rock outcrops. Our goals have been to determine the patterns of fish assemblages around both platforms and outcrops and to identify the processes that may have generated these patterns. In addition, we are attempting to understand the linkages between habitats among different fish life history stages.

Previous Research

Decommissioning decisions in California will have a biological as well as socioeconomic and cultural component. Therefore, it is timely to summarize what is known about the biology and ecology of the fauna of these structures. Our emphasis has been on the fish assemblages.

Our research on platforms and outcrops occurred between 1995 and 2001. Before our research began, only a few fish surveys had been conducted around California platforms. Most of this work was conducted around platforms Hilda and Hazel, two shallow-water platforms off Summerland, just below Santa Barbara (Carlisle et al. 1964; Allen and Moore 1976; Bascom et al. 1976). Both of these structures were removed in 1996. Carlisle et al. (1964) found an average of about 6,000 fish under each platform. Allen and Moore (1976) estimated an average of about 20,000 fishes, occasionally reaching at least 30,000. Rockfishes, particularly young-of-the-year fishes, and sea perches dominated the assemblages, kelp and barred sand bass were also abundant. Large numbers of young bocaccio and widow rockfish living around platforms A, B, and C in the Santa Barbara Channel were tagged by the California Department of Fish and Game (Hartmann 1987). Six bocaccio were recovered as adults. All had traveled to natural outcrops, one 148 km (94 miles) away from the platforms. Love and Westphal (1990) compared fishes captured around oil platforms and at two nearby natural outcrops in the Santa Barbara Channel. Rockfishes were the most commonly taken species. Young rockfishes were most abundant at the platforms, rockfishes on natural outcrops tended to be older. A pilot survey of fishes, using a remotely operated vehicle at Platform Hidalgo and nearby natural outcrops (Love et al. 1994), identified large numbers of young rockfishes at the platform and few at natural outcrops. Benthic rockfishes were more abundant at natural outcrops.

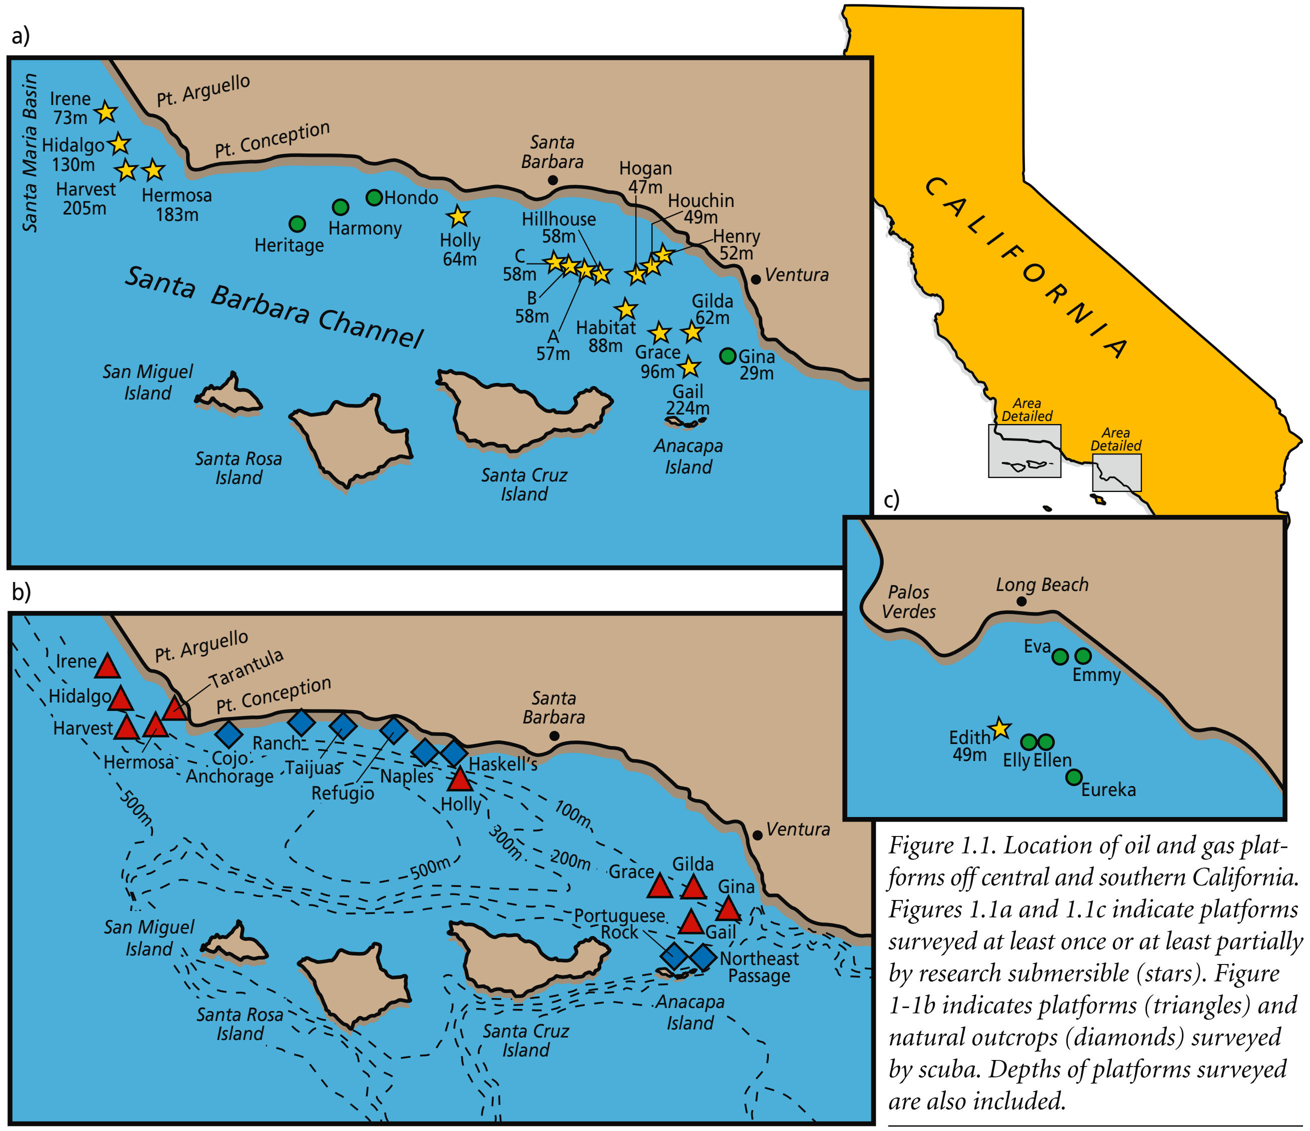


Figure 1.1. Location of oil and gas platforms off central and southern California. Figures 1.1a and 1.1c indicate platforms surveyed at least once or at least partially by research submersible (stars). Figure 1-1b indicates platforms (triangles) and natural outcrops (diamonds) surveyed by scuba. Depths of platforms surveyed are also included.

Our current research began in 1995, preliminary data is found in Love et al. (1999, 2000, 2001) and Schroeder et al. (1999) and we have incorporated that information into this report.

Study Area

Platforms

There are 26 oil and gas platforms off California, 23 in federal waters (greater than 3 miles from shore) and 3 in state waters (Figures 1.1a, b, and c). The platforms are located between 1.2 to 10.5 miles from shore and at depths ranging from 11 to 363 m (35–1,198 ft.). Information regarding location, depth, and other physical features of California's offshore platforms are described in Appendix 1.

All California platforms are similar in design (Figure 1.2); they primarily vary in size. The above-water structures, including oil and gas processing equipment and crew living and working quarters are termed the *topside* (also *topside facilities* and *deck*). The vertical pipes that carry the oil and gas are the *conductors*. The parts of the structure that are embedded in the bottom and protrude through the surface to support the topside structural components form the *jacket* that includes the crossbeams, legs, and the piles inside the legs. In general, the jackets of California platforms are made of carbon steel and the topsides are composed of steel plate and other structural steel components. Platforms also contain a relatively small amount of cement.

Crossbeams and diagonal beams occur about every 30 m (100 ft.), from near the surface to the seafloor. The beams extend both around the perimeter of the jacket and reach inside and across the platform. This web work of cross beams provides a great deal of habitat for both invertebrates

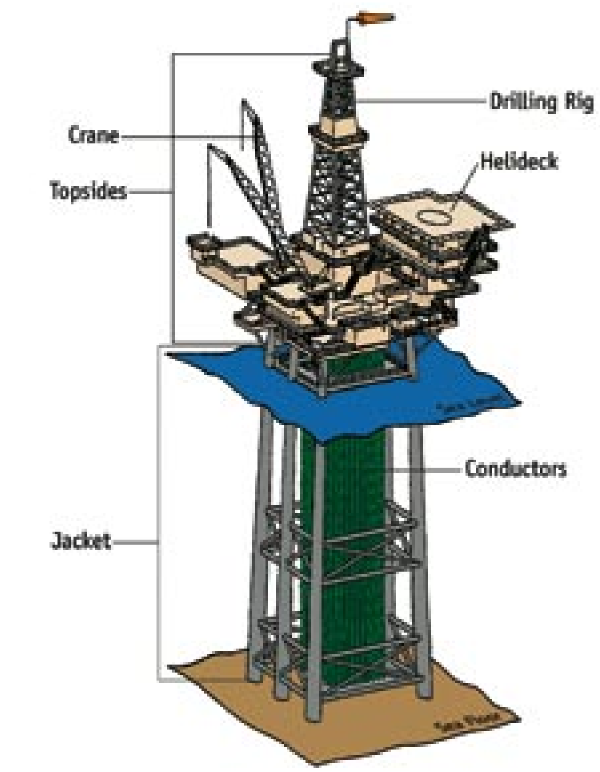

Figure 1.2. A typical oil/gas platform off southern California. Adapted from Manago and Williamson (1998).

and fishes. All of the platforms we studied have a crossbeam on the seafloor, although portions of the beam may be either buried in sediment or undercut by currents.

The seafloor surrounding a platform is littered with mussel shells. This "shell mound" (also called "mussel mound" or "shell hash") is created when living mussels, and other invertebrates, are dislodged during platform cleaning or storms. We observed shell mounds under and around all of the platforms we surveyed. Only a few of the more shallow shell mounds (around platforms Gina, Grace, Henry, and Houchin) have been accurately mapped (Sea Surveyor Inc. 2003). These mounds ranged from 4–6 m (13–19 ft.) high and were either oval or round in shape. Dimensions of these four mounds were: Gina, oval, 45 x 64 m (150 x 210 ft.); Grace, oval, 61 x 118 m (200 x 390 ft.); Henry, round, 76 m (250 ft.) in diameter; Houchin, round, 85 m (280 ft.) in diameter. Current patterns, rate of shell deposition, and age of platform all play a role in the size of shell mounds.

Rock Outcrops

An objective of our research was to compare fish assemblages and fish productivity at platforms and natural outcrops in central and southern California. Understanding spatial variability and trends in fish populations at these sites is important as it aids in understanding the regional importance of platforms as fish habitat. These sites included a wide range of such mesohabitats as banks, ridges, and carbonate buildups, ranging in size from a few kilometers in length to less than a hectare in area. On these features, we focussed on hard bottom macrohabitats, including kelp beds, boulder and cobble fields, and bedrock outcrops following standard, statistically based sampling methods and techniques.

Physical Oceanography and Biogeography of the Platform Study Area

General Description

The study area includes the Santa Barbara Channel and Santa Maria Basin (Figure 1.1). These oceanographic bodies are situated in a dynamic marine transition zone between the regional flow patterns of central and southern California. The Santa Barbara Channel is about 100 km long by about 50 km wide (60 x 20 miles) and is bordered on the south by the Northern Channel Islands (San Miguel, Santa Rosa, Santa Cruz, and Anacapa). Within the Santa

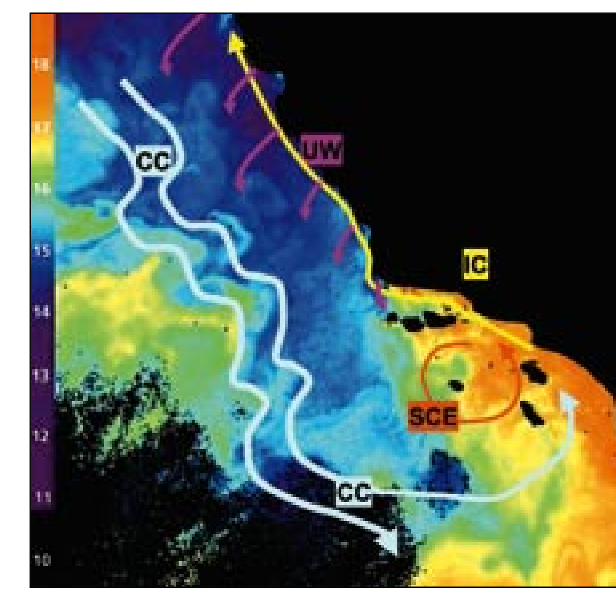

Figure 1.3. Satellite image of sea surface temperature (SST) and a diagram of the large-scale current patterns off the central and southern California coast. This image shows the predominant, large-scale SST pattern along with smaller scale features such as eddies and fronts (temperature scale, degrees Celsius). The generalized flow of the California Current (CC), the Inshore Countercurrent (IC), and Southern California Eddy (SCE) overlay the SST image. Plumes of cold, nutrient-rich, upwelled water (represented by dark blue and purple) originate near the coast and are directed offshore (magenta arrows).

The invertebrate communities of the jacket, conductors and shell mounds

DAN DUGAN
Rock crab

The jackets and conductors of all platforms are very heavily encrusted with invertebrates. Depth zonation of the invertebrate community is evident. An extremely thick layer of mussels extends from the intertidal zone to depths of at least 30 m (100 ft) (and to at least 44 m, 145 ft., on some platforms). Both *Mytilus galloprovincialis* and *M. californianus* occur in these upper depths, although *M. galloprovincialis* is more common in the shallower portions of this zone (J. Dugan, personal communication). Although mussels dominate this habitat, other invertebrate taxa are abundant in this upper layer. Common inhabitants include barnacles, seastars (primarily *Pisaster giganteus*), rock scallops (*Crassadoma gigantea*), rock oysters and jingle shells (*Chama arcana* and *Pododesmus cepio*), sea anemones (*Anthopleura xanthogrammica*, *Metridium* sp.), caprellid amphipods, rock crabs (*Cancer antennarius*), limpets (including *Lottia gigantea*, *Lottia* sp., *Tectura* spp., and *Acmaea mitra*), gooseneck barnacles (*Pollicipes polymerus*), and sessile tunicates. With greater depth, the diverse mussel community wanes and tends to be replaced by a blanket of club anemones (*Corynactis californicus*). At greater depths yet, white anemones (*Metridium* sp.) and sponges begin to dominate these platform structures. These organisms, along with crabs (*Munida* sp.) and sea stars, characterize the deepest parts of the deepwater platforms we surveyed (J. Dugan, personal communication; M. Love, unpublished observations).

Our observations indicate that, depending on bottom depth, a number of invertebrate species are abundant on the shell mounds. Common mound species include three species of seastars (*Pisaster brevispinus, P. giganteus,* and *P. ochraceus*), sunstars (*Pycnopodia helianthoides, Rathbunaster* sp.), bat stars (*Asterina miniata*), brittle stars, rock crabs (*Cancer anthonyi*, *C. antennarius,* and *C. productus*), king crabs (*Paralithodes rathbuni*), opisthobranchs (*Pleurobranchaea californica*), spot prawns (*Pandalus platyceros*), octopi (*Octopus* spp.), and sea anemones (*Metridium* sp.) (M. Love, unpublished observations).

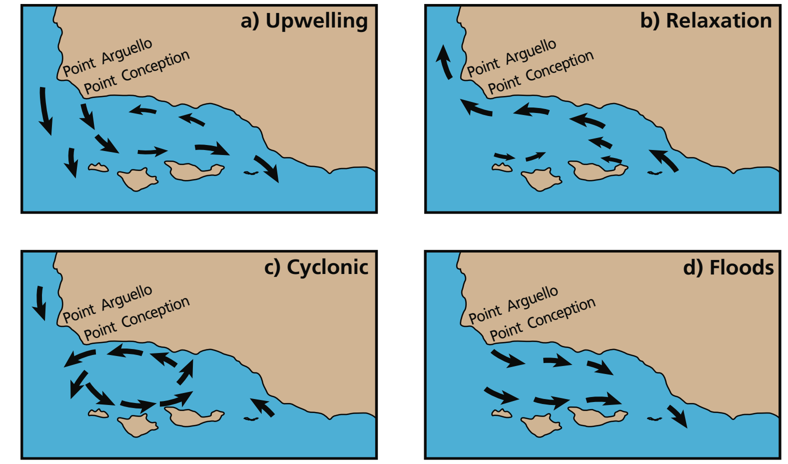

Figure 1.4. Generalized circulation patterns in the Santa Barbara Channel. (a) Upwelling; (b) Relaxation; (c) Cyclonic; (d) Flood east (shown) or west. Westward propagating train of cyclonic and anticyclonic eddies have also been observed (not shown). Adapted from Harms and Winant (1998).

Barbara Channel is a basin that is about 500 m (1,650 ft.) deep. The predominant large-scale patterns of sea surface temperature distributions off California and smaller scale, but persistent, features such as eddies, fronts (strong temperature gradients), and plumes of cold, upwelled water that extend offshore from coastal headlands are depicted in Figure 1.3. The coastal current patterns are embedded in the complex California Current System (CCS) that extends from the Strait of Juan de Fuca at the Canada-US border to the tip of Baja California, Mexico (Hickey 1998). A generalized scheme of the CCS is presented in Figure 1.3. Waters off northern and central California are typically cool because of the southerly flowing California Current offshore the continental shelf and upwelling events generated over the shelf. Upwelling, which is most intense during the spring and summer, is generated by winds that blow toward the south along the coast. Cool coastal waters enter the Santa Barbara Channel through its west entrance at Point Conception. Warm waters from the Southern California Bight flow in the opposite direction into the channel through its eastern entrance. The geographic orientation of the Southern California Bight shelters it from the winds that generate upwelling. Surface waters are substantially warmer in the Bight than north of Point Conception due to less wind-induced vertical mixing, the solar heating of surface waters, and currents of subtropical waters entering from the south (Lynn and Simpson 1987). The convergence of different water masses in the Santa Barbara Channel results in relatively large scale differences in physical parameters (e.g., temperature, salinity, oxygen, and nutrient concentrations) and biotic assemblages (e. g., flora and fauna).

Circulation in the Santa Barbara Channel is complex and highly variable (Hendershott and Winant 1996; Harms and Winant 1998; Winant et al. 1999). Santa Barbara Channel circulation typically is characterized by westward flow along the northern boundary of the Channel and eastward flow along its southern boundary (Figure 1.4). The relative strength of these opposing flows varies on scales of days to weeks and seasonally. Two opposing forces drive channel circulation: a wind gradient that is strongest in the west and a pressure gradient that is caused by higher water temperatures in the east. When these forces are balanced, a singular cyclonic (counter-clockwise rotating) eddy forms in the western channel over its central basin. Cyclonic circulation is observed to be the strongest in the summer and weakest in the winter. Unidirectional currents toward the east or west throughout the Santa Barbara Channel occur predominantly in the winter and tend to be short in duration. Throughout the year, smaller cyclonic and anticyclonic eddies, fronts, and jets are common in the Santa Barbara Channel and may be ephemeral or persistent for days to weeks. Circulation within this channel at any particular time is affected by a tendency for cyclonic flow and by the variability in the alongshelf currents that are of a scale larger than the channel.

The complex flow patterns and ocean conditions within the Santa Barbara Channel are affected by larger-scale oceanographic and atmospheric processes associated with intra-annual (e.g., storms and seasonal patterns) and inter-annual (e.g., El Niño and La Niña events) variability and interdecadal climate regime shifts. These events are teleconnected to tropical Pacific and Pacific basin-wide atmospheric phenomena. Oceanographic conditions within the Santa Barbara Channel and along the California coast at-large changed dramatically between 1997 and 1999. Strong, warm-water El Niño conditions began late in the summer of 1997 and continued into the summer of 1998. Cool-water La Niña conditions manifested in early 1999 (Lynn et al. 1998; Hayward et al. 1999). El Niño events are linked to delayed and reduced phytoplankton productivity, reduced zooplankton biomass, reduced growth and reproduction of coastal fishes, and increased mortality during their planktonic larval phase (Lenarz et al. 1995; McGowan et al. 1998; Kahru and Mitchell 2000). Our findings indicate that fish populations responded rapidly to the shift from El Niño to La Niña conditions along the coast.

Superimposed on the inter-annual variability, which include the El Niño and La Niña anomalies, are climate-ocean changes that occur throughout the entire North Pacific Basin on decadal scales. A well documented climatic shift occurred rapidly during 1976 to 1977. It was marked by abrupt changes in sea surface temperature patterns and the circulation of a predominant atmospheric feature of the northeast Pacific known as the Aleutian Low. Since that time in the northeast Pacific, macrozooplankton biomass and a number of nearshore fish stocks in the California Current system have declined (Roemmich and McGowan 1995). In 1999, a number of physical and biological changes in the northeast Pacific indicated another shift from a warm to cool regime (Bograd et al. 2000). Recruitment of young-of-the-year rockfishes to platforms in the Santa Barbara Channel was exceptionally high in 1999. The permanence of this shift to cool conditions is uncertain.

Small-Scale Oceanographic Variability within the Santa Barbara Channel

Interesting patterns of fish abundance are related to the complexity and dynamics of the hydrography and circulation within the Santa Barbara Channel. Certain aspects of our research are focussed on the biological significance of fronts and eddies to the transport and survival of early juvenile stages of marine fishes. Typically, these features are generated by local-scale interactions of wind, opposing water mass currents, and tides. This is especially true where the coastline is characterized by irregular topography and bathymetry, as is the case in the Santa Barbara Channel and the Southern California Bight (Owens 1980) (Figure 1.1). As mentioned, fronts and eddies affect how fishes are pelagically distributed in the region and may ultimately affect the timing and location of young-of-the-year settlement. For example, we sampled high densities of pelagic juvenile fishes within an eddy in the Santa Barbara Channel. The location of the eddy was determined by analysis of surface current maps generated from remote-sensing radar (Nishimoto and Washburn 2002). Furthermore, we have discovered that sea surface temperature fronts can be used to identify boundaries that separate reef habitat with high and low levels of juvenile rockfish settlement (Love, Nishimoto, Schroeder, and Caselle 1999). Mesoscale features that are visible in sea surface temperature images and surface current maps potentially can be used along with other oceanographic data to identify areas where benthic recruitment is likely.

The Santa Barbara Channel as a biological transition zone

Marine organisms from distinctively different northern and southern biogeographic communities occur in the Santa Barbara Channel as resident populations or as seasonal or occasional visitors making this a rich, biological transition zone (Horn and Allen 1978). A few examples of warm-temperate and subtropical fishes that are more common in southern California (defined as south of Point Conception) than in central California and that we have observed at platforms in the Santa Barbara Channel are Mexican rockfish, kelp bass, yellowtail, and Pacific barracuda. Examples of cool-temperate fishes that have distributions centered from central California to the Pacific Northwest and may occur at platforms include cabezon, kelp greenling, lingcod, and many rockfishes (e.g., blue, canary, widow, and yelloweye).

Methods

A major research objective of this project was to describe and compare the spatial and temporal patterns of fish assemblages around platforms and natural rock outcrops. Between 1995 and 2001, we surveyed platforms sited over a wide range of bottom depths, ranging between 29 and 224 m (95 and 739 ft.) and sited from north of Point Arguello to off Long Beach. We also surveyed shallow-water and deep-water rock outcrops, many in the vicinity of platforms. Scuba surveys were conducted at shallow depths (< 36 m, 119 ft.), and submersible surveys at deeper depths.

Most of our platform surveys were conducted at nine structures (Platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Gilda, Grace, Gina, and Gail) located in the Santa Barbara Channel and Santa Maria Basin (Figure 1.1). Between 1995 and 2000, we conducted scuba surveys on the shallow portions of these nine platforms (Figure 1.1b). The shallowest of the nine platforms, Gina, was surveyed from top to bottom using scuba. Deeper-water surveys between 1995 and 2001, using a research submersible, surveyed the same platforms excluding the bottom of Gilda and all of Gina (Figure 1.1a). In 1998, we made one submersible survey around Platform Edith, located off Long Beach (Figure 1.1c) and in 2000 we made partial submersible surveys around platforms C, B, A, Hillhouse, Henry, Houchin, Hogan, and Habitat (Figure 1.1a). Poor

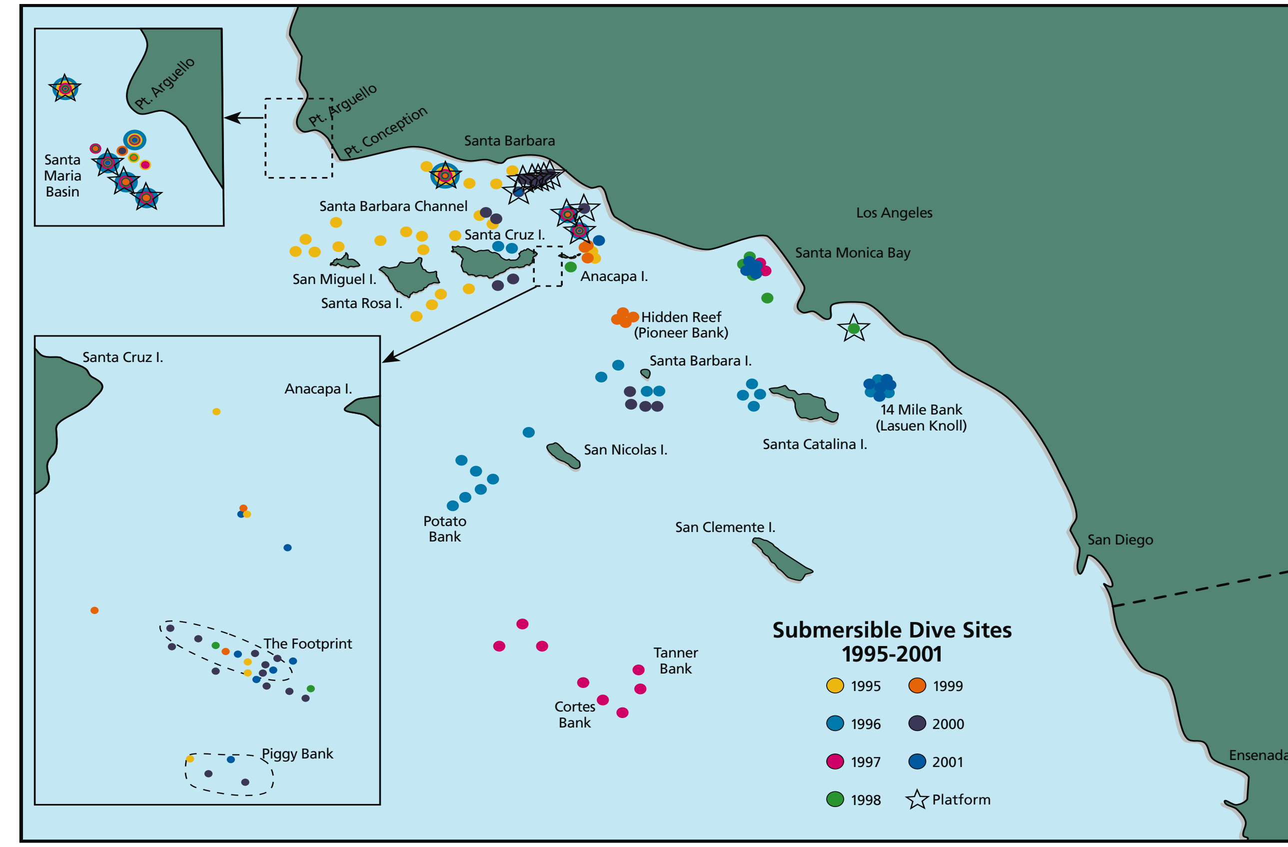

Figure 1.5. Platform and natural outcrops surveyed by Delta submersible, 1995–2001. Concentric rings denote sites surveyed in more than one year. Stars indicate platforms. See Figure 1.1 for names of platforms.

water visibility prevented us from completing the surveys around the latter eight structures. Appendix 1 lists all of the platforms and includes their dimensions, depths, locations, and the years these structures were surveyed.

Nine nearshore, shallow-water rock outcrops, seven on the mainland and two at Anacapa Island were surveyed from 1995 to 2000 by scuba (Figure 1.1b). These surveyed natural outcrops are distributed across the Santa Barbara Channel region and are exposed to water masses similar to that of the surveyed oil platforms. In addition, we surveyed over 80 deeper-water outcrops, in waters between 30 and 360 m (100 and 1,180 ft.) deep (Figure 1.5). Most of these deeper-water sites were visited once, a few were surveyed during as many as four years and one outcrop, North Reef near Platform Hidalgo, was sampled annually.

Shallow Portions of Platforms and Nearshore Natural Outcrops

Scuba surveys estimated density (individuals per hectare), mean size (total length), and species composition of reef fishes in shallow portions of platforms (0–36 m, 0–119 ft. depth) and natural outcrops (6–20 m, 20–66 ft.) (Figure 1.6). Typically, we performed three surveys from July to November of each year during 1995 to 2000, although some platforms were sampled less frequently. Fish enumeration methods consisted of fish counts and fish size estimates using both visual and underwater videography methods. Visual surveys recorded fish density and size (total lengths) using underwater plastic sheets and slates. All divers performing visual counts had received training in size estimation. Additional size estimates were obtained using a Hi-8 mm video camera and laser calibration system. The visual estimates of size and relative abundance were used first in data analyses and video size data were occasionally used to supplement visual estimates.

In each platform survey, scuba divers recorded observations while swimming a pattern which incorporated all four corner legs and the major horizontal crossbeams and portions underneath the platform jacket at three different depths (Level 1 range 6–10 m, 20–33 ft.; Level 2 range 12–21m, 40–70 ft.; Level 3 range 25–36 m, 83–119 ft.) (Figure 1.7). Natural reef surveys consisted of diver observations

Figure 1.6. A scuba diver surveys fishes around Platform Gina.

collected along four haphazardly placed 30 m length x 2 m width x 2 m (100 x 7 x 7 ft.) height belt transects, two transects each at approximately 7 m (23 ft.) and 14 m (46 ft.) bottom depths corresponding to the inshore and offshore portions of the reef. Each transect included sampling of three strata: surface, midwater, and bottom portions of the water column, one above the other. Habitat measures using a random point count method (2 points/m) were taken along the same transects for characterization of physical and biological attributes. Quantified habitat features included relief height (0 to 0.1 m, 0.1 to 1 m, 1 to 2 m, and > 2 m), substrate type (sand/mud, cobble, and rock), and percent cover of sessile invertebrates and fleshy algae. We also measured the percent cover of surface canopy of giant kelp, *Macrocystis pyrifera*, and stipe density of large kelps, especially *M. pyrifera*, *Pterygophora californica*, and *Eisenia arborea*, along the transects.

Deeper Portions of Platforms and Deeper Natural Outcrops

Below scuba depths, we surveyed fish assemblages using the *Delta* submersible, a 4.6 m, 2-person vessel, operated by Delta Oceanographics of Oxnard, California (Figure 1.8). Aboard the *Delta,* we conducted belt transects about two meters from the substrata, while the submarine maintained a speed of about 0.5 knots. At the platforms, transects were made around the bottom of the platform and around each set of cross beams to a minimum depth of 20–30 m (66–100 ft.) below the surface (e. g., midwater habitat). The belt transect was also used to sample the shell mounds and natural rock outcrops. The shell mounds and outcrops were sample in consistently the same fashion as the platform method described above.

Submersible surveys were conducted during daylight hours between one hour after sunrise and two hours before sunset. During each transect, observations were taken from one viewing port on the starboard side of the submersible. An externally mounted Hi-8 mm video camera with associated lights filmed the same viewing fields as seen by the observer. The observer identified, counted, and estimated the lengths of all fishes and verbally recorded those data on the video. All fishes within 2 m (7 ft.) of the submarine were counted. Densities were calculated as fish per 100 m^2. Fish lengths were estimated using a pair of parallel lasers mounted on either side of the external video camera. The projected reference points were 20 cm (8 in.) apart and were visible both to the observer and the video camera. An environmental monitoring system aboard the submarine continuously recorded date, time, depth, and altitude of the vessel above the seafloor. The environmental data was overlaid on the original videotape upon completion of each survey.

Transect videos were reviewed aboard the research vessel or in the laboratory. Field observations were transcribed into a database. For each fish, we recorded the following

information: (1) species (if known); (2) estimated total length; (3) the habitat it occupied (e.g., rock, sand, mud, cobble, boulder); (4) its position relative to the substrate (e. g., in crevice, on reef crest, on slope, above structure); and (5) the distance of the fish from that substrate.

Midwater Trawling and Oceanographic Surveys

Recruitment, the settlement to a benthic habitat of pelagic juveniles or larvae, is an important process influencing the fish assemblages found on platforms and natural outcrops. To better understand spatial and temporal patterns of recruitment and sources of recruitment variability, we conducted annual midwater trawling and oceanographic surveys in the vicinity of the Santa Barbara Channel and Santa Maria Basin. Our goal was to describe how regional patterns of circulation and distribution of hydrographic features (such as fronts and eddies) influenced the distribution and relative abundance of pelagic juvenile fishes. Our focus on this life stage would allow emphasis on settlement and delineation of nursery habitats, including both platforms and natural outcrops.

Annual midwater trawling and oceanographic surveys were conducted from 1995 through 2000. Sampling was conducted during June to coincide with the time when the most juveniles of the early spring spawning rockfishes would be present in the water column. A modified anchovy trawl with a codend of 9 mm mesh was used to collect samples at depths between 20 m and 55 m (66–182 ft.) below the surface (Figure 1.9). Towing speed was about 2 knots, and trawling time was 15 minutes at the targeted depth. All fishing was conducted at night to minimize net avoidance. Fishes were identified to species if possible and measured in the laboratory. The shipboard surveys included vertical profiling of water properties at all trawling stations so that we could associate patterns of fish abundance with local hydrographic conditions. Salinity, potential temperature, and potential density anomaly, and dynamic height were derived from the data collected using a conductivity-temperature-depth (CTD) profiler (SBE-19, SeaBird Electronics). The CTD was lowered to 200 m (660 ft.) or to about 10 m (33 ft.) above the bottom at shallower stations. Daily satellite imagery, hourly sea surface current maps, and underway sea surface temperature observations were used to direct sampling when it was based on the location of surface circulation features such as fronts and eddies. The specific objective of each survey differed from year to year, see Love et al. (1997, 1999, 2001), Nishimoto (2000), and Nishimoto and Washburn (2002) for details. Surveys were conducted throughout the Santa Barbara Channel, in adjacent waters outside of the channel, and around the Northern Channel Islands (Figure 1.10).

Chapter 2

A BRIEF HISTORY OF OIL DEVELOPMENT IN SOUTHERN CALIFORNIA

Milton S. Love

Oil and gas seeps, often the result of geological deformation of the oil-saturated strata, are a common global occurrence. The famous La Brea tarpits, found near downtown Los Angeles, is just one of many seeps found in California. Offshore, seeps are visible on the ocean surface as oil slicks or gas bubbles. As noted by California Resources Agency (1971), "Some [seeps] remain dormant for extended periods of time and then become reactivated, probably by pressure buildup or earth movement. Because of the transient nature of many seeps, an accurate count is difficult to obtain; however, it appears that there are probably 50 to 60 seeps and seep areas on the ocean floor between Point Conception in Santa Barbara County and Huntington Beach in Orange County."

Native Americans in many parts of California, but particularly along the southern California coast, mined those land seeps that contained hard, high-grade asphaltum. The soft tar derived from offshore seeps and diverted to beaches was rarely, if ever, used. California Native Americans used asphaltum in a variety of ways. Baskets and water bottles were made watertight, arrowpoints and hook barbs attached to shafts, broken stone vessels repaired, canoes caulked and sealed and shell decorations were inlaid on various objects. The Chumash of coastal southern California melted asphaltum and mixed it with pine resin to create an effective adhesive for many of these uses.

Early European explorers noted the presence of these seeps. "The Spanish explorer Fages, in 1775, said that 'At a distance of two leagues from this mission [San Luis Obispo] there are as many as eight springs of a bitumen or thick black resin…' Fr. Pedro Font, in 1776, while near Goleta in Santa Barbara County wrote '…much tar which the sea throws up is found on the shores, sticking to the stones and dry. Little balls of fresh tar are also found. Perhaps there are springs of it which flow out into the sea, because yesterday on the way the odor of it was perceptible, and today…the scent was as strong as that perceived in a ship or in a store of tarred ship tackle and rope" (Heizer 1943).

While European settlers in California also utilized asphalt from terrestrial seeps in limited ways, primarily for water proofing and lubrication, there was relatively little interest in oil seeps until about 1850, when it became more widely known that kerosene, an excellent substitute for whale oil in lamps, could be distilled from crude oil. While Dr. Abraham Gesner, a Canadian geologist, is officially credited with inventing this process in 1849, others may also have stumbled onto this idea. In California, the first person known to use partially refined oil for illumination was General Andreas Pico, the brother of Pio Pico, the last Mexican governor of California. In 1850, General Pico distilled kerosene from oil taken from hand dug pits in Pico Canyon (near Newhall, southern California) and used it for lighting a home. By 1854, miners had excavated into Sulphur Mountain in Ventura County (southern California), were hauling out the oil that seeped into their tunnels and had set up stills to produce kerosene. Throughout the 1850 and 1860s, various companies mined seeps for petroleum and produced kerosene or kerosene-like products.

In California, the first well (as opposed to hand-dug pit) that was designed to produce oil was a failure. It was drilled in Humboldt County in 1861 and it, along with others in the same county between 1861 and 1864, came up dry. However, the first productive well, drilled in 1865, came in from this county. This was quickly followed up by successful wells in Ventura and other localities. It was not until 1876 that the first truly commercial well was developed in Pico Canyon, the site of General Pico's first pit mine. The next 20 years saw production rapidly escalate, with new fields explored and developed in a number of locations in central and southern California.

The first oil production from submarine strata in California occurred in Summerland, a sleepy village south of Santa Barbara formally founded in 1889 as a spiritualist colony. For years, Summerland residents had noted both the heavy scent of oil that frequently hung over the community and the numerous seeps that dotted their coastline. In fact, natural gas was so plentiful that when boys wanted to play baseball at night "…they would drive short pieces of pipe into the ground about four or five inches, and would light them, and there would be a gas flame at least a foot high from the top of the pipe. Fifteen or twenty of these pipes along the edge of the road gave plenty of light for them to play after dark. When they got called in to go to bed, each had a flat board, and they would whack the board down over the flame, and out it would go." (Lambert 1975).

In the late 1880s and early 1890s, several Summer-

land residents had struck oil while digging water wells and at least one would fill barrels from a bucket, haul them by buckboard to Santa Barbara, and sell the oil to laundries. Drilling for oil just back from the ocean commenced shortly after and by 1897 both the beaches and short stretch between ocean and coastal hills were blanketed with drilling rigs. In 1896, W. L. Watts of the California State Mining Bureau reported that "It is also evident that the oil yielding formations extend south into the ocean…At low tide, springs of oil and gas are uncovered on the seashore." (Rintoul 1990).

True to the prediction, the first pier holding a well was built in 1897. This was perhaps the world's first well brought in over water, a record also reportedly claimed for the Baki (formerly Baku) (Republic of Azerbaijan) oil fields in the Caspian Sea and by Pennsylvania for drilling into Lake Erie. Within a few years there were 11 piers (harboring over 200 wells), one of them stretching 1,230 feet offshore (Figure 2.1). The Summerland piers continued to produce oil until 1939, when the last well was destroyed by high tides and high surf.

In the 1920s, a series of discoveries along the Santa Barbara Channel, particularly at Rincon (northwest of Ventura) and Ellwood and Capitan (west of Santa Barbara) led to additional offshore drilling. While all of these discoveries were made on land, development quickly extended onto piers. However, rather than being built of wood, these piers were more heavily constructed of steel pilings and reinforced concrete caissons.

The year 1932 saw the erection of the first oil platform off California and perhaps in the world. In that Depression year, the Indian Petroleum Company was faced with a dilemma. Geological evidence implied that productive oil-bearing strata lay offshore of Rincon (just northwest of Ventura). However, the costs of building a pier out to that formation were prohibitive. The company solved the problem by building part of a pier, located about 1,200 feet beyond the end of the nearest pier. Constructed of steel in 38 feet of water, the aptly named "Steel Island" was eventually home to three wells (Figure 2.2). It lasted until 1 January 1940, when "…mountainous waves battered the platform. The structure went down. There was no loss of life, but equipment was destroyed and wells damaged. Rohl-Connolly Company, marine contractors, removed equipment, derrick and steel pilings from the ocean floor; cut off casing at the floor of the ocean; and placed 6-foot cement plugs in the tops of the water strings" (Rintoul 1990).

Later oil and gas discoveries that were of importance to offshore development included those at Huntington Beach, Wilmington and Seal Beach. However, it was not until 1954, that the next step in offshore production oc-

PHOTO COLLECTION/LOS ANGELES PUBLIC LIBRARY

Figure 2.2. Built off Rincon, southern California, in 1932, the "Steel Island" was one of the first oil platforms in the world.

curred with the creation of the first man-made drilling island, "Monterey", situated 1.5 miles offshore of Seal Beach in 42 feet of water. Construction on the island commenced in 1952, but a lawsuit by the city of Seal Beach prevented drilling until 1954. The circular island "…75 feet in diameter, had an outer rim formed of interlocking sheet-steel piling driven into the ocean floor to depths of 15 to 20 feet. The interior was filled with rock and sand barged in from Catalina Island" (Rintoul 1990). In succeeding years five other oil islands (Grissom, White, Freeman, Chaffee, and Esther) were built.

Oil islands were only practical in relatively shallow waters and when industry-led seismic surveys and bottom coring discovered potential fields in deeper offshore waters, the stage was set for the development of oil platforms. In June 1958, the California State Lands Commission held its first sale of tidelands leases, ending a freeze that had held up offshore drilling on new sites. The first platform constructed was Platform Hazel, located about two miles offshore of Summerland in 100 feet of water. As noted in Rintoul (1990) regarding Hazel's construction, "In that same month, Standard [Oil] towed an imposing tower a distance of 210 miles… to the Summerland tract. The tower was 75 feet square and 170 feet high. It was a major component of Platform Hazel and was to serve as the foundation on which the 110-foot square deck would be mounted…The tower was floated to the job site on the four big caissons that formed the bottom portion of the tower's legs, each 40 feet high and 27 feet in diameter. Each caisson was pressurized to prevent leakage and also ballasted with 90 tons of sand for stability…Once on bottom, the caissons were sunk 22 feet into the ocean floor by means of high pressure water and air jets that literally hosed away the bottom sands, allowing the caissons to rest on hard ground. The final anchoring was accomplished by filling the caissons with 6,000 tons of sand

and concrete…The cost of building and installing the platform was $4 million." In September 1958, Standard Oil began drilling from the newly constructed platform and within one month the first well, bottoming out at 7,531 feet began producing 865 barrels per day. This was followed two years later by the construction of nearby Platform Hilda.

In subsequent years, a number of platforms were installed in both state and (beginning in 1967 with Platform Hogan) federal waters in southern California. However, expansion of offshore oil drilling came to an abrupt halt in 1969, with the disastrous blowout and subsequent oil spill at Platform A (installed in 1968) in the Santa Barbara Channel. And while discussion of both opposition and support for oil development are beyond the scope of this report (see Beamish et al. 1998, Nevarez et al. 1998, and Paulsen et al. 1998 for more information), it is safe to say that the subsequent environmental concerns about the safety of offshore oil exploration, development, and production delayed further drilling for a number of years. It was not until the late 1970s that installation of new platforms resumed. No new platforms have been erected since 1989 (Nevarez et al. 1998).

How do platforms get their names?

On the Pacific Coast, platform names have to conform to a set of rules promulgated by the U. S. Coast Guard. The Coast Guard created a series of zones ("15-minute quadrangles") along the Pacific Coast beginning at the U. S. – Mexican border. The names of all platforms in a zone must begin with the same letter. Platforms in the first zone, off San Diego, would begin with "A". The southern-most platforms (Emmy, Edith etc.) lie off Long Beach, in the "E" zone.

Industry personnel imply that the choice of names have often been made in a disarmingly casual way. For instance, the project engineer for Hermosa apparently named that structure after the elementary school attended by his daughter. Ellen and Elly are said to honor the wives of the engineers in charge of those platforms' construction. Hondo, meaning "big" in Spanish, was so christened because at the time it was the tallest (measured from the seafloor) of the California platforms. One story has it that, because a nearby platform was later installed to tap the same reservoir as Hondo, it was named Harmony. Hogan and Houchin were the surnames of two presidents of Phillips Petroleum.

Why do Platforms A, B and C, despite their locations in the H zone, not have "H" names? These were installed in the days before the Coast Guard regulations were mandatory.

CHAPTER 3

A REVIEW OF BIOLOGICAL AND OCEANOGRAPHIC SURVEYS: RESULTS AND ANALYSES

Milton S. Love, Donna M. Schroeder, and Mary M. Nishimoto

There was no single characteristic fish assemblage that could be described for the oil platforms and natural outcrops of central and southern California. However, we identified a number of patterns in fish diversity and abundance that corresponded to bottom depth, geographic area, and year. Depth played an important role because, in general, rockfishes numerically dominated fish assemblages around platforms and deep natural reefs, and rockfish species segregate themselves according to habitat depth. We also observed biogeographic partitioning in species composition, where northerly platforms show the influence of the Oregonian province and southerly platforms show the influence of the San Diegan province. These zoogeographic patterns were more conspicuous in shallow water fish assemblages. The large inter-annual fluctuations in juvenile fish recruitment observed during the studies may have been generated by the large inter-annual variability in oceanographic conditions (e.g., upwelling, El Niño-Southern Oscillation events). Since juveniles of many species inhabited shallow and midwater portions of oil platforms, the greatest temporal variability in fish abundance occurred at these depths.

We present more detailed summaries of fish assemblages identified by the two different survey methods (scuba and submersible) in the sections below. The common and scientific names of fishes observed in these studies are listed in Table 1.

1. Shallow Water Fish Assemblages: 0–36 m (119 ft.)

Findings at a Glance

A combination of regional and local processes influenced patterns of reef fish assemblages in shallow water. At regional scales, composition and relative abundance of reef fishes often shifted abruptly as oceanography changed. This shift delineated a cool-temperate assemblage in the western Santa Barbara Channel, and a warm-temperate assemblage in the eastern Santa Barbara Channel. This distinct spatial pattern was reflected in both platform and natural reef habitats. There was greater variability in platform species assemblages and population dynamics compared to natural outcrop assemblages and dynamics, and this was most likely caused by the offshore position and greater sensitivity of platform habitats to changing oceanographic conditions. Local processes which affected fish distribution and abundance were related to habitat features, where depth, relief height, and presence of giant kelp all played important roles. We found that the majority of juvenile rockfish recruits resided at depths greater than 26 m (86 ft.), although there were differences among species.

Except where noted, the following synopsis encompasses platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Grace, Gilda, Gail, and Gina and are based on diver surveys conducted between 1995 and 2000.

1a. General Patterns

The two primary research objectives were to (1) describe the spatial and temporal variability of shallow water (less than 36 m, 119 ft.) fish assemblages residing on oil/gas production platforms and natural outcrops, and (2) describe the relative importance of regional processes (e.g., oceanographic patterns) compared to local processes (e.g., habitat features) in generating observed patterns of reef fish assemblages. An understanding of mechanisms which structure marine populations is necessary to predict the outcome of resource management decisions related to marine fisheries, platform decommissioning, and marine protected areas on fish assemblages within the Santa Barbara Channel region (including the Santa Maria Basin). A list of species observed at each platform is given in Appendix 2.

We find that a combination of regional and local processes influenced patterns of reef fish assemblages in shallow water. At regional scales, composition and relative abundance of reef fishes often shifted abruptly as oceanography changed. This shift delineated a cool-temperate assemblage in the western Santa Barbara Channel, and a warm-temperate assemblage in the eastern Santa Barbara Channel. Rockfishes and surfperches dominated the cool-temperate assemblage, and damselfishes, wrasses, and sea chubs dominated the warm-temperate assemblage. This distinct spatial pattern was reflected in both platform and natural outcrop habitats.

Within each of the cool- and warm-temperate assemblages, local habitat features modified patterns of species abundance and distribution. For example, kelp surfperch and giant kelpfish were only observed on rocky outcrops that possessed stands of giant kelp, *Macrocystis pyrifera*. Other factors likely to have been important were outcrop or platform depth and relief height. These local scale features sufficiently decoupled sites within an oceanographic region (cool- or warm-temperate) to make broad generalizations about fish assemblages difficult, especially within platform habitats.

Temporal dynamics of reef fish assemblages also resulted from a complex, dynamic interaction between regional oceanography and local habitat features. The diverse array of oceanographic conditions that occurred during the six-year survey period appeared to strongly influence regional dynamics of fish assemblages. The 1997–1998 El Niño event corresponded to a large increase in juvenile recruitment of species which dominated the warm-temperate fish assemblage (e.g., blacksmith), while the 1999 La Niña event corresponded to a large increase of juvenile recruitment of species which dominated the cool-temperate fish assemblage (e.g., rockfishes). Severe winter storms that accompany El Niño events propagated into small-scale variability at some sites. For example, the scouring effect of severe storm waves depleted red algal turf (a forage base for small crustaceans and fish) on two shallow natural outcrops. This forage base reduction may have been the primary cause of the observed synchronous decline in surfperch abundance at the same outcrops.

1b. Shallow Water Fish Assemblages Surrounding Oil/Gas Production Platforms

As observed on natural outcrops (see Section 1d), shallow water fish assemblages surrounding oil/gas production platforms show distinct spatial patterns which correspond to oceanographic patterns in the Santa Barbara Channel. Rockfishes are numerically dominant in west channel platform fish communities, although 1999 was a strong recruitment year for juvenile rockfish at all platforms. Blacksmith and halfmoon are numerically dominant in east channel platform assemblages. Platform fish assemblages appeared to respond faster and more dramatically to changing oceanographic conditions than natural reef assemblages, perhaps due to their offshore position and higher proportion of juvenile fishes.

There were notable differences among platforms within an oceanographic region. These differences may be due to water depth in which the platform is positioned, where deeper water can inhibit species such as surfperches from migrating onto platform habitat. Among-platform differences may also be influenced by food availability or other factors. During the 1997–1998 El Niño event, juvenile blacksmith recruited onto all platforms, but did not recruit onto Tarantula Reef, the closest natural reef to west channel platforms surveyed in this study. This observation suggests that platforms may "capture" pelagic stages of some reef fish species that might have otherwise perished.

The fish assemblage observed at Platform Gina (depth 29 m, 95 ft.) is noteworthy because of its very high density of kelp bass and because of the large diversity of rockfishes that recruit to its shell mound habitat. Anecdotal observations at a nearby shipwreck did not record either of these characteristics in its local fish assemblage. High turnover of fish species diversity has also been noted at Platform Gina (Love, Nishimoto, Schroeder, and Caselle 1999).

JAMES FORTE

Kelp bass at a nearshore platform.

1c. Depth Distribution of Juvenile Fish Recruitment on Oil Platforms

For all fishes observed at all Southern California Bight platforms surveyed at shallow depths, approximately 27% were observed in the shallowest portions of platform habitat (6–12 m, 20–40 ft.). Most of these were pelagic fishes, such as anchovy and barracuda. Twenty-seven percent of all fishes were observed at intermediate depths (15–26 m, 50–86 ft.), and 46% were observed at deeper depths (27–36 m, 89–119 ft.). We observed that the majority of juvenile rockfish recruits resided at depths greater than 26 m (96 ft.) (Figure 3.1), although there were differences among species. The olive-yellowtail group and copper-complex species group (black-and-yellow, copper, gopher, and kelp rockfishes) had the largest percentages residing at shallower depths. Our observations on copper-complex rockfishes represent a somewhat different vertical distribution than that described by Holbrook et al. (2000). This disparity may be due to differences in surveyed platforms and program duration (6 platforms within one biogeographic area during 1995–7 versus 9 platforms in 3 biogeographic areas during 1995–2000). This difference underscores the importance of evaluating platforms on a case-by-case basis and in developing monitoring programs over multiple years.

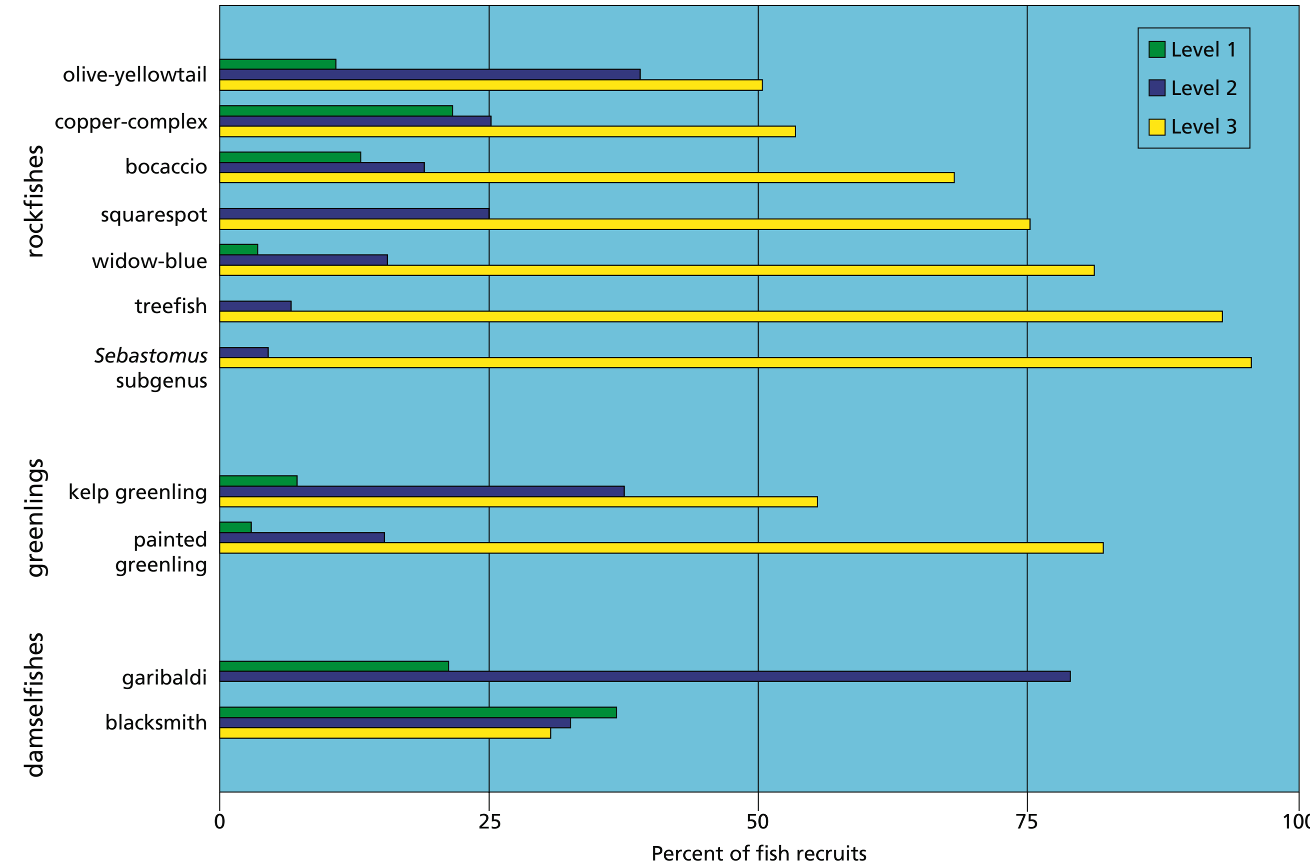

Figure 3.1. Percent of juvenile fish density observed during scuba surveys at different depths on offshore platforms during 1995–2000. Depth ranges for each strata: level 1 (6–12 m), level 2 (15–26 m), level 3 (27–36 m).

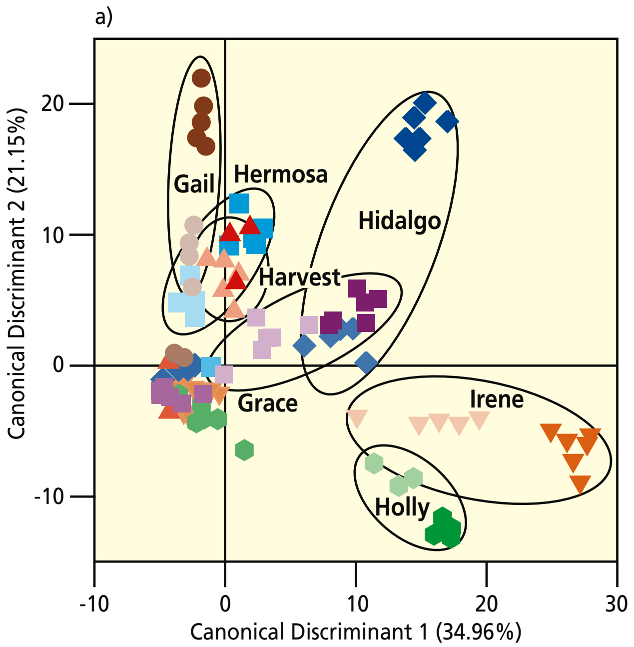
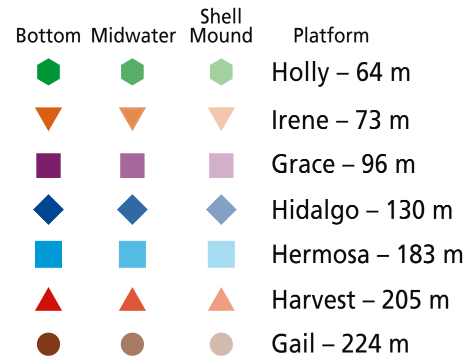
Our results correspond with Holbrook et al. (2000) regarding vertical distribution of midwater juvenile rockfishes (e.g., bocaccio, blue, and widow) where the vast majority of individuals recruited to depths greater than 26 m (86 ft.). The majority of individuals of other rockfish species such as squarespot, treefish, and the *Sebastomus* subgenus (e.g., rosy, greenspotted, starry rockfishes, and others) are also found below 26 m (86 ft.). Kelp and painted greenling recruits, two species associated with the cool-temperate fish fauna, mimic the vertical distribution of rockfish recruits, preferring deeper portions. In contrast, garibaldi and blacksmith recruits, two species associated with the warm-temperate fish fauna, favor upper portions of platforms, suggesting temperature may play a role in determining depth distribution of juvenile fishes at platforms.

1d. Fish Assemblages on Nearshore Natural Outcrops

The relative importance of spatial versus temporal variability in structuring fish assemblages on shallow natural outcrops differed among sites. Ordination analysis revealed that natural outcrops in the west channel tended to be more sensitive to temporal variability than those outcrops positioned in the east channel. This seems intuitive since west channel outcrops are closer to areas of intense and temporally variable upwelling processes which affect mean water temperature, primary production, and dispersal processes of larvae.





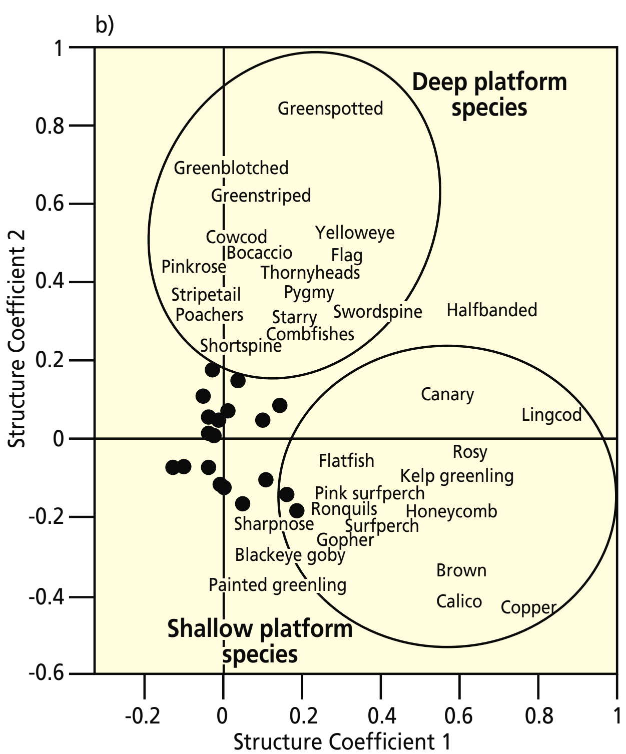


Figure 3.2. 3.2a. Canonical Discriminant Analysis of the bottom and shell mound fish assemblages at seven platforms, 1996–2001. 3.2b. Canonical Discriminant Analysis of the bottom and shell mound species found around seven platforms, 1996–2001. Two groups, one characteristic of shallow platforms, the other of deeper structures are apparent. Black dots represent species that were not strongly associated with either axis.

Similar to platform habitats, the fish assemblages on natural outcrops showed distinct spatial patterns that seemed to correspond to regional oceanographic patterns in the Santa Barbara Channel. Rockfishes and surfperches were important species in west channel fish communities, although 1999 was a strong recruitment year for juvenile rockfishes at most natural outcrops. Blacksmith, garibaldi, sheephead, opaleye, and rock wrasse were important species in east channel fish communities. Kelp bass, black surfperch, and senorita were abundant at all sites. Because we observed abrupt spatial changes in abundance for many species in the Santa Barbara Channel, it is tempting to attribute these patterns solely to oceanographic processes. However, habitat features may covary with oceanography, and we are currently unable to distinguish between these processes.

Dispersal of pelagic stages does not appear to be the primary factor in structuring fish assemblages. For the eight common species in the warm-temperate assemblage that have pelagic larvae, six species exhibited very low or no juvenile recruitment onto shallow rocky outcrops in the Santa Barbara Channel. This suggests that dispersal of benthic stages plays a critical role in the dynamics of reef fish communities and local temperature may be an important criterion in habitat selection. Some species important in the warm-temperate fish assemblage (e.g., kelp bass and opaleye) declined in abundance during the cold La Niña year of 1999. The response of reef fish communities to oceanographic regime shifts may be faster and less persistent than previously thought.

2. Deeper-water Platform Fish Assemblages: 31–224 m (103–739 ft.)

Except where noted, the following synopsis encompasses platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Grace, and Gail, based on surveys conducted between 1995 and 2001 from the research submersible *Delta*.

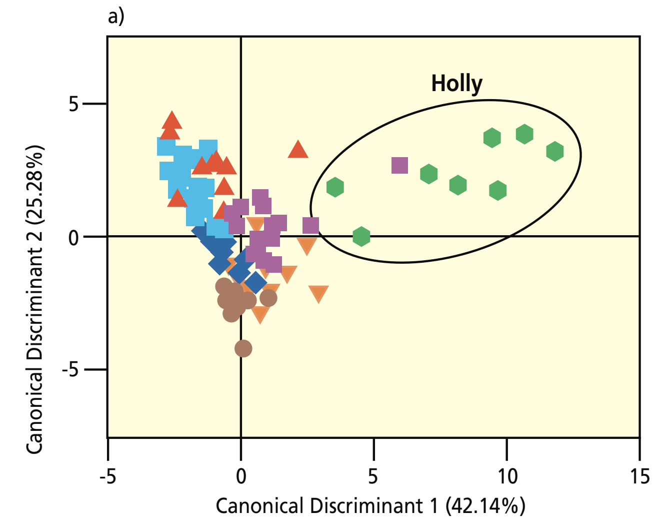
2a. General Patterns

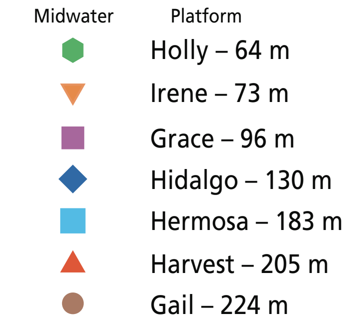
All of the platforms studied by submersible had three distinct fish assemblages, midwater, bottom, and shell mound (Figure 3.2a). Rockfishes, totaling about 35 species, dominated all three fish assemblages. Fish densities at most platforms tended to be highest in the midwater reflecting the depth preferences of young-of-the-year rockfishes that represented the most abundant size class of fishes.

Midwater assemblages were more similar to each other regardless of platform location and bottom depth. The assemblage at Platform Holly had the only distinct midwater assemblage (Figure 3.3a). A suite of species (e.g., calico, copper, and gopher rockfishes, pile, and sharpnose seaperches) characterized this particular assemblage (Figure 3.3b). Holly has the shallowest bottom depth (standing in 64 m, 211 ft.), and it might be that these shallow demersal species were able to occupy these shallow midwater crossbeams. The midwater fish assemblages around the other platforms showed no systematic depth or geographic relationships.

The composition of platform bottom and shell mound fish assemblages was dependent on the bottom depth of the platform (Figure 3.2a) and certain species are characteristic of either shallow or deep benthic habitats (Figure 3.2b). Platforms Holly and Irene (64 m and 73 m; 211 and 241 ft., respectively) were dominated by brown, calico, copper, and vermilion rockfishes and lingcod. In deeper waters, Platforms Hermosa, Harvest, and Gail (183 m, 205 m, and 224 m; 604, 677, and 739 ft., respectively) were dominated by greenblotched, greenspotted, and greenstriped rockfishes. Platform Hidalgo, and to a certain extent Platform Grace, both at intermediate depths (130 m and 96 m, 429 and 317 ft., respectively), were inhabited by species common to both the shallower and deeper platforms. In general, our data suggests that shell mound fish assemblages most closely resemble the fish assemblages of their adjacent platform bottoms (Figure 3.2a). Fishes living on the shell mounds are generally smaller, and presumably younger, than the same species living around the platform bottom.

RESULTS AND ANALYSES





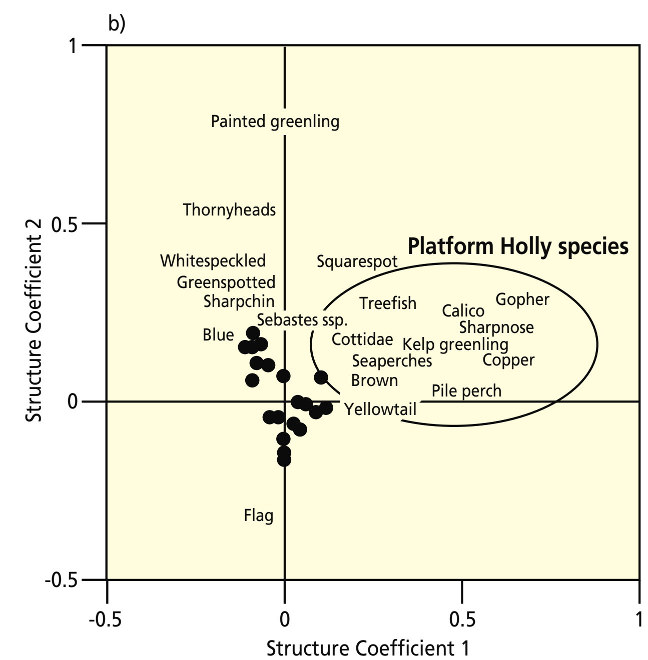


Figure 3.3. 3.3a. Canonical Discriminant Analysis of midwater fish assemblages at seven platforms, 1996–2001. Note that the Platform Holly fish assemblage is distinct from the others. 3.3b. Canonical Discriminant Analysis of the midwater species found around seven platforms, 1996–2001. Note that a group of species tends to be more characteristic of Platform Holly than other platforms. Dots represent species that were not strongly associated with either axis.

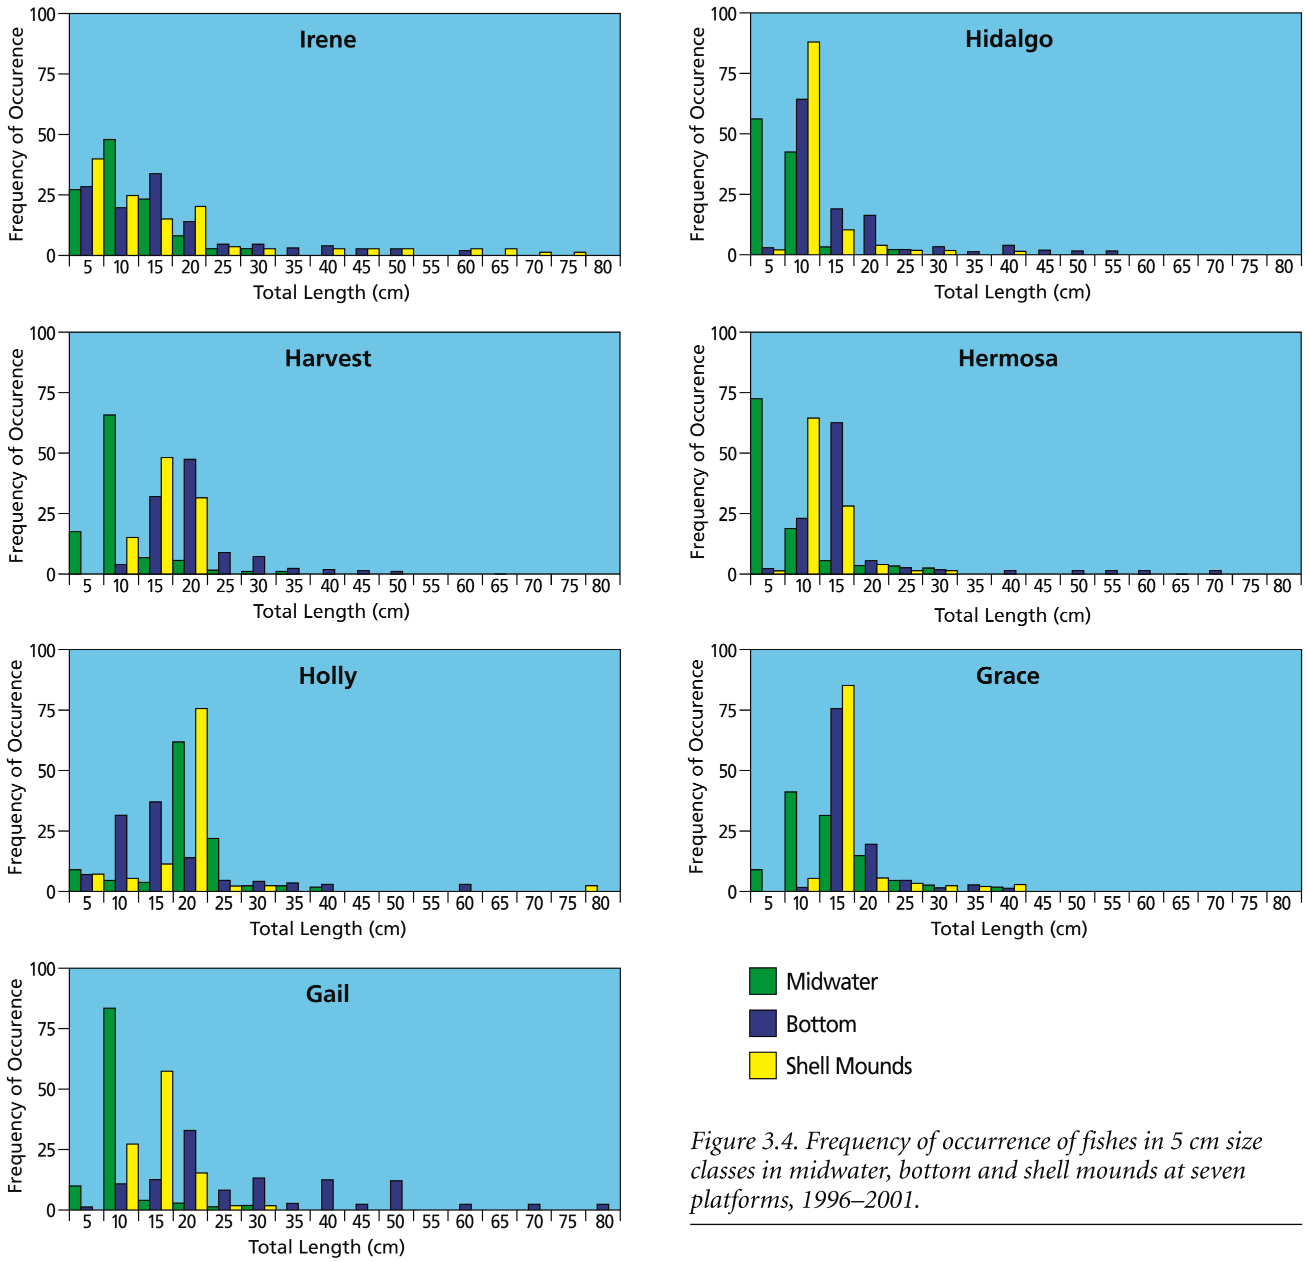

Figure 3.4. Frequency of occurrence of fishes in 5 cm size classes in midwater, bottom and shell mounds at seven platforms, 1996–2001.

The size distribution of fishes differed by habitat type. The midwater assemblages harbored few fishes over 20 cm (8 in.) long (Figure 3.4). Immature, mostly young-of-the-year rockfishes and young painted greenling dominated midwater depths. In addition, seaperches, blacksmith, and several less abundant species inhabited this zone. In contrast, older and larger rockfishes, lingcod, and several other benthic species, occupied the platform bottom habitat. Rockfishes also dominated the shell mounds. The size frequency of shell mound fishes tended to be intermediate between the two other habitats (Figure 3.4). This apparent partitioning of different size modes was most evident in the deepest platforms. Around shallow platforms, there was significant settlement of young-of-the-year rockfishes both in the midwater and at the bottom. This common feature blurred the distinctions between these two habitats.

Young-of-the-year rockfishes showed strong depth preferences around platforms (Figure 3.5). Young-of-the-year were often very abundant in the shallowest portions (above 30 m, 100 ft., depths) of the platform but were also abundant between 31 and 120 m depths (102–396 ft.). They were most abundant at depths between 61 and 90 m (201–297 ft.).

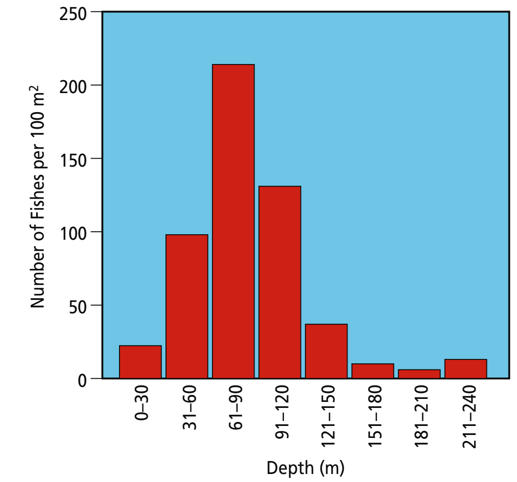

Figure 3.5. Density of young-of-the-year rockfishes observed from the Delta *submersible, by depth, at all platforms surveyed, 1995–2001. Note that large numbers of these fishes were also observed by scuba divers in the shallower sections of the platforms.*

Among platforms, total fish densities typically fell within a relatively small range (Figure 3.6). In general, platforms furthest offshore and in deepest waters had somewhat lower fish densities than did those closer to shore in shallower waters. However, the absolute number of fishes around deeper water platforms may be greater than those in shallower waters, as deeper platforms are much larger than shallower water structures.

2b. Midwater Assemblages

Findings at a Glance

Platform midwaters are nursery grounds for rockfishes as well as for other marine fish species such as cabezon and painted greenling. The young-of-the-year of at least 15 rockfish species inhabit these midwater habitats.

Benthic settlement success is greatly influenced by oceanographic conditions. During our study, densities of young fishes varied greatly between years and platforms. Young-of-the-year rockfish densities often varied

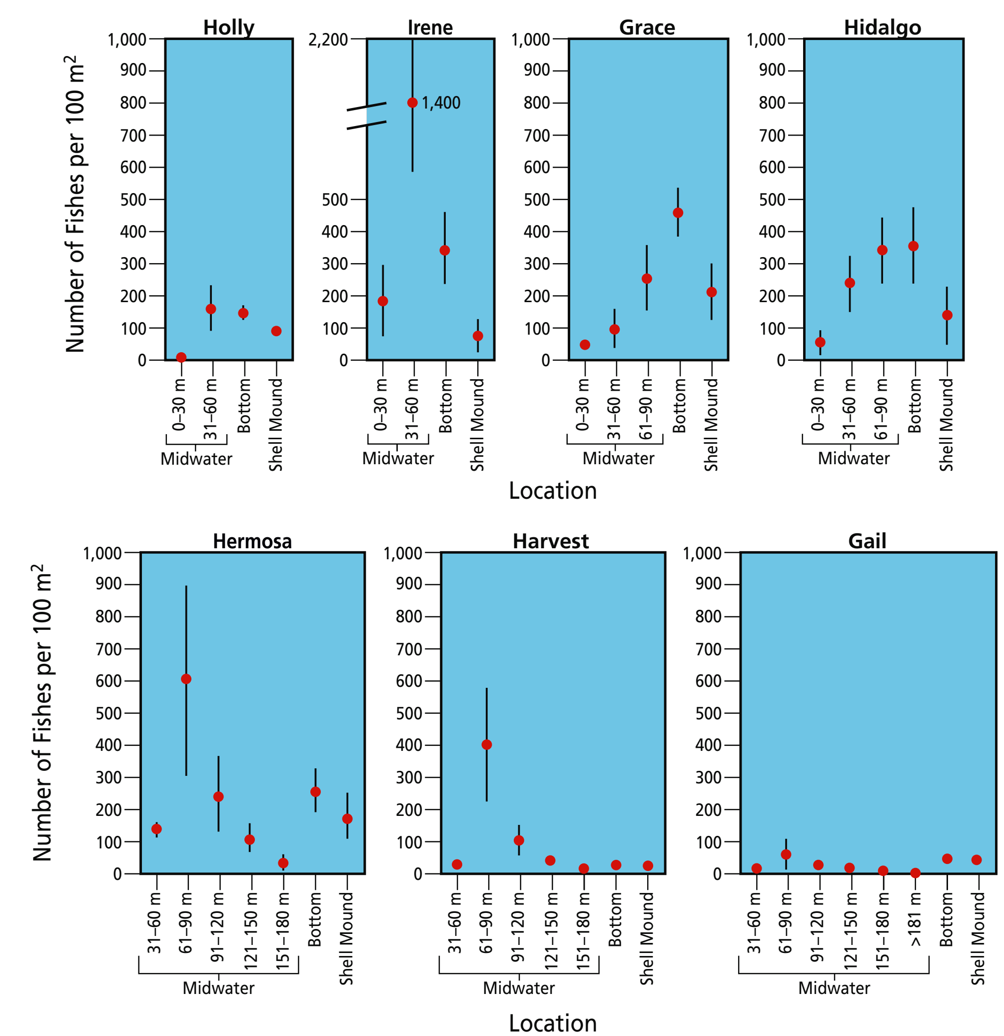

Figure 3.6. Density, with standard error bars, of all fishes in midwater (by 30 m depth zones), bottom and shell mounds, at seven platforms, 1996–2001.

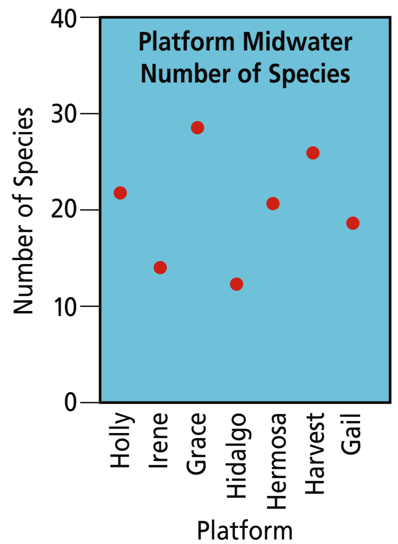

Figure 3.7. Number of species observed in the midwaters of seven platforms, 1996–2001. Platforms are listed from left to right, from shallowest to deepest.

by a factor of 10 or even 100 among survey years at some platforms. From 1996 through 1998, rockfish settlement was generally higher around the platforms north of Point Conception compared to those structures in the Santa Barbara Channel, reflective of generally colder, more productive waters in central California. Colder waters in 1999 were associated with relatively high densities of young-of-the-year rockfish recruitment at all of the platforms surveyed. In 2000 and 2001, rockfish recruitment at platforms in the Santa Barbara Channel remained higher than pre-1999 levels. We hypothesize that this was related to the oceanographic regime shift to cooler temperatures that may be occurring in southern California.

Depending on platform location, we observed between 13 and 29 fish species in the midwater habitats below 31 m (102 ft.) depths (Appendix 3). There was no relationship between platform bottom depth and either the number of species or species diversity in the midwater habitat (Figures 3.7 and 3.8). Relatively abundant non-rockfish species included blacksmith, sharpnose seaperch, and juvenile painted greenling. Occasionally, we observed influxes of migratory species such as Pacific sardine, jack mackerel, and Pacific mackerel. However, because our surveys are snapshots in time, they do not adequately capture the importance of platform habitats to these and other pelagic species. The most abundant fishes were young-of-the-year and older juvenile rockfishes and blacksmith. These are planktivorous and thus are not dependent on

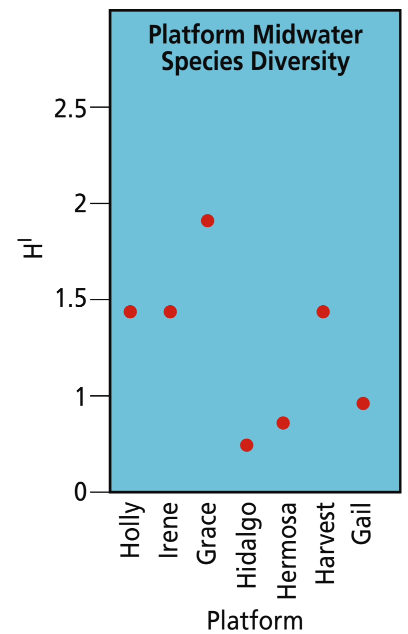

Figure 3.8. Species diversity of fishes in the midwaters of seven platforms, 1996–2001. Platforms are listed from left to right, from shallowest to deepest.

the platform for food. They utilize these structures for orientation in the water column and as refuge from predation. Less common species, such as seaperches, painted greenling, opaleye, and cabezon do feed on animals or algae living on the platform jacket or conductors.

Our research shows that oil and gas platforms off California provide important nursery grounds for many species of rockfishes. The most conspicuous faunal characteristic of the platform midwaters below scuba depth is the dominance of young rockfishes. Over the course of the study, young-of-the-year and older juvenile rockfishes almost always comprised more than 90% of all fishes observed in this habitat (Appendix 3). In some years, young-of-the-year rockfishes were virtually the only fishes present at some platform midwaters (Appendix 3).

The young-of-the-year of at least 16 rockfish species (bank, blue, copper, darkblotched, flag, gopher, kelp, olive, pygmy, shortbelly, squarespot, widow, yellowtail rockfishes, bocaccio, cowcod, and one or more members of the subgenus *Sebastomus*) recruited to the midwater habitat. Many of the species that were most abundant (e.g., blue, olive, pygmy, squarespot, widow, and yellowtail rockfishes and bocaccio) are those that are epibenthic or semipelagic as adults. Of these diverse young rockfishes, widow rockfishes were consistently the most abundant species at platforms. Among adult rockfishes, kelp and whitespeckled rockfishes were commonly observed.

MARY NISHIMOTO

Juvenile bocaccio and widow rockfish, midwaters of Platform Grace.

Young-of-the-year and 1-yr old rockfishes of many species (e.g., bank, blue, olive, pygmy, shortbelly, squarespot, widow, and yellowtail rockfishes, and bocaccio) often formed highly mobile schools in the midwater habitat. During years of high abundance, these schools contained many thousands of individuals. Our experience suggests that these schools remained either inside the platform or ventured only a few meters outside it. Schools of young rockfishes tended to more closely associate with the jacket substrate during years of low recruitment or when water visibility was poor. However, when their numbers were high or water clarity was good, young rockfishes, while still living within the platform structure, only loosely associated with the crossbeams and vertical structure. In general, the schools occurred throughout 50 to 100 m or more (150–300 ft.) of the water column. Young copper, gopher, kelp, and flag rockfishes, treefish, and cowcod, as well as cabezon and painted greenling were generally observed either as solitary individuals or in small groups, usually intimately associated with the platform jacket.

RICK STARR

Young-of-the-year yellowtail rockfish, midwaters of Platform Irene.

Young-of-the-year rockfish settlement (recruitment) to midwater habitats is also strongly influenced by oceanographic conditions. The density of these fishes varied greatly inter-annually by location and among platforms (Figure 3.9). Spatial and temporal differences in young-of-the-year rockfish densities often varied by a factor of 10 or even 100. In several instances, a species that was entirely absent from a platform midwater in one year would recruit in great numbers in the following year. Between 1996 and 1998, young-of-the-year rockfish recruitment was generally higher around the platforms north of Point Conception in the Santa Maria Basin (Irene, Hidalgo, Harvest, and Hermosa) than at the structures in the Santa Barbara Channel (Holly, Grace, and Gail) (Figure 3.9). In contrast, these three years were a period of low rockfish recruitment for many species south of Point Conception both at platforms (Holly, Grace, and Gail) and natural outcrops. The colder water conditions of 1999 brought with it widespread recruitment for a number of rockfish species in California compared to the previous decades. This was reflected at all of the platforms surveyed (Figure 3.9). We should note that the 2000 data at Platforms A, B, C, Hillhouse, Hogan, Houchin, and Henry (see sidebar) strongly suggest that recruitment for some rockfish species, particularly blue and widow rockfishes, had been very successful in 1999. In 2000 and 2001, recruitment of some rockfish at Platforms Gail and Grace remained higher than pre-1999 levels (Figure 3.9). We hypothesize that this represents a successful response to the oceanographic regime shift to cooler temperatures that may be occurring in southern California and the greater northeast Pacific.

The population dynamics of bocaccio exemplifies the annual and geographic variability that occurs in rockfish recruitment at both platforms (Figure 3.9) and natural

Figure 3.10. Patterns of young-of-the-year (YOY) bocaccio settlement in 1999, as observed from the Delta *submersible surveys.*

outcrops (Figure 3.10). Prior to 1999, young-of-the-year bocaccio were absent at the platforms we surveyed (except Irene in 1996 and 1997). During 1999, large densities of young-of-the-year bocaccio were observed at Platforms Irene and Grace; small numbers of at least a few individuals were observed at most other platforms. Platform Grace provided the most striking example of inter-annual variability. Almost no young-of-the-year bocaccio were observed at Platform Grace prior to 1999. In contrast, during 1999, the platform harbored the third highest densities (after 1996 and 1999 at Platform Irene) of young bocaccio we observed around either platforms or natural outcrops during the six years of research. It is important to realize that even in years of relatively high rockfish recruitment, the actual process of settlement may result in a patchy distribution of young-of-the-year benthic recruits. Such patchiness was observed in the bocaccio recruitment pattern in 1999 at Platforms Grace and Gail, which are located only 8 km (5 miles) apart. While Platform Grace harbored large numbers of young bocaccio, they were much less abundant at nearby Platform Gail. Furthermore, our research has shown that successful rockfish recruitment at platforms does not always translate to similar high densities of these species at nearby natural outcrops. Using the *Delta*, in 1999 we also surveyed 12 natural outcrops located in depths suitable for bocaccio recruitment and found little evidence of bocaccio recruitment over any of these structures (Figure 3.10).

In 2000, we studied the midwater habitats of Platforms C, B, A, Hillhouse, Henry, Houchin, Hogan, and Habitat. These platforms, located off Summerland east of Santa Barbara (Figure 1.1), were home to many typical midwater reef fishes, including juvenile blue, olive, and widow rockfishes (of the 1999 year class), blacksmith, kelp rockfish, kelp bass, painted greenling, halfmoon, and sharpnose seaperch. Unlike the species assemblage of the further offshore and the more northerly platforms, both garibaldi and California sheephead were common. In 1998, we surveyed Platform Edith and again found a typical mix of reef fishes, including blacksmith, halfmoon, opaleye, sheephead, and garibaldi. Complete species assemblages for all of these platforms are found in Appendix 3.

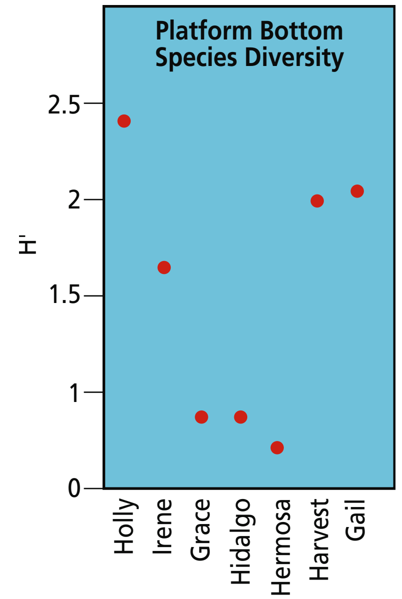

Figure 3.12. Diversity of fishes at the bottom of seven platforms, 1996–2001. Platforms are listed from left to right, from shallowest to deepest.

2c. Bottom Assemblages

Findings at a Glance

The bottom habitat of platforms is dominated by subadult and adult rockfishes. Young-of-the-year rockfishes were also abundant around some platform bottoms, occasionally in large numbers. In general, more than 90% of all the fishes found around platform bottoms were rockfishes. The numbers and estimated densities of all fishes in the bottom habitats are shown by platform in Appendix 3. Bottom depth strongly influenced the number of species, species diversity, and density of fishes living around platform bases. This is in direct contrast to the midwater habitat. The presence of young-of-the-year and older aged juveniles indicates that the bottom habitat of some platforms may be important nursery habitat for some species. The platform base appears to be important to many marine species, as it provides both refuge and prey.

Depth strongly influences fish assemblages in platform bottom habitat. Species richness varied widely from about 33 species at Platform Holly to 17 species at Platform Harvest. Generally, the shallower-water platforms harbored more species than platforms in deeper depths although this trend may have begun to reverse at Gail, the deepest platform (Figure 3.11). Species diversity was high at the shallowest and deepest platforms and lowest among the mid-depth structures (Figure 3.12). Conversely, overall fish densities were much higher at the mid-depth platforms than at the deepest platforms (Figure 3.13).

Diversity and abundance patterns were driven by the depth preferences of a suite of rockfishes that dominate the bottom habitats. For instance, brown, calico, copper, and vermilion rockfishes were most abundant around the shallower structures but were absent from the deepest platforms (Figure 3.13). Pile perch, painted greenling, and young-of-the-year lingcod displayed the same pattern. Juvenile lingcod were also abundant at the shallowest platforms, particularly at Platform Irene, but these were also occasional around even the deepest structures surveyed. Halfbanded rockfish and flag rockfish were typically found at the intermediate-depth platforms. Greenblotched, greenspotted, greenstriped, pinkrose, and stripetail rockfishes were most abundant around the deeper structures (Figure 3.13). The juveniles of many of these species were found in shallower water or on the shell mounds.

Platform structure in the bottom habitats may influence the distribution of fishes. This habitat encompasses that area where the platform jacket and conductors physically meet the seafloor. At all of the platforms surveyed, there is a crossbeam that rests on, or is close to, the bottom. Some portions of this crossbeam may be completely buried by sediment or undercut by currents. The platform jacket and, in particular, the undercut crossbeam, appears to provide many of the attributes of a natural outcrop, providing high relief and large crevices. Many species, such as canary, flag, vermilion, and widow rock-

fishes, bocaccio, pile perch, and painted greenling closely associate themselves with the platform jacket, particularly with the crossbeam. Similarly, larger copper, greenspotted, greenblotched, and pinkrose rockfishes and cowcod tend to shelter inside or immediately next to the platform. These fishes were particularly abundant where a space formed between the lowest crossbeam and the seafloor. Calico and greenstriped rockfishes and various life stages of lingcod were less closely associated with the structure. While most species rarely ascend more than a meter or two above the seafloor, bocaccio and halfbanded rockfish often rose as much as 5 m (17 ft.) above the bottom.

LINDA SNOOK

Mexican and greenspotted rockfishes, bottom of Platform Gail.

Most platform bottom species are either solitary or shelter in small groups. The exceptions are young-of-the-year rockfishes, juvenile and subadult brown, copper, halfbanded, and vermilion rockfishes, and bocaccio. On a number of occasions, we observed aggregations of tens and hundreds of brown, copper, and vermilion rockfishes and bocaccio and large schools of halfbanded rockfish comprised of thousands of individuals.

Compared to midwater habitats, the fish species compositions at platform bottoms were relatively stable over time (Figures 3.14a, b). The dominant species varied little between years at any platform. Thus a platform, such as Gail, that was dominated by adult greenspotted and greenblotched rockfishes, bocaccio, and cowcod in one year tended to be inhabited by these same species in all years in about the same abundances. Similar patterns were observed for such common species as painted greenling (Platforms Irene and Holly), greenspotted rockfish (Platforms Hidalgo and Hermosa), copper rockfish (Platforms Irene and Holly), and flag rockfish (Platform Hidalgo). It is likely that we were observing some of the same individuals each year. This constancy would be expected as these assemblages are at least partially composed of subadult and adult stages of relatively sedentary and long-lived rockfishes. Thus, the composition of the bottom assemblages is not determined by the year-to-year fluctuations in year-class success that is characteristic of the platform midwaters. However, the densities of a few important species, particularly halfbanded rockfish, varied annually. In some years halfbanded rockfish were essentially absent from a platform bottom, only to be extremely abundant the following year. Schools of this species are highly mobile and may have been present but not in the vicinity of the submersible when the survey was made.

Our observations indicate that the bottom habitat of some platforms may be particularly important for certain species. For example, young-of-the-year lingcod densities were much higher at Platform Irene and Hidalgo than at any natural outcrop during any year of the survey (Appendix 4).

Unlike most of the fishes living in the platform midwater, it is likely that the majority of the platform bottom-dwelling species feed on platform-associated prey. Many of these species, such as brown, copper, and flag rockfishes, eat a variety of crustaceans, molluscs, and small fishes, many of which live in and around the jacket, conductors, and shell mound. Other species, such as lingcod, cowcod, and bocaccio are opportunistic feeders, preying on a very wide range of organisms, including benthic and water column fishes, molluscs, and crustaceans (Love et al. 2002). Thus, for many benthic fishes, the platform base provides not only shelter but also an abundant source of food.

We conducted one survey, in 1998, around the base of Platform Edith. We found that California scorpionfish, sharpnose seaperch, blacksmith, and blackeye goby were the most abundant species. See Appendix 3 for a complete species list.

2d. Shell Mound Assemblages

Findings at a Glance

Shell mounds support a rich and diverse fish assemblage. As at other platform habitats, rockfishes comprise the vast majority of the fishes. The many small sheltering sites created by mussels, anemones, and other invertebrates on the shell mounds provided structure in a habitat dominated by small fishes. Many of these fishes are the young-of-the-year and older-aged juveniles of lingcod and copper, flag, greenblotched, and pinkrose rockfishes and cowcod. The adults of these species inhabit the platform bottom.

Depending on platform, we observed between 17 and 30 species living on this habitat. In the shell mound habitat, the patterns of species numbers, diversity, and fish densities were similar to those observed around the platform bottoms. Species numbers generally decreased with increasing depth (Figure 3.15) although it increased sharply at the Platform Gail, the deepest structure. This increase was due to the occurrence of a number of deeper water species (e. g., rex sole, blackgill rockfish, and California smoothtongue) that were absent from other platforms. As in the platform bottom habitat, species diversity was highest at the shallowest and deepest platforms compared to shell mounds in intermediate depths (Figure 3.16).

The shell mounds surrounding all platforms provided habitat and refuge for a diverse assemblage of fishes. Fish densities were highest on the intermediate-depth platform shell mounds (Figure 3.17). However, as in the platform midwater and bottom, a majority of these fishes are rockfishes; between 53% and 98% of all fishes living on the shell mounds are rockfishes (Appendix 3). Furthermore, when highly migratory and non-resident species, such as Pacific hake and Pacific sardine, are eliminated from the analysis, rockfishes comprise more than 80% of the shell mound fauna at each of the seven platforms surveyed. Those species most characteristic of the shell mounds exhibited distinct depth preferences (Figure 3.17) and the abundance of some of these fishes was responsible for the higher densities in the intermediate bottom depths. The dominant species of the shallow water shell mounds were vermilion, copper, and calico rockfishes, young-of-the-year and immature lingcod, and painted greenling. A few species, such as greenspotted and halfbanded rockfishes, were most common in the intermediate bottom depths. It was primarily the very high densities of halfbanded rockfish that were responsible for the overall high densities at intermediate-depth shell mounds. Greenstriped, pinkrose, and stripetail rockfishes

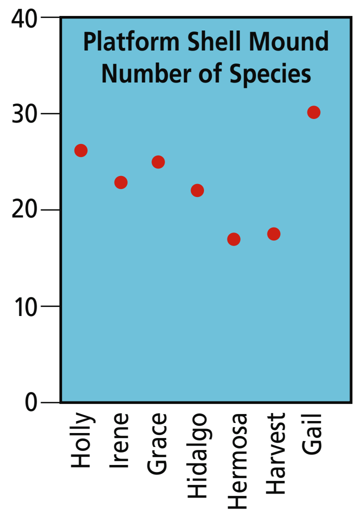

Figure 3.15. Number of fish species observed on the shell mounds of seven platforms, 1996–2001. Platforms listed left to right from shallowest to deepest.

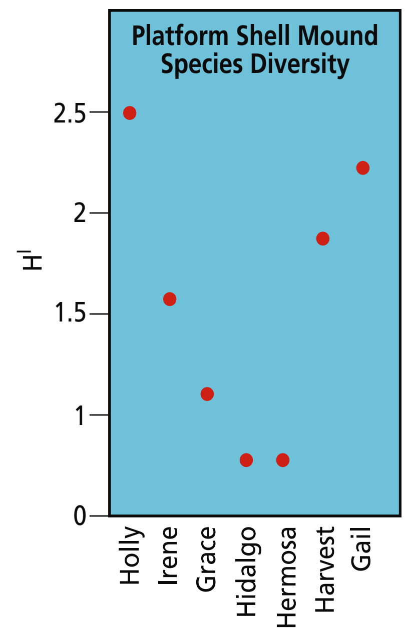

Figure 3.16. Diversity of all fishes observed on the shell mounds of seven platforms, 1996–2001. Platforms are listed left to right from shallowest to deepest.

were most abundant at the deepest platforms surveyed.

The mosaic of small refuge sites created by mussels, anemones, and other invertebrates are occupied by small fishes. Many of these fishes are the juveniles of such species as lingcod and copper, flag, greenblotched, and pinkrose rockfishes and cowcod, whose adults inhabit the adjacent platform bottom. Small sheltering sites are rarely found at the platform bottom. In part, this explains why fishes tend to be smaller on a shell mound than on the associated platform bottom (Table 2). This also explains why the shell mound assemblage so closely resembles its counterpart around the adjacent platform bottom. Painted greenling, calico, and halfbanded rockfishes, shortspine combfish, blackeye goby, and the poachers are among the dwarf species occupying the shell mound. Juveniles of the species characteristic of platform midwaters, such as blue and widow rockfishes, are rare over the shell mounds.

Most shell mound species are solitary fishes, living just above the seafloor or nestled among the shell debris or around anemones, seastars, and other large invertebrates. The only schooling species is the halfbanded rockfish that often forms highly mobile schools of 100 to 1,000 or more individuals.

It is likely that many of the fishes, including most of the rockfishes, combfishes, painted greenling, and other benthic species are resident to the shell mound habitat. Highly mobile and migratory species, such as northern anchovy, Pacific sardine, and juvenile Pacific hake, that were observed over the shell mounds probably spend only a relatively short period associated with this habitat.

Shell mound surveys were conducted around Platform Edith in 1998 and around Platform C in 2000. Young vermilion rockfish, as well as halfbanded and calico rockfish, were the most abundant species around Platform C. These species were also characteristic of the shell mound at Platform Holly, which lies in a similar depth. California scorpionfish and blackeye goby dominated the shell mound around platform Edith. Edith lies a few miles southeast of Long Beach and near a known California scorpionfish spawning grounds (Love et al. 1987). California scorpionfish are relatively uncommon in the Santa Barbara Channel and are rare north of Point Conception. This distribution explains the near absence of this species from other shell mounds we surveyed.

3. A Comparison of Fish Assemblages at a Deeper Platform and a Nearby Natural Outcrop: Hidalgo and North Reef

Findings at a Glance

The species composition at Platform Hidalgo and North Reef are quite similar as both structures are dominated by rockfishes. In general, the distinctions between the platform and reef assemblages were based on differences in species densities (rather than species presence or absence). Most species were more abundant at Platform Hidalgo than at North Reef. Halfbanded, greenspotted, flag, greenstriped, and canary rockfishes, all three life stages of lingcod (young-of-the-year, immature, adult), and painted greenling all had higher densities around the platform. Five species (i. e., pink seaperch, shortspine combfish, pygmy, squarespot, and yellowtail rockfishes) were more abundant at the reef. The dominance of small fishes at North Reef probably reflects fishing pressure that has cropped larger individuals. Young-of-the-year rockfishes were found at both Platform Hidalgo (primarily in the midwaters) and at North Reef. In each of five years, young-of-the-year rockfish density was higher at the platform than at the reef. In several years, densities of these young fishes were more than 100 times greater at Platform Hidalgo than at North Reef.

We surveyed the fish assemblages at Platform Hidalgo and a nearby natural outcrop, North Reef, for the period 1996–2001. North Reef was compared with Platform Hidalgo because it is close to the platform (about 1,000 m, 3,300 ft., north of the platform) (Figure 3.18), and its depth (112 m, 370 ft.) is comparable to the platform's 130 m (430 ft.). North Reef is a hard carbonate scarp, which is 1–4 m (3–13 ft.) high, 3,353 m^2 in area and contains numerous boulders, caves, and crevices.

The species composition at Platform Hidalgo and North Reef are very similar (Table 3). Both habitats are dominated by rockfishes; they comprised 98.3% and

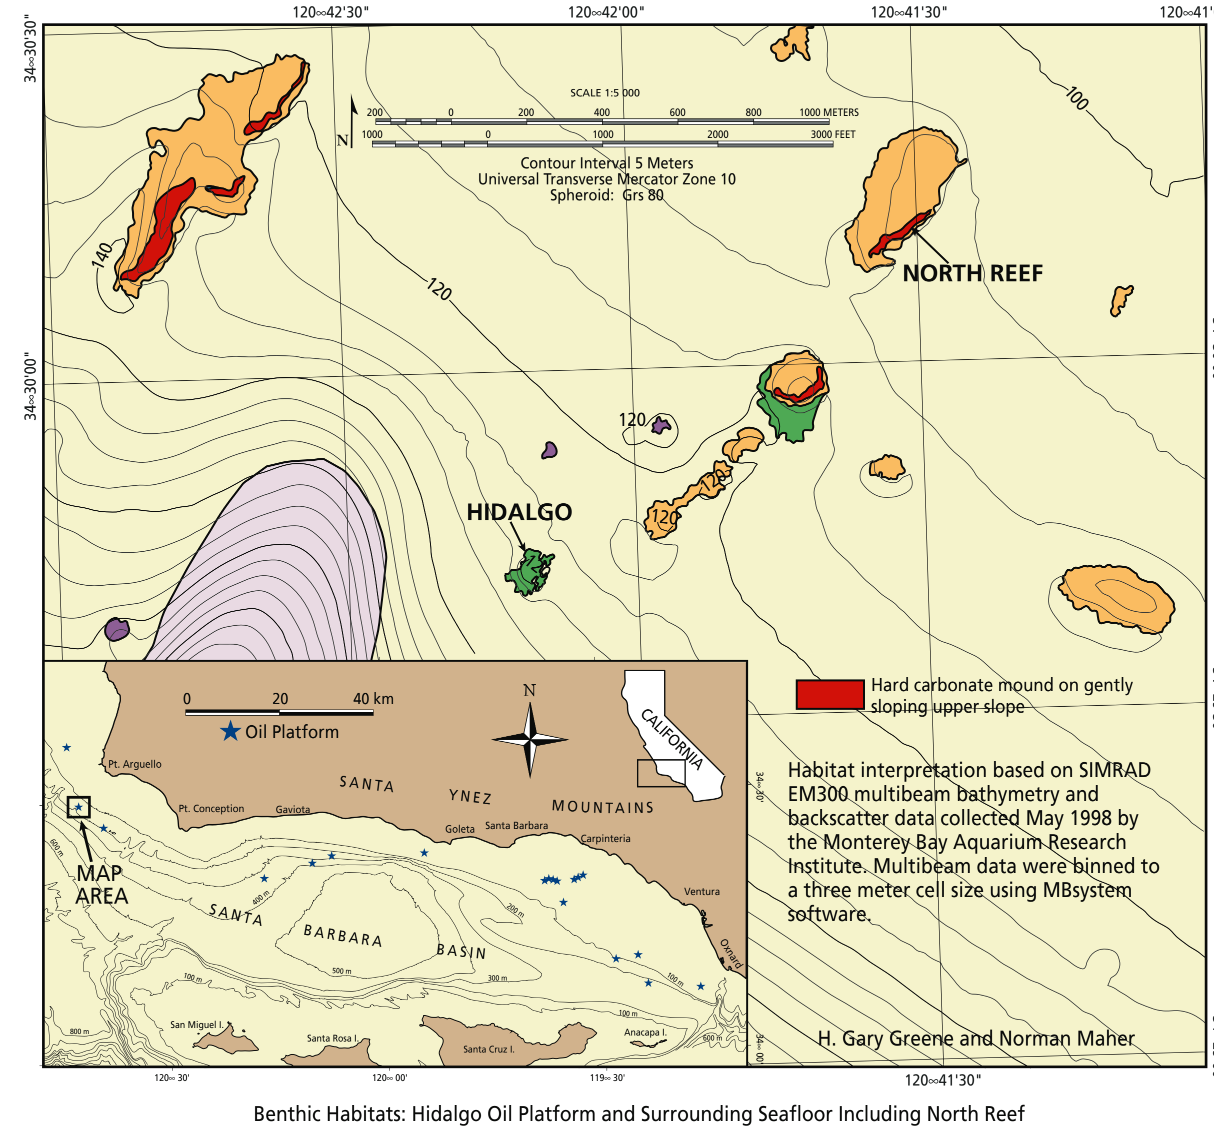

Figure 3.18. Locations of Platform Hidalgo and North Reef. Seafloor characterization by Gary Greene, Moss Landing Marine Laboratory.

96.6% of all fishes at Platform Hidalgo and North Reef, respectively. We observed a minimum of 34 fish species at each location. A few species were unique to each structure. Copper and stripetail rockfishes and California scorpionfish were found only at Platform Hidalgo, while blackeye goby, bluebarred prickleback, Pacific argentine, speckled sanddab, and an unidentified cuskeel were present only at North Reef. None of these species were major constituents of their respective fish communities.

However, when taking into consideration the fish assemblages of the three habitats (midwater, bottom, and shell mounds) at Platform Hidalgo, each was somewhat distinct from that of North Reef (Figure 3.19). To characterize and distinguish between the species assemblages at Platform Hidalgo and North Reef, we compared only the benthic assemblages of the platform bottom and shell mound and North Reef. Canonical discriminant analysis showed that species assemblages at the bottom of Platform Hidalgo and its shell mound were somewhat different from each other and from the North Reef assemblages (Figure 3.20a). The platform bottom assemblage was characterized by a suite of rockfishes, including bocaccio and cowcod, flag, vermilion, and widow rockfishes and lingcod. The shell mound assemblage was similar to and overlapped with the platform bottom, but was characterized by smaller fishes, such as swordspine,

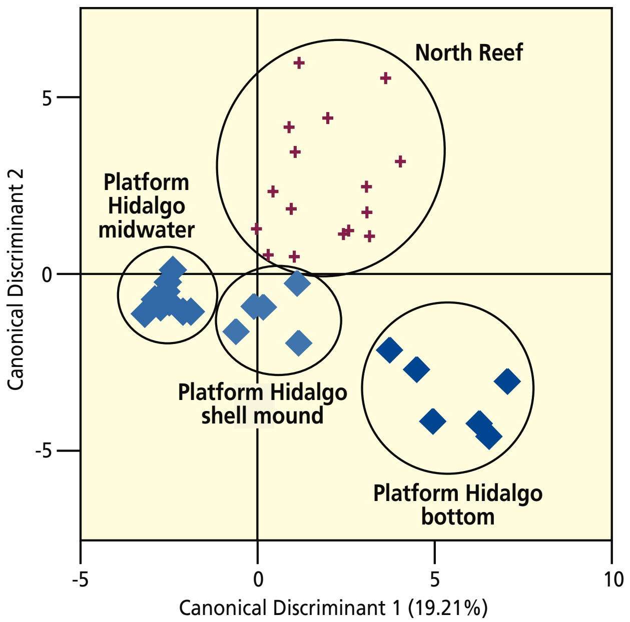

Figure 3.19. Canonical Discriminant Analysis of fish assemblages at Platform Hidalgo, midwater, bottom, and shell mound habitats and North Reef, 1996–2001.

greenstriped and halfbanded rockfishes, painted greenling, and juvenile lingcod (Figure 3.20b).

In general, the distinctions between the platform and reef assemblages were based on differences in species densities rather than species presence and absence. The densities of a range of species varied between the two sites (Figure 3.21) and most exhibited higher densities at Platform Hidalgo than at North Reef (Figure 3.21). Halfbanded, greenspotted, flag, greenstriped, canary rockfishes, all three life stages of lingcod (young-of-the-year, immature, adult), and painted greenling were among the species that were more abundant around the platform. Five species (pink seaperch, shortspine combfish, pygmy, squarespot, and yellowtail rockfishes) were more abundant at the reef.

Young-of-the-year rockfishes were common at both Platform Hidalgo (primarily in the midwaters) and at North Reef, although species differences were observed. From our submersible surveys, we identified at least seven species of young-of-the-year rockfishes at Hidalgo (e.g., blue, bocaccio, olive, pygmy, squarespot, widow, and yellowtail). Our scuba surveys around that platform also noted young-of-the-year of the "copper complex," composed of black-and-yellow, copper, gopher, and kelp rockfishes. Most of the young-of-the-year rockfishes at North Reef appeared to be pygmy, squarespot, and widow rockfishes.

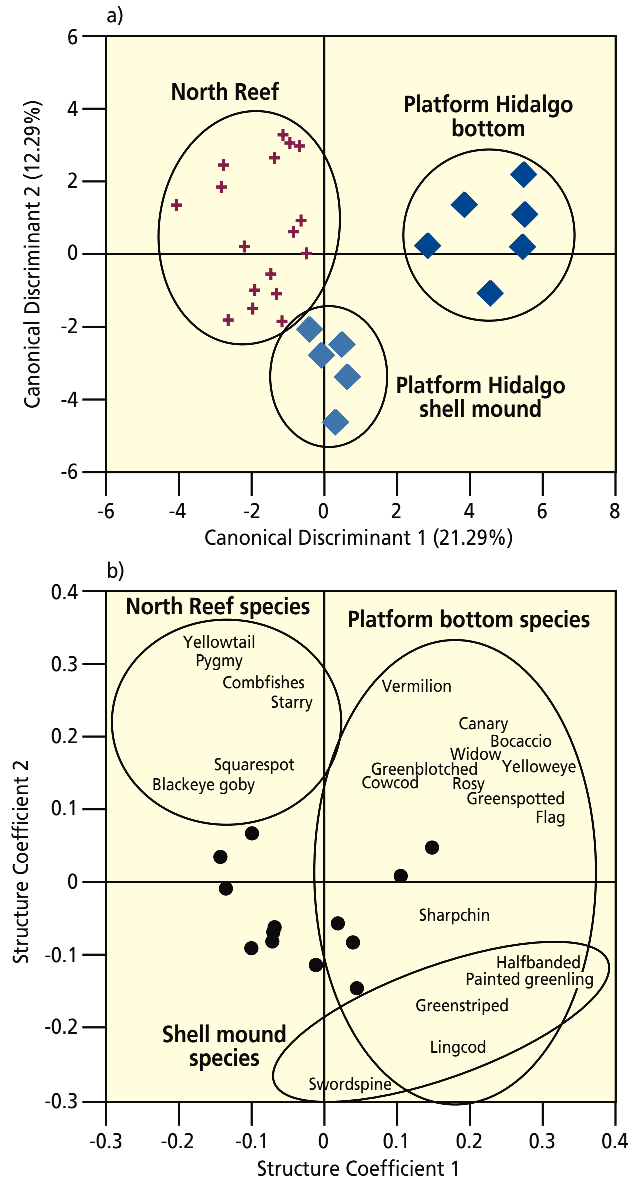

Figure 3.20. 3.20a. Canonical Discriminant Analysis of fish assemblages at Platform Hidalgo bottom and shell mound habitats and North Reef, 1996–2001. Each yearly survey at North Reef was comprised of 2–3 transects and thus each year's survey is represented by more than one cross. 3.20b. Canonical Discriminant Analysis of the species found around Platform Hidalgo, bottom and shell mound and North Reef, 1996–2001. Dots represent species that were not strongly associated with either axis.

The mean density of young-of-the-year rockfishes in the midwater habitat of Platform Hidalgo was higher than at North Reef (Figure 3.21). This probably reflects greater rockfish recruitment to the platform. This has important implications with respect to platform habitat values regarding settlement and fish production around

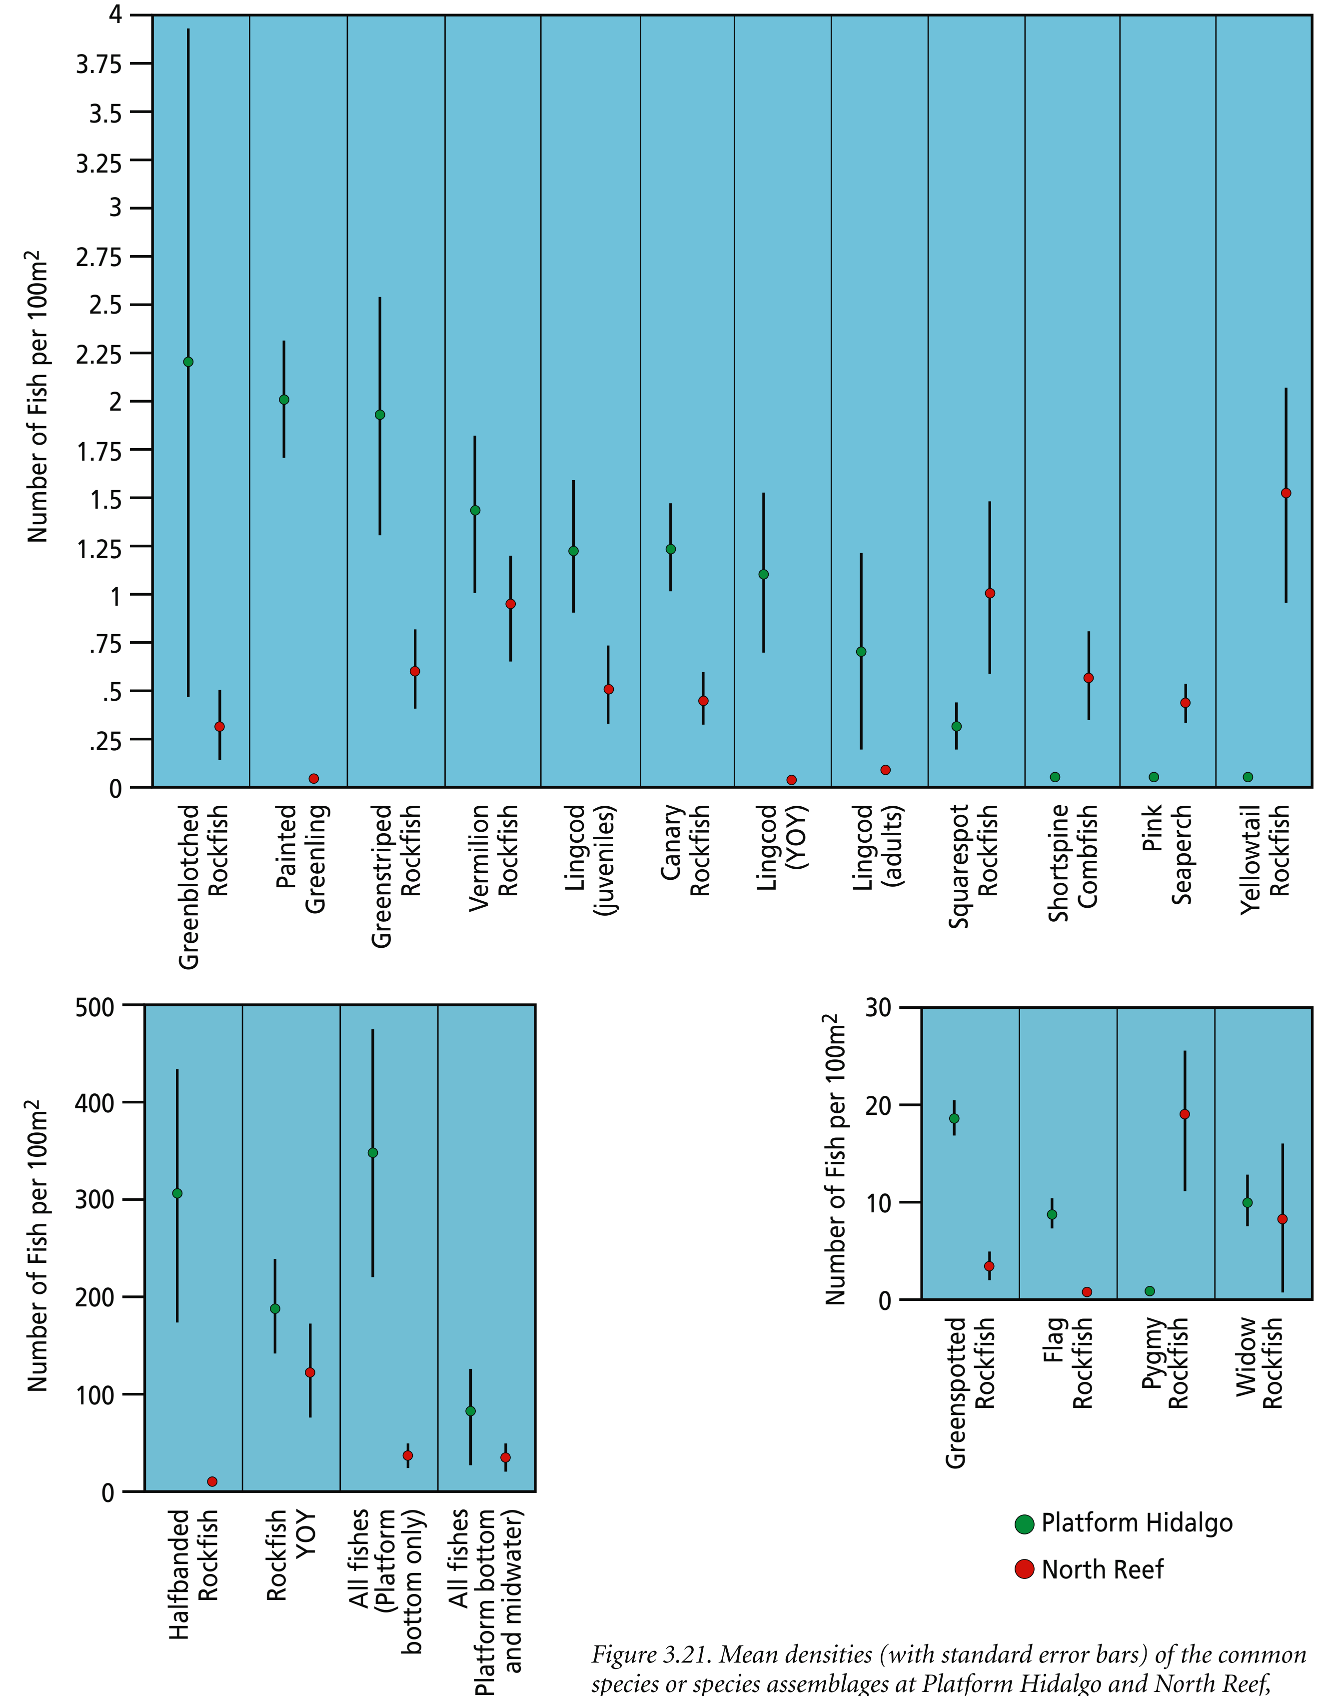

Figure 3.21. Mean densities (with standard error bars) of the common species or species assemblages at Platform Hidalgo and North Reef, 1996–2001. Species or species assemblages are grouped by abundance.

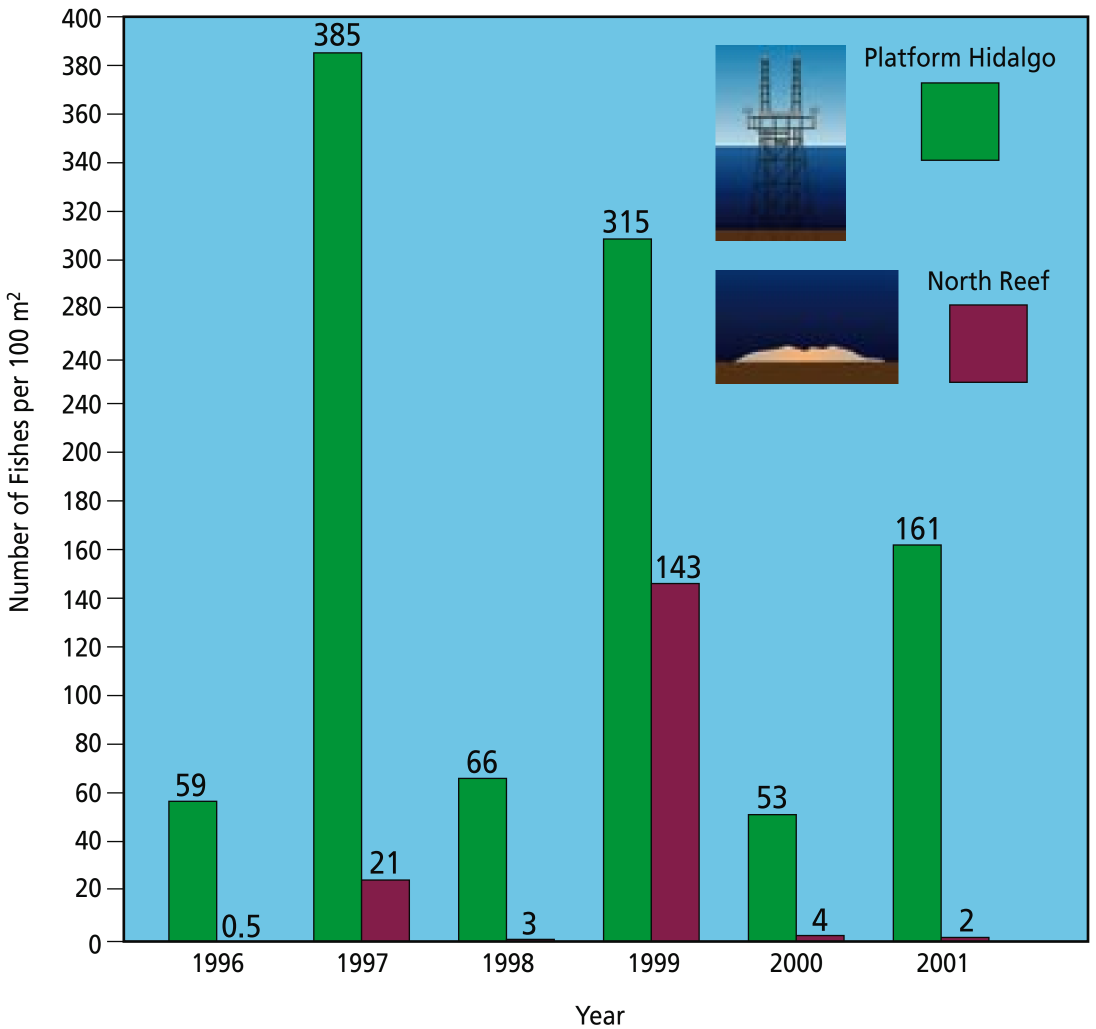

Figure 3.22. Mean densities of young-of-the-year rockfishes, all species combined, at Platform Hidalgo midwater and North Reef, 1996–2001.

these structures. This recruitment pattern was repeated in each year of our surveys as young-of-the-year rockfish densities were always greater at the platform than at the outcrop (Figure 3.22). In some years, densities were more than 100 times greater at the platform.

4. A Comparison of Fish Assemblages of Platforms and Natural Outcrops off Central and Southern California

Findings at a Glance

Based on surveys of seven platforms and over 80 natural outcrops, rockfishes dominate almost all of the platform and hard seafloor habitats. A greater number of species was observed at the natural outcrops (94) than at the platforms (85). There is a high degree of overlap in species composition and differences are primarily due to generally higher densities for more species at platforms. In particular, widow rockfish young-of-the-year, canary, copper, flag, greenblotched, greenspotted, greenstriped, halfbanded, and vermilion rockfishes, bocaccio, painted greenling and all life history stages of lingcod were more abundant at platforms. Yellowtail rockfish and the dwarf species pygmy, squarespot, and swordspine rockfishes were more abundant on natural outcrops. Some of these differences can be explained by recruitment (settlement) processes and the greater chance for survival at the platform habitats. We believe that as fish size increases with age the platforms act as de facto marine reserves because fishing pressure is light or nonexistent. Platforms can be characterized as having higher densities of young-of-the-year rockfishes than natural outcrops.

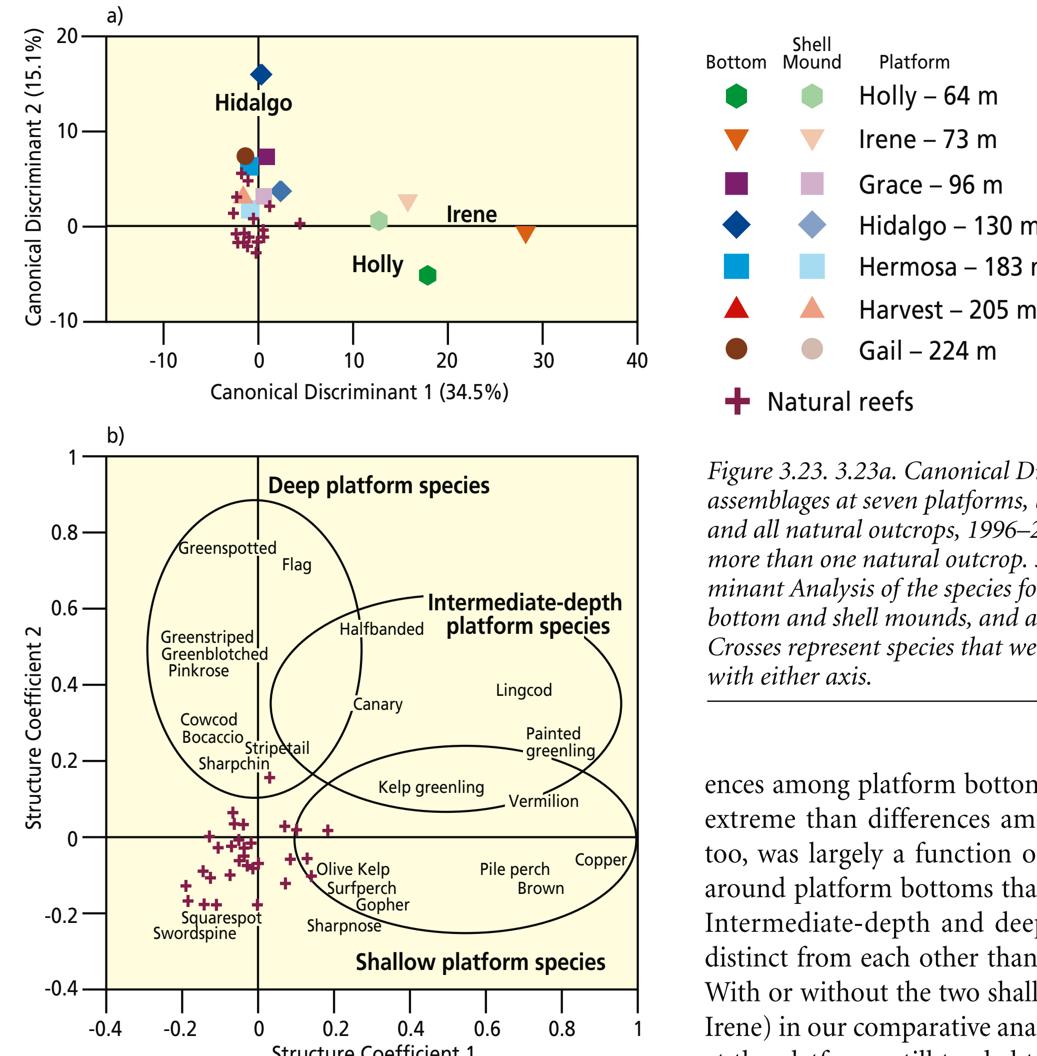

Figure 3.23. 3.23a. Canonical Discriminant Analysis of fish assemblages at seven platforms, bottom and shell mound, and all natural outcrops, 1996–2001. Each cross represents more than one natural outcrop. 3.23b. Canonical Discriminant Analysis of the species found at seven platforms, bottom and shell mounds, and all natural reefs, 1996–2001. Crosses represent species that were not strongly associated with either axis.

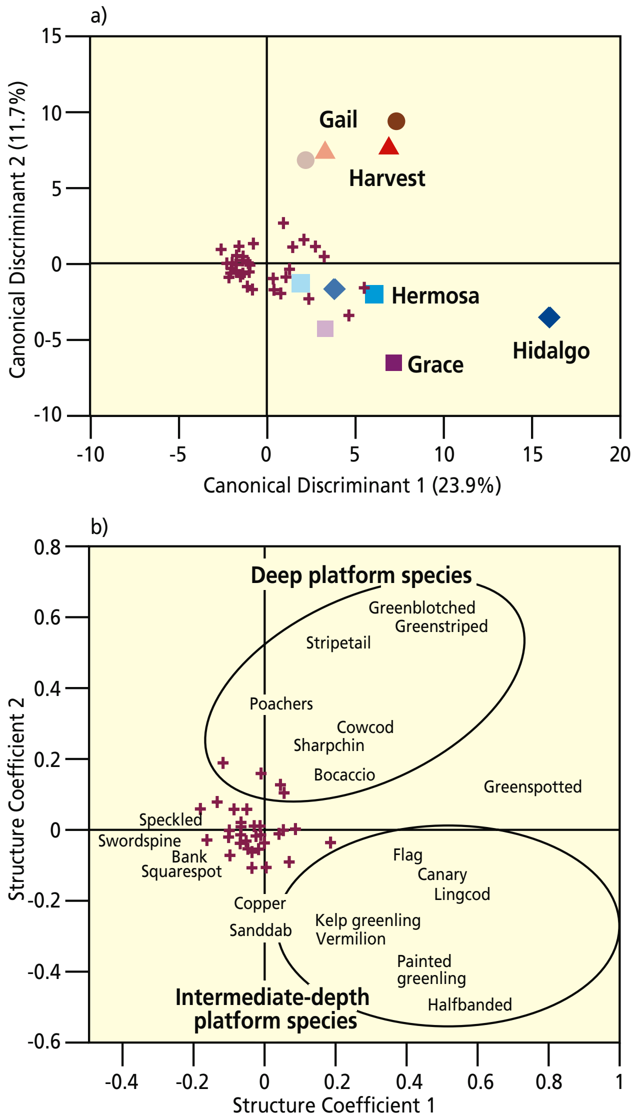
We compared the fish assemblages from the deeper parts of seven platforms (below about 30 m, 100 ft.) with those of similar depth natural outcrops. Analyses were based on platform surveys and on 133 dives at over 80 natural outcrops throughout southern California and off Point Conception and Point Arguello (Figure 1.5).

We observed at least 85 species at platforms and 94 species at outcrops (Table 4). Rockfishes dominated both habitats, comprising 89.7% of all fishes at platforms and 92.5% at outcrops. Platform fish assemblages were somewhat different from those of natural outcrops (Figures 3.23a, b). However, these differences were due almost entirely to the generally greater numbers, of more species, of fishes around platforms, rather than differences in species composition between platforms and outcrops.

There was a distinct assemblage of fishes at the two shallow platforms, Holly and Irene, and another composed of species occupying the deeper platforms. Differences among platform bottom assemblages were more extreme than differences among shell mounds. This, too, was largely a function of greater fish abundance around platform bottoms than over the shell mounds. Intermediate-depth and deepest platforms were less distinct from each other than from shallow platforms. With or without the two shallow platforms (Holly and Irene) in our comparative analysis, the fish assemblages at the platforms still tended to be different from those at the natural outcrops (Figures 3.24a, b). These differences were primarily due to most fish species being more abundant at platforms than at outcrops (Figure 3.25). Widow rockfish young-of-the-year, canary, copper, flag, greenblotched, greenspotted, greenstriped, halfbanded, and vermilion rockfishes, bocaccio, painted greenling, and all life history stages of lingcod were more abundant at platforms. Species that were more abundant at natural outcrops than platforms included pygmy, squarespot, swordspine, and yellowtail rockfishes.

Platforms tended to harbor higher densities of young-of-the-year rockfishes than did natural outcrops. Young-of-the-year rockfishes primarily occurred in the platform midwaters. Thirteen of the 20 highest young-of-the-year rockfish densities were observed at Platforms Grace, Harvest, Hermosa, Hidalgo, Holly, and Irene (Table 5). The highest young-of-the-year rockfish densities over natural outcrops were usually at high relief sites well away from the mainland. The California Current, which is centered



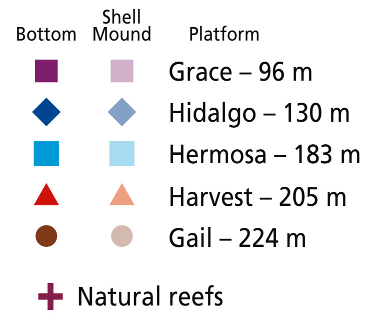


Figure 3.24. 3.24a. Canonical Discriminant Analysis of fish assemblages at five platforms (shallower platforms Holly and Irene deleted), bottom and shell mound, and all natural outcrops, 1996–2001. Each cross represents more than one natural outcrop. 3.24b. Canonical Discriminant Analysis of the species found at five platforms (shallower platforms Holly and Irene deleted), bottom and shell mound, and all natural outcrops, 1996–2001. Crosses represent species that were not strongly associated with either axis.

offshore of the coastal shelf, influences these locations (e.g., San Nicolas and San Miguel islands) more than the mainland sites we surveyed. Furthermore, our observations strongly imply that the midwaters of many platforms bear a striking resemblance to some of the relatively shallow and steep-sided outcrops (such as those on Hidden Reef) that dot the outer continental shelf of southern California. In both cases, the assemblages are dominated by young rockfishes and larger fish predators are relatively uncommon. Thus, survivorship of young fishes may be higher in both habitats due to lowered predation rates.

The role that some platforms play as defacto marine refuges is supported by evidence of greater densities of rockfishes, particularly the larger size classes, at platforms compared to natural outcrops. As an example, densities tended to be higher at some platforms than at natural outcrops for: (1) all rockfishes regardless of size, (2) all rockfishes greater than or equal to 30 cm (12 in.), (3) adult bocaccio, and (4) adult cowcod (Figures 3.26–3.29). Our experience is that rockfishes are most susceptible to being caught by both recreational and commercial gear when they reach about 30 cm (12 in.); thus, densities of fishes of this or larger sizes would be an indication of fishing pressure. Adult bocaccio and cowcod are overfished species with population sizes at levels less than 10% of unfished stock. These fishes at one time were abundant in southern California.

Rockfishes were observed at all of the platforms and outcrops we surveyed, with the exception of two sites on Piggy Bank (Figure 3.26). The highest rockfish densities (500 rockfishes or more per 100 m^2) occurred at four platforms and at five natural outcrops; all of these structures were nursery grounds for young-of-the-year rockfishes. The assemblages of most of the other platforms and outcrops that harbored relatively high rockfish densities also were primarily composed of small rockfishes, both immature individuals and dwarf species. This can be clearly seen when we focussed on rockfishes 30 cm (12 in.) or larger (Figure 3.27). The paucity of rockfishes 30 cm (12 in.) or larger is evident even at the most productive sites (Figure 3.27). Highest densities of large rockfishes (10 rockfishes or more per 100 m^2) occurred at three platforms and two natural outcrops. Many sites harbored no or only a few larger rockfishes.

Almost all of the natural outcrops we studied should have harbored large numbers of larger rockfishes. Their absence or rarity is almost certainly attributable at least

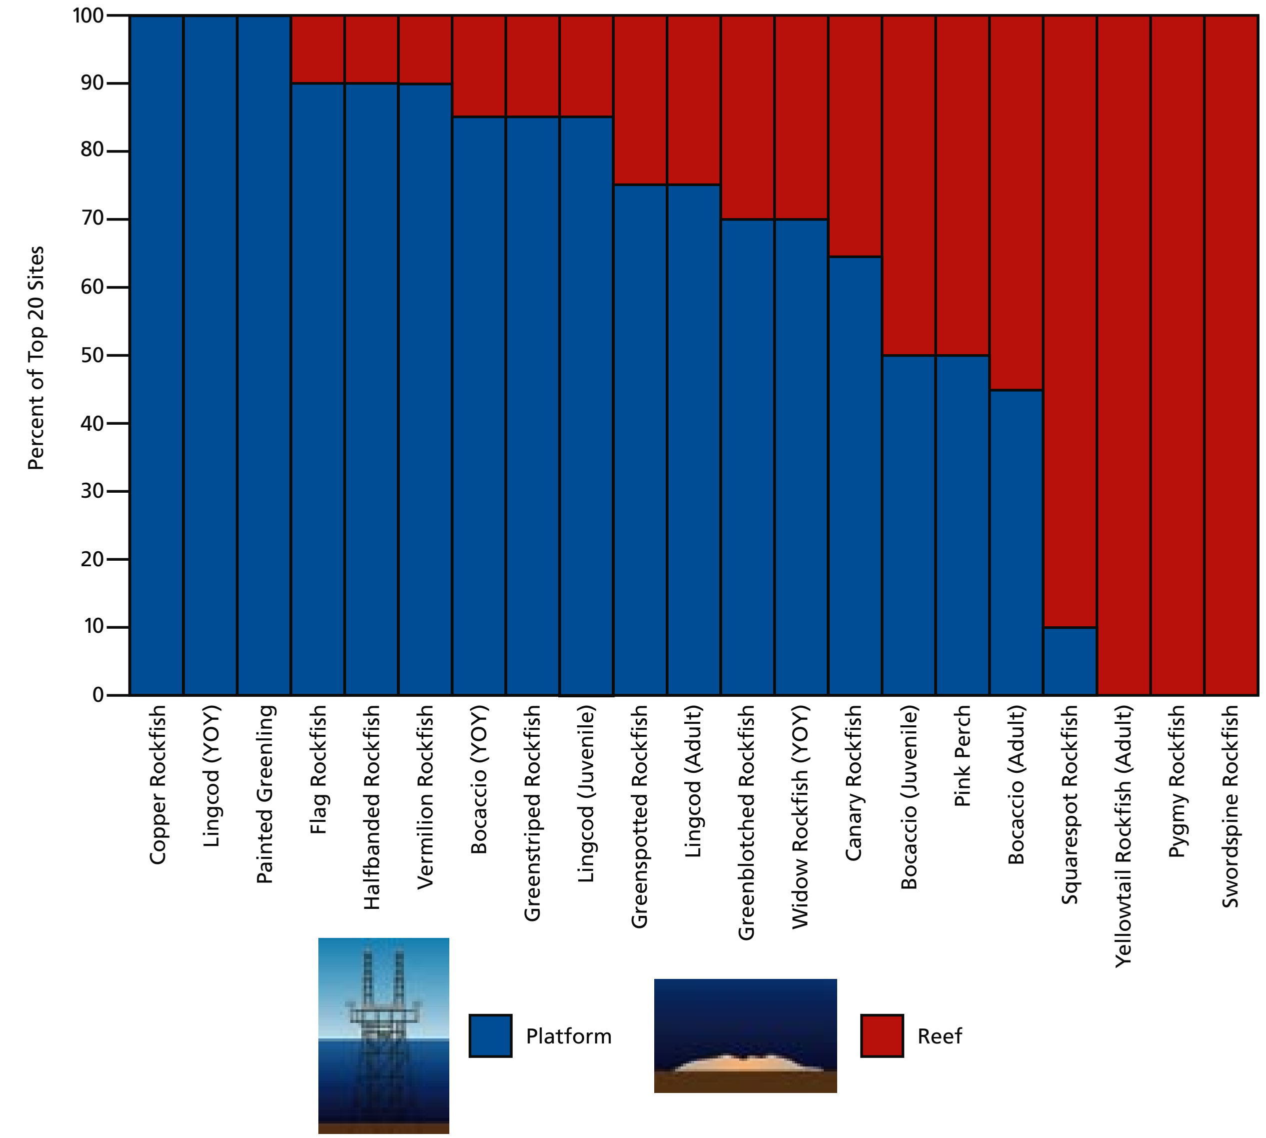

Figure 3.25. The relative importance of seven platforms (Irene, Hidalgo, Harvest, Hermosa, Holly, Grace, and Gail) and about 80 natural outcrops off central and southern California as habitat for common reef fish species. Densities of these species were computed for each year, at each location (platform midwater, bottom and shell mound, and natural outcrops) and ranked from highest to lowest. This figure displays the percentage that platforms or natural outcrops comprised of the top 20 densities for each species (or species' life history stage). For example, of all sites where copper rockfish were observed, the highest 20 densities were at various platforms, in a number of years. Similarly, the highest 20 densities of swordspine rockfish were all at natural outcrops. See Appendix 4 for underlying data.

in part to fishing pressure. These sites were comprised of boulders or other structures that were suitable shelter sites for larger sized rockfishes. A few outcrops, such as sites near the Potato and Osborn Banks, were composed of cobble, a habitat that is less likely to harbor large rockfishes. Adult bocaccio were only abundant around Platform Gail and were relatively common at Platform Hidalgo, Reef "D" near that platform and a few sites around the northern Channel Islands (Figure 3.28). Even at these natural outcrops, many shelter structures contained no or few adult bocaccio. Cowcod densities were also depressed (Figure 3.29). Relatively few rock outcrops surveyed contained adults, and platform Gail harbored the highest densities, although even here numbers were low. In general, the highest densities of adult bocaccio and cowcod occurred at platforms or at those outcrops that were protected from harvest by distance from ports or by being situated in areas susceptible to poor weather conditions.

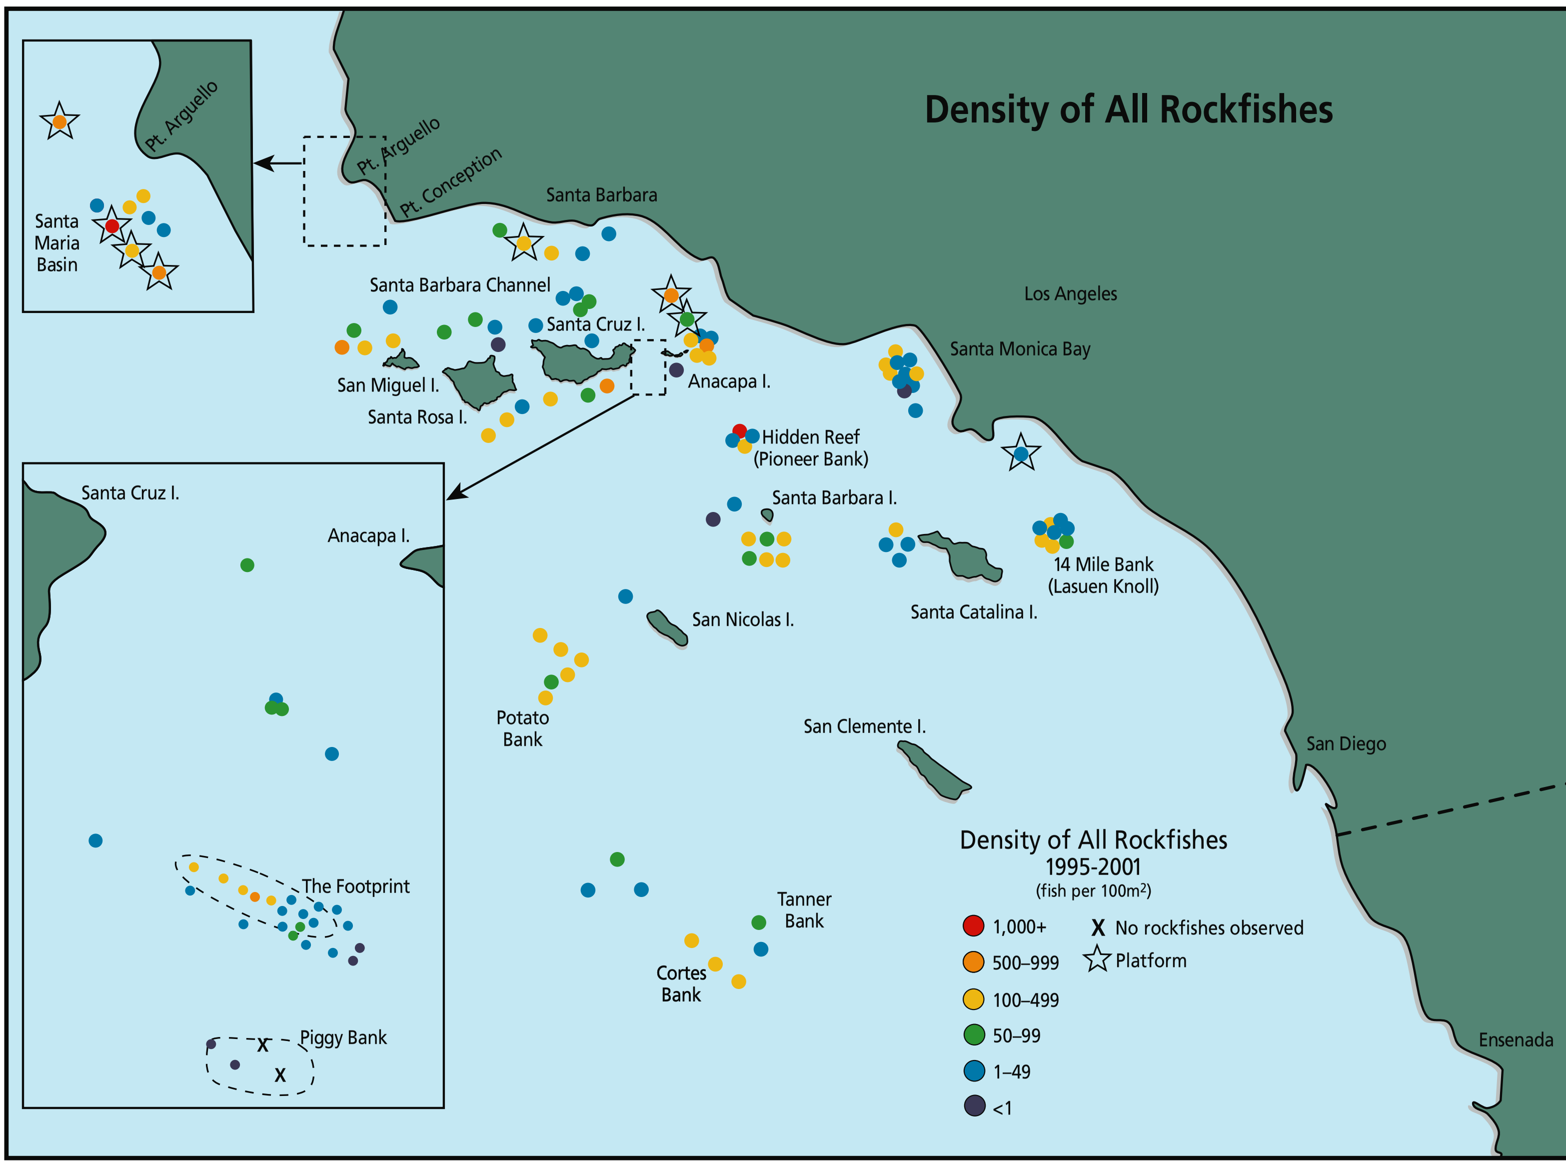

Figure 3.26 . Density of all rockfishes, regardless of size, as observed from the Delta *submersible on platforms and natural outcrops, 1995–2001. Fish densities for Platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Grace and Gail, North Reef and reefs "A", "B", "C" and "D" in the vicinity of Platform Hidalgo represent means of years.*

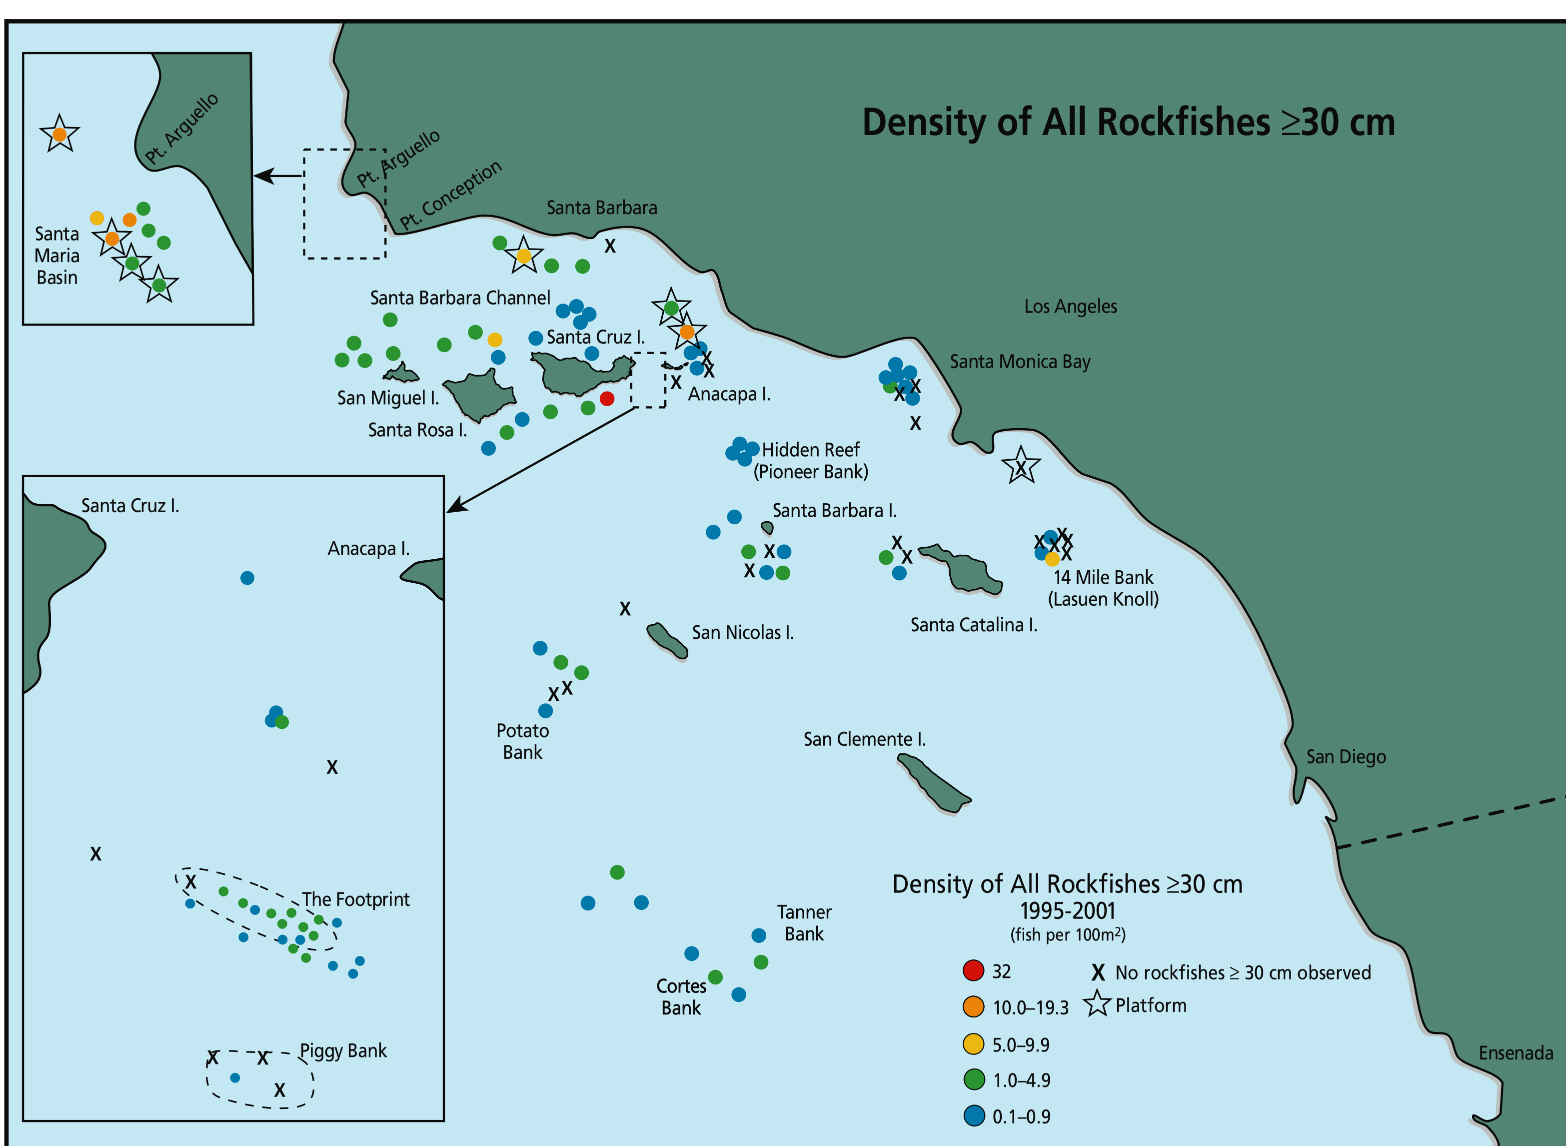

Figure 3.27. Density of all rockfishes larger than or equal to 30 cm as observed from the Delta *submersible on platforms and natural outcrops, 1995–2001. Fish densities for Platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Grace and Gail are from platform bottoms and densities for these seven platforms and for North Reef and reefs "A", "B", "C" and "D" in the vicinity of Platform Hidalgo represent means of years. Platforms C, B, A, Hillhouse, Hogan, Houchin, and Henry were not included because they were not completely surveyed.*

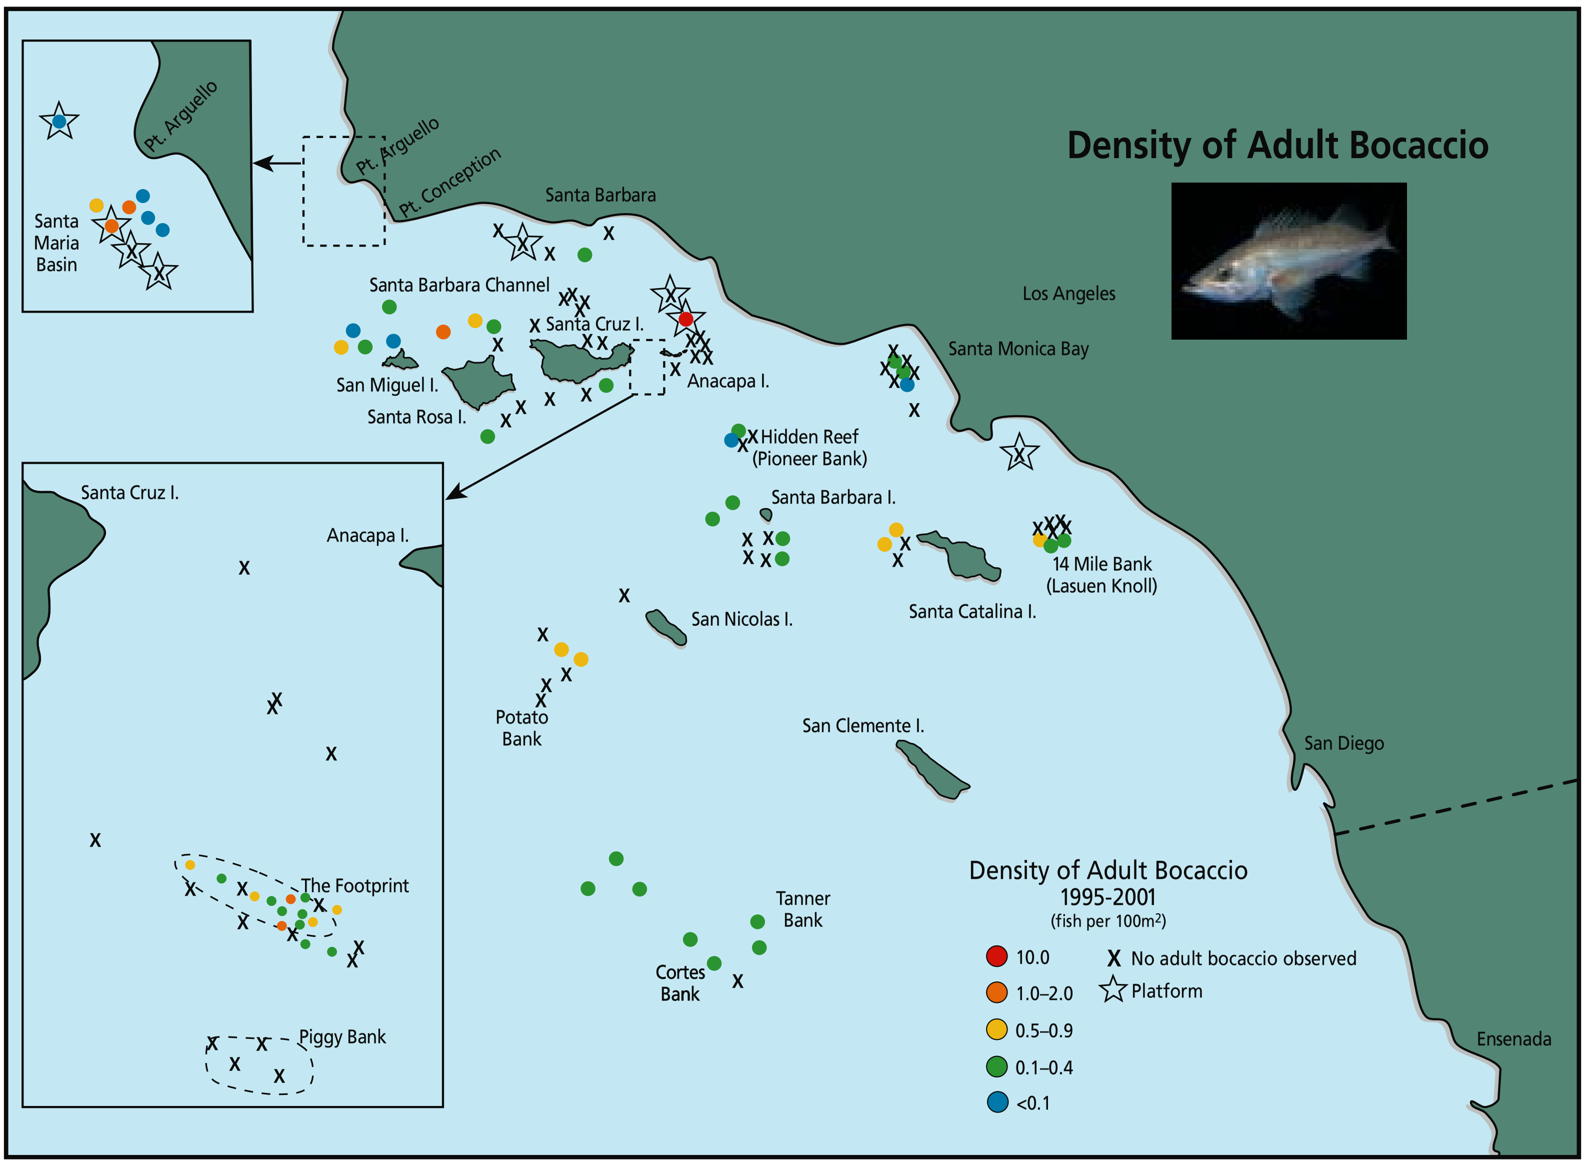

Figure 3.28. Density of adult bocaccio (defined as fish larger than 35 cm total length) as observed from the Delta submersible on platforms and natural outcrops, 1995–2001. Bocaccio densities for Platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Grace and Gail are from platform bottoms and densities for these seven platforms and for North Reef and reefs "A", "B", "C" and "D" in the vicinity of Platform Hidalgo represent means of years. Platforms C, B, A, Hillhouse, Hogan, Houchin, and Henry were not included because they were not completely surveyed.

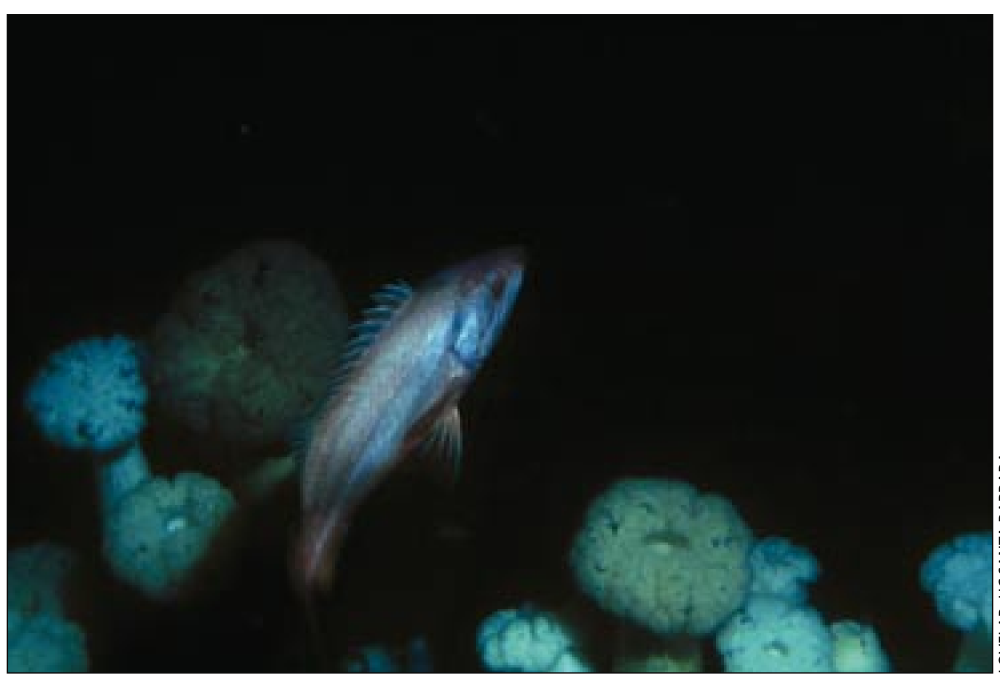
Cowcod densities for Platforms Irene, Hidalgo, Harvest, Hermosa, Holly, Grace and Gai are from platform bottoms and densities for these seven platforms and for North Reef and reefs "A", "B", "C" and "D" in the vicinity of Platform Hidalgo represent means of years. Platforms C, B, A, Hillhouse, Hogan, Houchin, and Henry were not included because they were not completely surveyed.*

Why platforms support higher densities of young rockfishes than do nearby natural outcrops.

Platforms are important nursery habitat for many species of rockfishes. This research demonstrates that, in general, platforms may be more important nursery habitats than nearby natural outcrops or, indeed, most other outcrops surveyed in central and southern California. Why is this? First, platforms occupy more of the water column than do most natural outcrops. Presettlement juvenile rockfishes, swimming in the midwater, are much more likely to encounter these tall structures than the relatively low-lying natural rock outcrops. It is interesting to note that most of the natural outcrops we found that had high densities of young-of-the-year rockfishes (e.g., Hidden Reef and outcrops around islands) were very high relief features that thrust their way well into the water column.

In addition, there are also relatively fewer large predators in the platform midwaters. By comparison, even on heavily fished outcrops there tend to be at least a few larger fishes. Many of the major predators of young rockfishes are species that live close to the bottom, such as lingcod, copper and vermilion rockfishes, cowcod and large bocaccio. In general, these species do not ascend the platform jacket. Thus, even when they are abundant at the bottom of a platform, they are absent from the platform midwaters. In this respect, platforms are similar to some of the offshore pinnacles on the southern California continental shelf. Predatory species, such as cowcod, lingcod, and greenblotched rockfishes are also not abundant around the steep, smooth sides of offshore outcrops.

At most of the platforms, we observed both harbor seals and California sea lions, both resting on the platforms and swimming in the water column among the jackets and conductors. Based on the known food habits of these animals, it is likely that they feed on platform fishes, but their low numbers probably have little effect on the abundance of young rockfishes. We also observed both harbor seals and California sea lions swimming over natural outcrops and it likely that here, too, predation on young rockfishes occurs.



LOVELAB, UC SANTA BARBARA

Platforms as defacto marine refuges

The role that some platforms play as defacto marine refuges is supported by evidence of greater densities of rockfishes, particularly the larger size classes, at platforms than at natural outcrops. The role that platforms may play as de facto reserves should not be underestimated at a time when many fish populations are in decline on natural outcrops. A number of benthic fishes, including such economically important species as bocaccio, cowcod, copper, and vermilion rockfishes and lingcod find refuge within the platforms and this is probably a factor in their relatively high densities compared to most natural outcrops. Schroeder and Love (2002) compared the rockfish assemblages at three deeper-water areas subjected to variable fishing pressures. Two were natural outcrops, one outcrop open to all fishing and one open only to recreational fishing, and the third was Platform Gail, acting as a de facto marine refuge. The outcrop allowing open fishing had the highest densities of rockfishes (7,212 fish/ha); however, the assemblage was dominated by dwarf species. The recreational fishing area had the lowest rockfish density (423 fish/ha) and this assemblage was also dominated by small fishes. Platform Gail possessed a relatively high density (5,635 fish/ha), and the fishes tended to be larger than individuals at either of the fished sites. Two federally listed overfished species, cowcod and bocaccio, had 32- and 408-fold higher densities, respectively, at Platform Gail than the recreational site, and 8- and 18-fold higher densities, respectively, than the all-fishing area.

There is some fishing effort around most platforms in the Southern California Bight and Santa Maria Basin. The relative amount of fish pressure among platforms is dependent on ease of access and local ocean conditions. Platforms in the Santa Maria Basin are located in an area that is far from ports, usually windy, and unprotected from weather. It is difficult to fish around the bottom of platforms, especially the deeper ones, because of the threat to gear imposed by the large number of crossbeams, other platform structural elements, conductors, and strong currents. Many anglers also believe that operators do not welcome fishing near their platforms.

Some platforms are important fishing areas for recreational anglers. Historically, commercial passenger fishing vessels and small private vessels fished around some of the shallower platforms in the Santa Barbara Channel (Love and Westphal 1990). Platforms Hilda and Hazel were targeted for kelp bass. During years with strong rockfish recruitment, large numbers of juvenile bocaccio, blue, olive, and widow rockfishes were caught at Platforms Holly, A, B, C and Hillhouse. In all of these instances, fishing effort was directed at surface or midwaters, rather than at the platform bottom. The removal of Hilda and Hazel and the poor rockfish recruitment of the 1980s and much of the 1990s reduced the overall fishing effort at oil/gas platforms. Some recreational fishing continues around Platform Gina, and there is minimal effort around a few other structures in the Santa Barbara Channel.

Overfishing has drastically altered the species composition of many outcrops off central and southern California (Yoklavich et al. 2000; M. Love, unpublished data). Over most moderate-depth and deep outcrops in central and southern California, many, or sometimes all, of the larger predatory fishes, such as lingcod, cowcod, bocaccio, yelloweye, and canary rockfishes are gone. In contrast, surveys made over an unfished outcrop in central California showed very high densities of large predatory fishes, including lingcod, cowcod, bocaccio, and yelloweye rockfish (Yoklavich et al. 2000). At many natural outcrops, these larger individuals have been replaced by very large numbers of dwarf species, particularly pygmy, swordspine, and squarespot rockfishes. Fish assemblages at platforms, such as Gail, Hidalgo, and Irene, with relatively high densities of many economically important species and low numbers of dwarf species, may more closely resemble unfished assemblages than those at many natural outcrops.

5. The Origins of Platform Fishes: Production and Attraction

Finding at a Glance

Our research suggests that platforms, like natural outcrops, both produce and attract fishes, depending on species and location. Platform fish assemblages around the deeper and further offshore platforms may be generated primarily from the recruitment of larval and pelagic juvenile fishes, not from attraction of fishes from natural outcrops. Some fishes may live their entire lives around a single platform but their movement patterns are poorly known. A pilot study comparing growth rates showed that young-of-the-year blue rockfish grew faster at a platform than at a natural outcrop.

In recent years, public attention has been drawn to artificial reefs and their function in the marine environment. While a variety of issues have been raised, much of the discussion has centered around the question of whether artificial reefs are producers or attractors of marine life (Carr and Hixon 1997; Lindberg 1997). Some researchers suggest this question is biologically simplistic, because it "imposes an unrealistic either-or-dichotomy…" (Lindberg 1997). Nevertheless, this issue continues to arise in the context of the importance of platforms as fish habitat off California (Carr and Stephens 1998; Krop 1998).

Attraction suggests the net movement of juvenile and adult fishes away from natural outcrops to platforms. While there is not complete agreement on the definition of production, most researchers agree that it involves larval or pelagic juvenile settlement at a structure and the survival and growth of these organisms in this habitat (Carr and Hixon 1997).The attraction/production debate is framed around three questions (Carr and Stephens 1998; Krop 1998): (1) Do larval and juvenile fishes settle onto platforms from the plankton, or do fishes move from other structures to platforms as older juveniles or adults? (2) If a species does settle onto a platform, are growth and survivorship at least as good as on a natural outcrop? (3) If a species does grow and survive well around a platform, did the structure take away larvae or pelagic juveniles that would have settled onto natural outcrops?

5a. Do Fishes Settle from the Plankton onto Platforms or Do They Swim There from Other Structures as Juveniles or Adults?

A large number of fish species settled out of the plankton and took up residence around platforms. We observed young-of-the-year of about 46 fish species at these structures (Table 6) and, including species observed by other researchers (Carlisle et al. 1964), at least 50 fish settle on to platforms from the plankton. During some years, the midwaters of many platforms had very high densities of juvenile rockfishes. Young-of-the-year blacksmith, kelp and painted greenlings, and cabezon also were abundant in this habitat at times. Young-of-the-year rockfishes, lingcod, and other species were abundant around platform bottoms and shell mounds. With a few exceptions, species that settled on the bottom and shell mound were different from those found in the midwaters.

Juveniles of some species were rarely or never observed around platforms. For instance, young-of-the-year kelp bass were rarely seen around any platform, although adults were very abundant at one platform. Young seaperches also were rare or absent. In these cases, older juveniles or adults immigrated to the platforms or juveniles settled there at times other than our surveys.

5b. The Biological Influence of Oceanographic Conditions on Recruitment Success at Platforms and Natural Outcrops in the Santa Barbara Channel and Santa Maria Basin

Most coastal fishes and invertebrates, including those inhabiting platforms, are planktonic during early stages of their life histories. These life stages, which may last from weeks to months, can begin as fertilized eggs (e.g., lingcod, cabezon, and garibaldi) or larvae (e.g., rockfishes). Some fishes, including rockfishes, continue to develop in the pelagic environment until they transform to the juvenile stage (Figure 3.30).

Pelagic life stages are at risk from starvation and predation and transport away from the specific habitats required for their growth and survival. Therefore, the type of water mass an animal finds itself may have a profound effect on its survival. There are a number of water masses in our study area, including waters from the Southern California Bight, the central California coast, upwelling from Point Conception, and from more distant places such as Baja California. How these waters enter, circulate and mix in the Santa Barbara Channel and Santa Maria Basin affects marine populations and community diversity on both platforms and natural habitats.

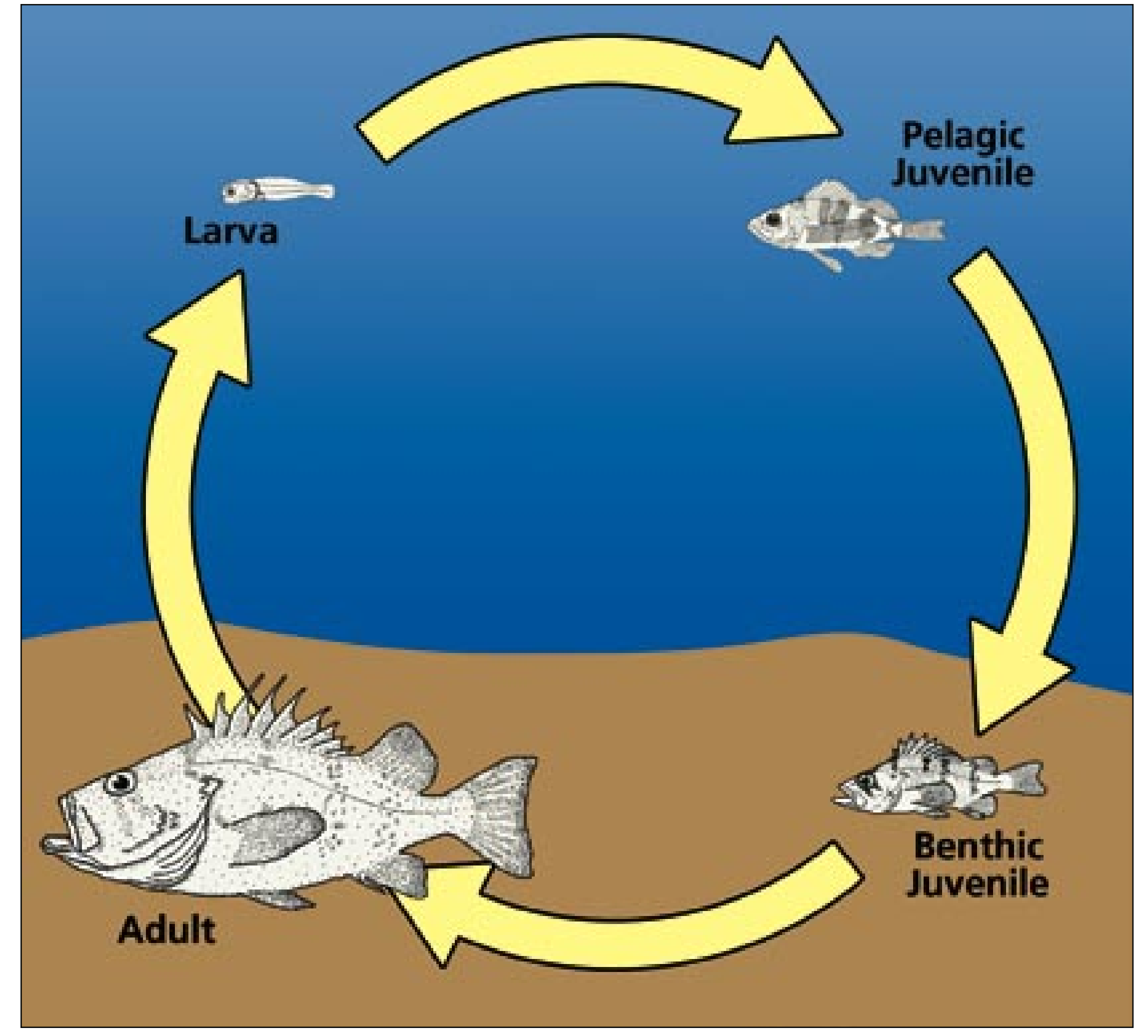

Figure 3.30. A typical rockfish life history cycle using the cowcod as an example.

Upwelling processes, the wind-induced pulling of deeper, colder water to the surface and displacement of warmer waters offshore, is a major factor in larval and pelagic juvenile survival. During years when upwelling coincides with larval fish production, fish survival may be enhanced. Because deep waters are nutrient-rich, upwelling increases reproduction of phytoplankton and encourages the growth of zooplankton, providing food for larval and pelagic juvenile fishes. Upwelling may also increase survivorship of some species by moving larvae and pelagic juveniles somewhat offshore, away from high densities of nearshore predators. Conversely, the offshore transport that accompanies upwelling can be detrimental to the survival of larvae and pelagic juveniles. Wind-induced turbulence in surface waters can make it difficult for larvae to come into contact with prey. Larvae risk being swept well offshore by strong upwelling and far removed from suitable habitat. Spatial and temporal variability in circulation, however, can provide some larvae and pelagic juveniles with conditions that enhance survivorship including delivery to optimum settlement.

The timing, location, intensity, and duration of upwelling events may have a large effect on rockfish settlement. For instance, recruitment may be hampered at sites constantly exposed to newly upwelled water. Through much of the late-spring and summer when presettlement-stage rockfishes are in the pelagic environment, upwelling from the mainland at Point Conception impacts the west channel. Our summer oceanographic data confirm that the upwelling plume can extend across the western portion of the Northern Channel Islands (Love et al. 1999). We found that pelagic juvenile rockfishes were relatively rare in this newly upwelled water (Figure 3.31) (Nishimoto 2000). As an example, when cool upwelled waters moved into an area off the south side

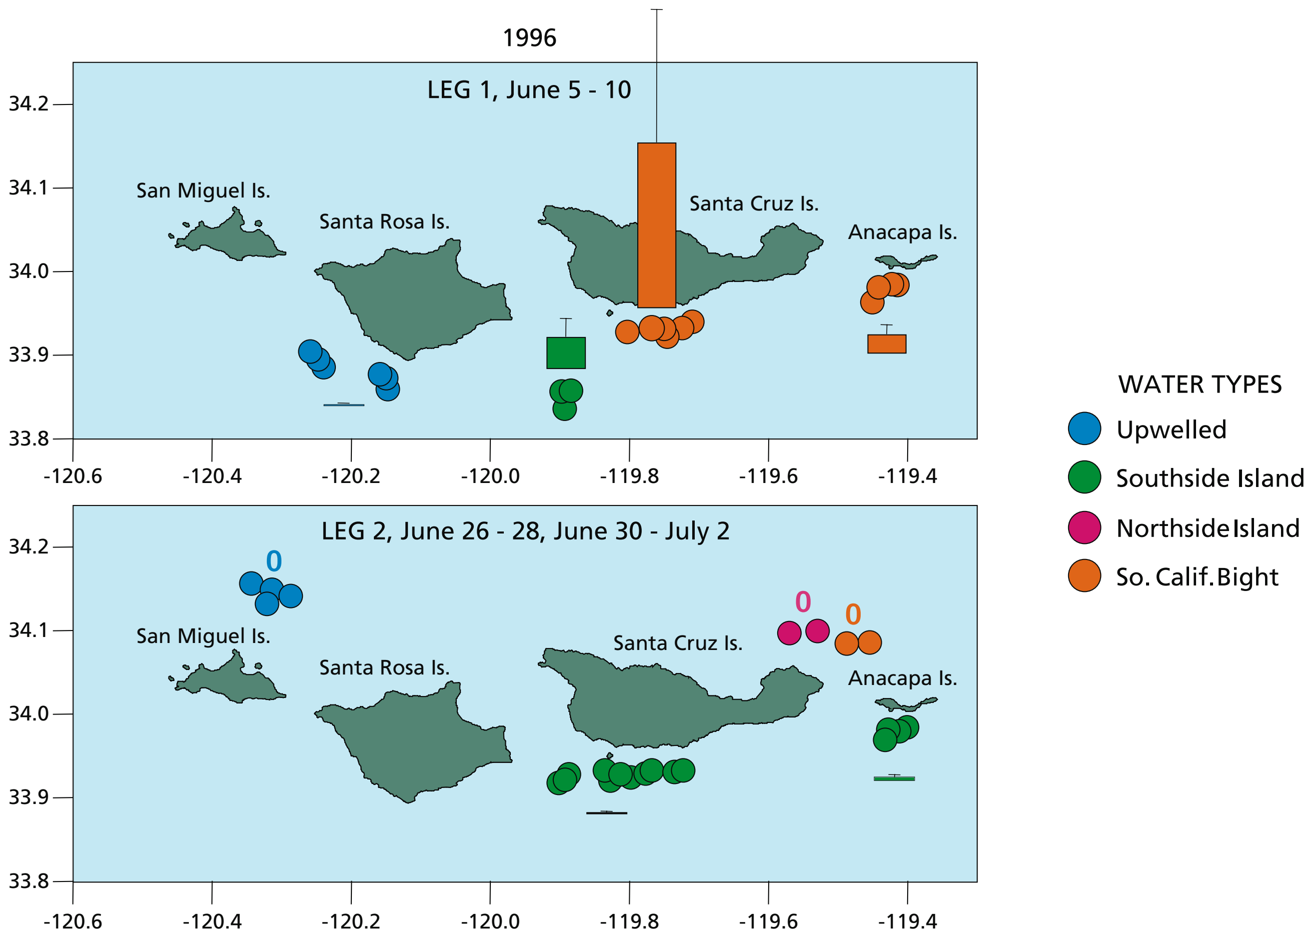

Figure 3.31. The abundance of late-larval stage and pelagic juvenile rockfishes decreases off the south side of Santa Cruz Island when one water mass replaced another between two sampling periods, June–July 1996. Temperature and salinity properties were used to identify four water masses: Upwelled water, Southside Island water, Northside Island water, and Southern California Bight water. Hauls are represented by colored circles. Fish abundance was estimated using the mean collected in midwater trawl hauls within a water mass. Bars illustrate the relative abundances among the water masses. Zeros indicate that no rockfishes were collected in the hauls within a water mass.

of Santa Cruz Island, the fish assemblage changed from one with relatively abundant pelagic juvenile rockfishes to one where these fishes were almost absent. We suspect that the upwelled water, the coldest and most saline water mass that we identified, was recently brought to the surface from depths where few larval and juvenile rockfishes reside**.**

Inter-annual oceanographic conditions, including the intensity of seasonal, coastal upwelling, are highly variable and this affects year class success and population variability. A shift from El Niño to La Niña conditions between 1998 and 1999 was marked by abrupt changes in the marine ecosystem off southern and central California. Our survey data of young-of-the-year rockfishes in 1999 indicates an increase in rockfish recruitment. The number of several juvenile rockfishes and other fish species observed on oil/gas production platforms and rocky outcrops in 1999 far exceeded those of 1998 and previous years. This increased recruitment coincided with intense coastal upwelling off Central California (among the strongest events in 50 years) in spring 1999 followed by high phyto- and zooplankton production (Lynn et al. 1998; Hayward et al. 1999). High productivity in the region likely contributed to the increased survivorship of the fishes including those that recruited to the platforms and natural outcrops.

Relatively transitory phenomena, such as fronts and eddies, may also play an important role in fish settlement and year-class success. Fronts, the zones where different water masses collide and mix, may prevent weak-swimming

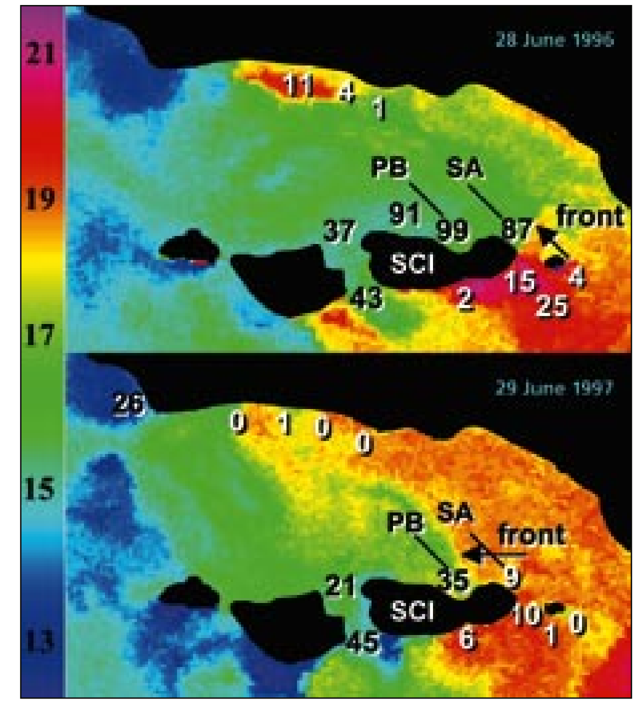

Figure 3.32. The strong correspondence between exposure to cool water and young-of-the-year rockfish density. A shift in position of the thermal front on the north shore of Santa Cruz Island (SCI) in 1996 and 1997 corresponded with a striking spatial shift in juvenile rockfish densities (see sampling sites, Pelican Bay (PB) and Scorpion Anchorage (SA)). Numbers overlaid on images represent mean densities of juvenile rockfishes (number/60 m^2) that recruited to giant kelp canopy at sites within the survey area.

planktonic animals from swimming between these masses (Moser and Smith 1993; Wing et al. 1998). The strength of recruitment to a platform or outcrop may be determined in part by the habitat's exposure to those fronts carrying ready-to-settle fish larvae and juveniles. Our research at Santa Cruz and Anacapa islands indicates that the recruitment of nearshore rockfishes was sparse on outcrops separated from cool, fish-rich waters by a frontal boundary (Figure 3.32) (Love, Nishimoto, Schroeder, and Caselle 1999).

Eddies, cyclonic currents that can concentrate and retain plankton, may retain fishes and affect the dispersal of larval and juvenile fishes to outcrops and platforms. For instance, in summer 1998 we sampled a stationary and persistent cold-core cyclonic eddy in the western Santa Barbara Channel. In this feature, we found very high concentrations of small fishes, including late-stage larval and pelagic juvenile rockfishes (Figure 3.33). Eddies may also be very transitory. During the summer of 1999, we observed a much different circulation pattern of shorter-lived, propagating eddies and collected few young rockfishes.

We suspect that the high levels of recruitment of young-of-the-year rockfishes at some platforms were associated, in part, with eddies and fronts retaining larvae that had been locally produced at either platforms or natural outcrops. For instance, Platform Irene is located to the north of the frontal boundary of the upwelling plume that extends off Point Conception. The platform is also situated in an area where a semi-persistent eddy is frequently observed during spring and summer (L.Washburn, personal communication). Similarly, both fronts and eddies were observed at Platforms Gail and Grace in the eastern channel north of Anacapa. As noted previously, Platform Gail harbors important habitat for adult bocaccio in the Santa Barbara Channel. Local retention of bocaccio larvae produced at Platform Gail would explain the high levels of bocaccio settlement at nearby platform Grace and Gilda.

The variability of oceanographic conditions in the Santa Barbara Channel between 1995 and 2001 appears to have strongly influenced settlement as young-of-the-year recruitment to platforms and natural outcrops was highly variable both temporally and spatially. For instance, while the 1997–1998 El Niño corresponded with a large increase in juvenile recruitment of species that dominate the warm-temperate fish assemblage (such as blacksmith), the 1999 La Niña corresponded to a strong settlement of cool-temperate species, such as rockfishes. While settlement of many rockfish species to platforms was generally higher north of Point Conception than in

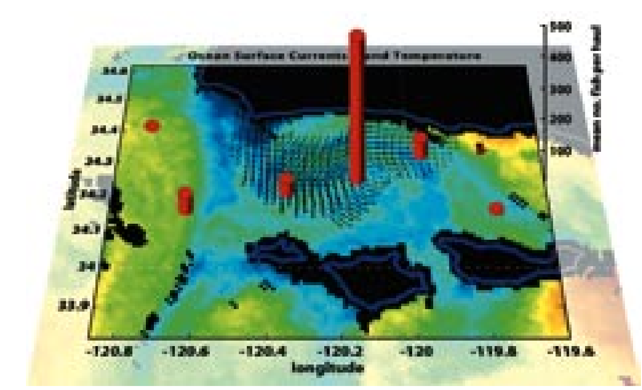

Figure 3.33. The strong link between eddy circulation and the distribution of pelagic young-of-year rockfishes. A persistent eddy about 30 km (19 mi.) wide was evident in satellite sea surface temperature imagery and in surface current mapping generated from coastal-based high frequency radar observations. The abundance of fishes were extraordinarily high in the center of the eddy (red bars represent the mean number of late-stage larval and pelagic juvenile rockfishes in midwater trawl samples from different areas).

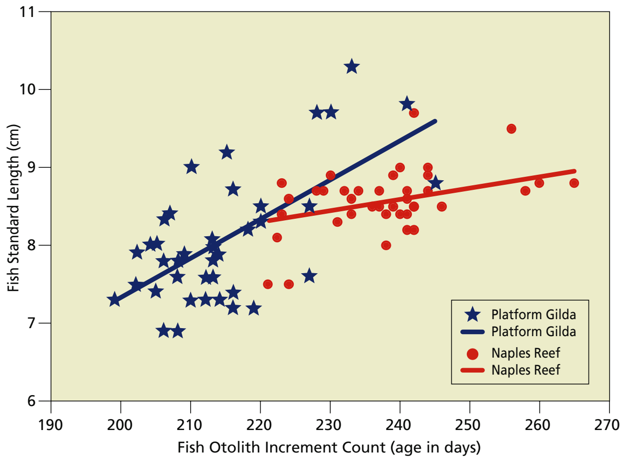

Figure 3.34. A comparison of daily growth rates of young-of-the-year blue rockfish collected at Platform Gilda and Naples Reef in 1999. Fish from Platform Gilda grew at a statistically faster rate than did those from the natural outcrop.

the Santa Barbara Channel during 1996 through 1998, the cooler waters of 1999 brought with it a relatively good year for cool-temperate rockfish recruitment throughout the channel.

The timing of this upsurge in young-of-the-year rockfish settlement in the Santa Barbara Channel also coincided with what may have been a Northeast Pacific oceanographic regime shift from warm to cool waters that overlaid the El Niño and La Niña events. This may have been reflected in the 2000 and 2001 rockfish recruitment at platforms in the eastern channel, which remained higher than pre-1999 levels. We should note that the last cold water regime off southern California occurred in the 1970s, a period that saw heavy settlement of young-of-the-year blue, olive, and widow rockfishes and bocaccio to some of the platforms near Santa Barbara (Love and Westphal 1990).

5c. If a Species Does Settle around a Platform, How Well Does It Grow and Survive, Particularly Compared to the Same Species on a Natural Outcrop?

While our studies in this area are preliminary, they are sufficiently compelling that we can begin to draw some conclusion regarding production of fishes at platforms. On many platforms, we believe that larval and pelagic juvenile recruitment is a major force in shaping platform fish assemblages. We have observed young-of-the-year of about 46 species at the platforms. Of these species, at least 35 were observed as adults at the same structures (Table 7). Adults of some species, such as pygmy, widow, and yellowtail rockfishes, are relatively uncommon around platforms suggesting different habitat requirements. Conversely, adults of many more species, including blacksmith, bocaccio, cabezon, cowcod, lingcod, painted greenling, shortspine and longspine combfishes, and calico, copper, flag, greenblotched, greenspotted, greenstriped, halfbanded, kelp, and pinkrose rockfishes are abundant at the platforms.

Pilot research suggests that at least some juvenile fishes may be growing as well or better at the platforms than at natural outcrops. In 1999, we collected young-of-the-year blue rockfish from Platform Gilda and from Naples Reef (Figure 1.1). Daily growth rates derived from these fishes from otoliths (ear bones) indicated that the platform fish grew at a statistically faster rate than did those from the natural outcrop (F-test, $F = 2.96$, $p = 0.0006$) (Figure 3.34).

Recruitment patterns of flag rockfish at Platform Grace and bocaccio at Platform Gail in 1999 and subsequent annual monitoring of year classes at these sites is providing important new information about the production value of platform habitats. In 2000, and again in 2001, we observed the 1999 year classes of these species at the bottoms of the platforms (Figures 3.35 and 3.36). Length-frequency data indicate substantial survival of the 1999 year classes at the platforms (Figure 3.36). Flag rockfish mature at about six years of age (M. Love and M. Yoklavich, unpublished data) and bocaccio at four or five years (A. MacCall, personal communication). Thus, it is conceivable that these fishes will mature at the platforms. This would be strong evidence of production at these structures. [Added in proof: We again observed these fishes during our 2002 surveys of Platforms Gail and Grace.]

5d. Both Attraction and Production Play Important Roles in Shaping Fish Assemblages at Platforms

Our research suggests that populations of fishes at platforms far removed from natural outcrops, as is true for Platforms Gail and Grace, are most likely dependent on larval and juvenile recruitment from the plankton. Our research is developing information about recruitment and residence of fishes at platforms and we have provided evidence of fishes not only settling out at platforms but also maturing there. Recruitment process is highly variable at all habitats from year to year. Adult abundance, at least for some species, is dependent on the strength of recruitment in previous years. Furthermore, recruitment variability may contribute to the year class success (i.e., demographics) of platform and outcrop species such as flag rockfish and bocaccio.

While the movement patterns of some deeper-water rockfishes are unknown, it is likely that many benthic species, such as greenspotted, greenblotched, pinkrose, and cowcod are residential (Starr et al. 2001; Love et al. 2002). Certainly many are restricted to hard substrata seafloors and probably rarely traverse large expanses of soft sediment (Love et al. 2002). Thus, it is likely that the high densities of many platform rockfishes, as well as such species as combfishes, painted greenling, and perhaps lingcod, are due to successful settlement from the plankton and subsequent survival.

The shallow-water species that do inhabit offshore platforms are further evidence that larval and juvenile recruitment play a dominant role in these structures' assemblages. Shallow species that do occur on Gail and/or Grace include kelp bass, garibaldi, and grass and kelp rockfishes. All of these fishes have pelagic larvae. Pile perch and rubberlip seaperch, species without a pelagic life stage, while found on the shallower platforms, are not present on Gail and Grace. This reflects the difficulty these species have in crossing deep waters along the seafloor.

Thus, there is growing evidence that individuals of a number of species, particularly those that are relatively resident and benthic, not only settle out at platforms but also mature there. Such species include, but are not limited to, blacksmith, bocaccio, cowcod, flag, grass, greenblotched, greenspotted, kelp, pinkrose rockfishes, painted greenling, and combfishes.

A dependence on pelagic juvenile recruitment, rather than attraction of older fishes from other structures, explains some of the differences in species composition we observed among the platforms. For instance, until 1999, we observed high densities of adult flag rockfish only at Platform Hidalgo. These densities were far higher than at other platforms or natural outcrops. In 1999, there was a strong recruitment of pelagic juvenile flag rockfish to Platform Grace, and as noted above, these fish remained there at least through 2001. [Added in proof: We observed these fish in 2002.] Annual recruitment of rockfish is highly variable. Thus, the large numbers of flag rockfish observed at Platform Hidalgo are almost certainly the result of a previous successful recruitment, similar to that at Platform Grace. Spatial variability is indicated by the paucity of this species at the other platforms. Similarly, the high densities of adult bocaccio at Platform Gail, and their absence at Platform Harvest (which is located in about the same depth), also suggests spatial variability in the recruitment process.

In contrast, the fish assemblages at platforms that are closer to shore, and in shallow waters, are probably derived both from larval/pelagic juvenile settlement and movements of juveniles and adults from other structures. Carlisle et al. (1964) clearly demonstrated that inshore reef species, such as kelp bass and sheephead, are very mobile and able to traverse shallow, soft seafloors from outcrop to artificial reef. Platform Gina, for instance, is a shallow water platform that seasonally harbors very large numbers of kelp bass, halfmoon, opaleye, pile perch, and other reef species. Fishes are abundant around that platform during summer and fall, but move elsewhere in late winter and spring.

CHAPTER 4

A GUIDE TO ECOLOGICAL AND POLITICAL ISSUES SURROUNDING OIL PLATFORM DECOMMISSIONING IN CALIFORNIA

Donna M. Schroeder and Milton S. Love

Decommissioning Alternatives

Within one year of an OCS lease termination, the Minerals Management Service (MMS) requires that the lessee remove the oil platform structure to a depth of fifteen feet below the mud line, and the leased area must be cleared of obstructions (*see generally*, 30 C.F.R. Part 250, subpart Q, § 250.1700 *et seq.*). However, the MMS may waive these requirements to accommodate conversion of a platform structure to an artificial reef provided that (1) the remaining structure does not inhibit future oil or other mineral development, (2) the resulting artificial reef complies with the Army Corps of Engineers permit requirements and procedures outlined in the National Artificial Reef Plan, and (3) a state fishing management agency accepts liability for the remaining structure (30 C.F.R. §§ 250.1703, 250.1730). In addition, the National Fishing Enhancement Act of 1984 (NFEA), which authorizes the Corps of Engineers' permit program and the National Artificial Reef Plan (33 U.S.C. § 2101 *et seq.*), allows other organizations or agencies (such as the operator) to assume liability for the artificial reef, although MMS policy to date has required a state agency to accept liability.

The timing of future decommissioning activities is not fixed. It depends on the length of the lease, the rate of reservoir depletion, the market value of oil or gas, and whether the platform might serve an extended use for the operator, such as a gathering system for the production of other platforms. There are three stages in the decommissioning process: planning, permitting, and implementation. Platform decommissioning alternatives fall into four general categories: complete removal (the default option), partial removal, toppling, and leave-in-place (Figure 4.1). The suite of decommissioning alternatives that proposes to leave part or all of the abandoned platform structure in the marine environment is often collectively referred to as "rigs-to-reefs".

Alternative 1: COMPLETE REMOVAL

A typical full-removal project begins with well abandonment in which the well bores are filled with cement. The conductors are then separated from below the seafloor by being pulled, cut-off, or removed using explosives. Next the topsides, which contain the crew quarters and the oil and gas processing equipment, are cut from the jacket and removed. Finally, the piles that hold the jacket to the seabed are severed with explosives and the jacket is removed. Other typical decommissioning requirements include the removal or abandonment of pipelines and electrical cables and the removal of any debris from the seafloor.

After deciding to totally remove a platform from the seafloor, operators have several options (O'Connor 1999; van Voorst 1999; Gibbs 2000; Terdre 2000). (1) The platform can be taken to shore, where it is disassembled and the components either recycled, sold as scrap, or discarded in landfills or other depositories. To date, managers have selected this option for most decommissioned platforms. (2) The structure can be reconditioned and reused. As an example, in 1997 a platform was removed from the North Sea, taken to shore and cleaned, refurbished, shortened by 10 m (33 ft.), and installed in another North Sea location. A few small platforms have also been reused in the Gulf of Mexico. (3) A platform can be towed to another site and reefed. This has occurred a number of times in the Gulf of Mexico, with the most zealous example towing structures of two Tenneco platforms over 1480 km (920 mi) from offshore Louisiana to a site 1.5 miles off Dade County, Florida (Wilson et al. 1987).

Alternative 2: PARTIAL REMOVAL

In this scenario, the wells are abandoned, the topsides are removed, and the remaining jacket and possibly the shell mound are left in place to continue to function as an artificial reef. Navigation aids are added.

Despite what has been implied in other reports, conductors need not be completely removed. Dauterive (2000) notes "Recognizing the preservation of environmental values associated with the method of partial removal of the platform, the MMS in 1997 established a policy to allow the industry the option to partially remove

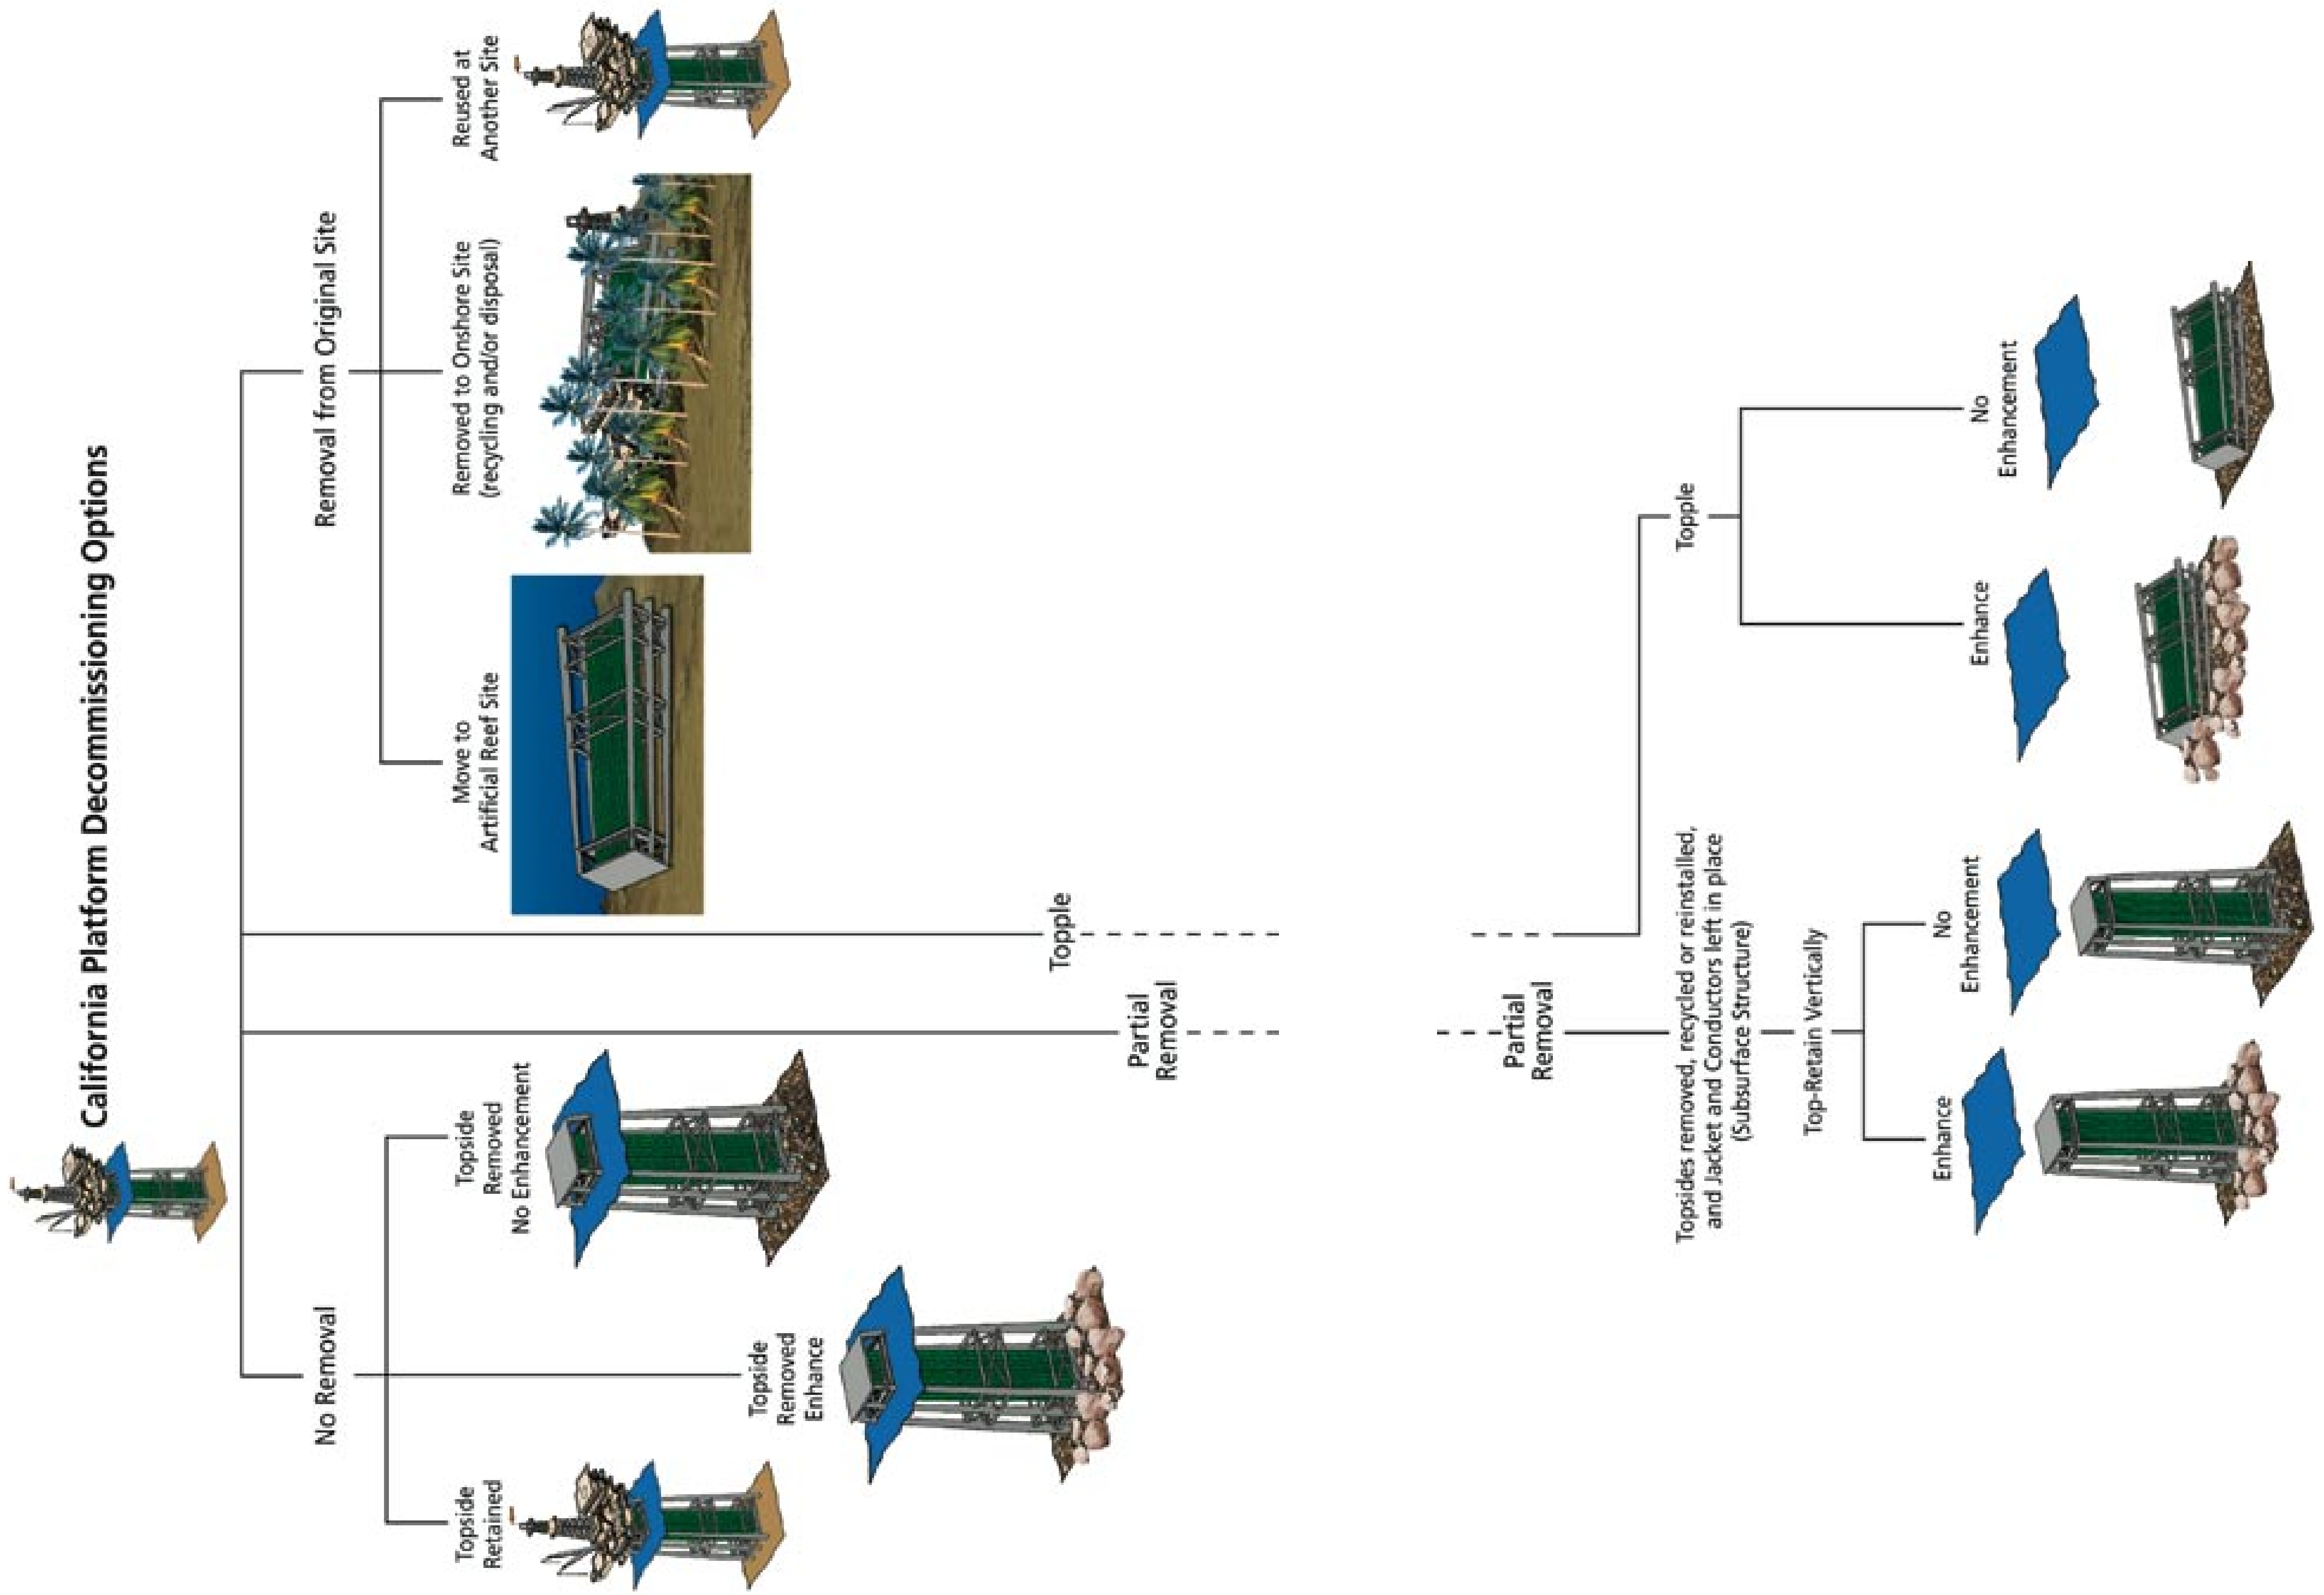

Figure 4.1. Platform decommissioning options.

the well conductors at the same depth below the water line (WL) at which the industry had proposed to remove the platform jacket." Retaining platform conductors has two consequences. First, it adds additional complexity to remaining structure. Second, explosives are usually used to remove the conductors and retaining these pipes eliminates the need for explosives (Dauterive 2000).

After cleaning, disposition of topsides may be handled in a couple of ways. It can be moved to a new platform and reinstalled, or it can be taken onshore, where the steel and other valuable components are recycled and other material sent to landfills. Certain parts of the topsides, such as the cleaned deck, have occasionally be used in forming artificial reefs.

Alternative 3: TOPPLING

As in partial removal, the wells are abandoned and the topsides are removed. The shell mounds may be either removed or left in place. The primary difference between partial removal and toppling is that, in toppling, explosives are used to sever the jacket from the seabed and then a derrick barge or pull barge drags the jacket over and it is allowed to settle to the seafloor (Twachtman 1997). Navigational aids, if necessary, are then put in place.

Alternative 4: NO REMOVAL (LEAVE-IN-PLACE)

A platform and its surrounding shell mound could be left in its original location at the time of decommissioning. The topside would be stripped and cleaned and navigational aids installed.

In the Gulf of Mexico this scenario has been discussed on a number of occasions, although it has not been attempted. For instance, a platform in the Flower Garden Banks National Marine Sanctuary was studied as a possible research laboratory. However, the cost of maintaining cathodic protection and navigational aids (together running to $300,000 per year) proved too high (L. Dauterive, personal communication). Other creative suggestions offered by stakeholders for decommissioned, left-in-place platforms include wind and aquaculture farms, meteorological stations, hospitals, hotels, gambling casinos, and penal institutions.

Agencies Responsible for the Decommissioning Process

By law, various coastal states and the federal government share the administration of submerged lands, subsoils and seabeds off the United States. Thus, depending on where platforms are positioned, responsibility for mineral extraction, including oil and gas development, is either under state or federal jurisdiction. Similarly, decisions regarding the decommissioning of platforms fall under either state or federal control, although the final decisions are based on consultation and mutual agreements among a number of agencies.

Responsibility for the fate of platforms in federal waters rests with the MMS (33 U.S.C. § 1331 *et seq.*) Federal agencies that are consulted in the decommissioning process include the Environmental Protection Agency (33 U.S.C. §§ 1311(a), 1342), Army Corps of Engineers (33 U.S.C. §§ 403,1344), National Oceanic and Atmospheric Administration (NOAA) Fisheries (16 U.S.C. § 1801 *et seq.*), and Coast Guard (14 U.S.C. § 85: 43 U.S.C. § 1333(d)). State agencies, such as the California Department of Fish and Game do not have jurisdiction in federal waters but may comment in the decision making process. Under the federal Coastal Zone Management Act (16 U.S.C. § 1451 *et seq.*), MMS decisions on platform decommissioning that will affect coastal resources are also reviewed by the appropriate state agency for consistency with the state's coastal zone management program. In California, the California Coastal Commission conducts review for consistency with the state program. In turn, state agency consistency decisions can be appealed to the U. S. Department of Commerce (16 U.S.C. § 1456(c)(3)(A), (c)(3)(B)(iii); 15 C.F.R. Part 930, subpart H).

Decisions regarding the decommissioning of platforms in California state waters are the province of the State Lands Commission (Cal. Pub. Res. Code § 6216), along with such agencies as the California Coastal Commission (Cal. Pub. Res. Code § 30330), Department of Fish and Game (Cal. Fish & Game Code § 1602), local Air Pollution Control Districts (Cal. Health & Safety Code 40000), U. S. Army Corps of Engineers (33 U.S.C. §§ 403, 1344), and the U. S. Coast Guard (14 U.S.C. § 85).

Jacket and conductor removal: the role of the U. S. Coast Guard in decommissioning

Local United States Coast Guard districts are responsible for the safety of vessel traffic in their respective geographic areas and have the authority to dictate aids to navigation for obstacles in the water (14 U.S.C. §85; 43 U.S.C. § 1333(d); 33 C.F.R. Part 67). Therefore, in instances where some part or all of a platform is to be reefed, the Coast Guard will specify the necessary navigational aids. Discussions regarding decommissioning of platforms off California have often erroneously assumed that the Coast Guard will require that the jacket be removed to about 26 m (85 ft.) below the surface. However, decommissioning experience in the Gulf of Mexico demonstrates that there is no set removal depth. Indeed, the Coast Guard decision-making process appears to be quite flexible; it reviews each decommissioning on a case-by-case basis. For instance, in the decommissioning of the mile-long Freeport-McMoRan sulfur mine platform and bridge off Louisiana, the Coast Guard required piles to be cut 9 m (30 ft.) beneath the surface (Kasprzak 1999).

Generally, the requirements for aids to navigation become more restrictive (and therefore more expensive) the closer to the surface the obstacle lies. As an example, here is a generic set of conditions for decommissioned platforms in the Gulf of Mexico based on recent Coast Guard decisions (G. Steinbach, personal communication):

- If the obstacle is greater than 61 m (200 ft.) in depth: no requirement for aids to navigation
- If the obstacle is from 61 m to 26 m (200 ft. to 85 ft.) in depth: unlighted buoys are required
- If the obstacle is 26 m to 11 m (85 ft. to 35 ft.) in depth: lighted buoys are required
- If the obstacle is from 11 m (35 ft.) to protruding through the surface: lights or lighted buoys and foghorns are required.

In the rigs-to-reefs programs in the Gulf of Mexico, the states are responsible for aids to navigation on reefed platforms. The costs of these aids are paid for from the funds created by the industry's donations. As a cost savings measure, these states generally have selected greater water clearances. The requirements for California waters may be different from those in the Gulf of Mexico. The local Coast Guard District will determine these requirements based on vessel traffic and other local conditions.

The question of liability for a reefed platform off California

Liability, who retains responsibility for a reefed platform, is a major issue in the decommissioning process. MMS policy states the "The MMS supports and encourages the reuse of obsolete offshore petroleum structures as artificial reefs in U. S. Waters." Current MMS regulations provide that a platform operator may be released from removal obligations in the federal lease instrument if a state agency responsible for managing fisheries resources will accept liability (30 C.F.R. § 250.1730). However, in situations where reefs are not managed by a state agency, another organization or agency must assume liability, as provided in the National Fishing Enhancement Act of 1984 (Stone 1985). In such cases, liability could possibly be retained by the oil company, transferred to a private entity, or handled in some other manner as long as MMS approval is received (G. Steinbach, personal communication).

An extensive body of policy and research outlines proper procedures for siting and deploying artificial reefs, and this information bears upon liability of such structures. The National Artificial Reef Plan (NARP) states "When a reef has been properly located, marked on navigation charts if necessary, and any required surface markers affixed, there should be very little potential for liability" (Stone 1985). Regarding accidents, which may occur during recreational activities near artificial reefs, the NARP further declares, "Diving accidents may occur with use by recreational divers. In this respect, an artificial reef is like a public park — there are dangers in those parks, guardrails and fences cannot be placed everywhere, and everyone who visits the park assumes some risk of injury. A warning could be placed on nautical charts and posted in local dive shops to warn of these dangers. However, each case would probably involve determination of comparative negligence" (Stone 1985). Parker (1999) notes that no lawsuits have ever been filed against the California Department of Fish and Game with respect to their artificial reef program.

Regardless of which decommissioning alternative is selected, the federal government cannot be held liable. Regarding State liability, the NARP notes, "If the permit holder is a State government, it may have sovereign immunity from liability. It is unclear whether the National Fishing Enhancement Act affects any State's claim of sovereign immunity." (Stone 1985)

National Artificial Reef Plan

Decommissioning options other than complete removal must be consistent with the National Artificial Reef Plan (33 U.S.C. § 2104(a)(4)). The National Fishing Enhancement Act of 1984 directed the development of a long-term National Artificial Reef Plan (NARP) to provide guidance and criteria on planning, construction, and evaluating artificial reef use, as well as introducing liability and mitigation issues (33 U.S.C. § 2103). Goals of the NARP seek to enhance fishing and fishery resources and minimize user conflicts and environmental risks without creating unreasonable obstruction to navigation (33 U.S.C. § 2102). In 1998, the NARP was supplemented by the Coastal Artificial Reef Planning Guide, which incorporates new language from relevant federal and state agencies, fishing interests, and the general public.

California Department of Fish and Game Rigs-to-Reef Guidelines

"These guidelines stipulate that the project must benefit living marine resources, habitat, and user groups; that disposal or use of contaminated materials is not permitted; that wherever possible the subsurface structure of the platform should remain in place; that where possible subsurface structure that must be removed could be relocated to the base of the rig or other appropriate sites; and that the remaining structure be augmented by rocks or other materials to assure that the site functions as a diverse and productive reef habitat. To replace the biotic productivity from that part of the platform removed for navigational purposes, rock or concrete reefs should be placed in nearshore locations. A rigs-to-reef project sponsor must provide sufficient funds to the Department to evaluate the benefits to biotic productivity, user groups, and the overall management of fishery resources." (Holbrook et al. 2000)

Social Values in Platform Decommissioning

Defining the social and ecological goals of decommissioned platforms as artificial reefs will be critical in evaluating the efficacy of any potential rigs-to-reef program and the current and future performance of any artificial reef. Therefore, it is likely that various stakeholder groups will vie in defining the goals (and therefore the usefulness) of decommissioned platforms as artificial reefs. In this report, we sort the multitude of stakeholder viewpoints regarding a rigs-to-reef program into three groups, each of which is primarily defined by one concern: community membership, resource accessibility and environmental (marine life) issues. Of course, an individual may be influenced by more than one social value, and others may use arguments from multiple categories to promote a desired decommissioning outcome.

The first group consists of stakeholders who are concerned about community membership, and either oppose or support local presence of the oil industry. Those that wish to promote a community without the oil industry often view reefing alternatives as bundled together with all oil industry activities (e.g., continued exploration and production), the whole of which should be locally opposed (although they may not be opposed to oil industry activities in the Gulf of Mexico). For example, Camozzi (1998a) states that complete removal should be the preferred alternative in decommissioning because, after decades of fighting oil development on the California Coast, it acts as a "catharsis" for the local community. Camozzi (1998b) reiterates this point by stating that, in regard to mussel mound removal, "Sending a message to oil companies that they must clean up our coast when they are done extracting their profits is the most vital issue in this case." Individuals who wish to encourage or maintain the presence of the oil industry in the local community, presumably for economic reasons, favor some sort of reefing option because reefing is less expensive than complete removal (Pulsipher et al. 2000). Further information regarding local community views on the oil industry in California can be found in Lima (1994) and Smith and Garcia (1995).

The second group of stakeholders is primarily concerned with resource accessibility. A heterogeneous group, these citizens will either favor or oppose decommissioning alternatives depending on how these alternatives aid or inhibit their ability to access a particular resource. For example, commercial trawlers in the Southern California Bight favor complete removal because fishing gear may snag on platform structure or shell mounds (Southern California Trawlers Association 1998; McCorkle 1999). Other commercial fishers benefit from oil industry activities. Shrimp trawlers in the Gulf of Mexico drag within 0.4 km (0.25 mi) of platform structures, reporting that these fishing grounds tend to be more productive (Wilson et al. 1987). The rocky habitat associated with Rincon Oil Island in California provides excellent lobster fishing grounds and trap fishers would oppose seeing this habitat removed (Miller 1999). Recreational fishers often dominate the debate surrounding platform decommissioning, and they have driven the formation of artificial reef policy at both state and federal levels (Stone 1985; Wilson et al. 1987). Many recreational fishers favor a reefing alternative in decommissioning because catch per unit effort is often high at offshore platforms for targeted fish species such as kelp bass (Love and Westphal 1990; McCrea 1998). In the Gulf of Mexico, Reggio (1987) estimates that 70% of fishing excursions target oil platform habitats. Citizens participating in non-consumptive activities also possess a variety of viewpoints regarding decommissioning alternatives. Many scuba divers find that underwater portions of oil platforms provide outstanding diving and underwater photographic opportunities, and favor decommissioning alternatives that preserve such opportunities, (Vallette 1999). Other members of the public may view the topside structure of platforms as denying them access to unobstructed, scenic ocean views, and consequently they oppose the leave-in-place decommissioning option (Wiseman 1999).

The third stakeholder group makes decisions regarding decommissioning based on their perception of how certain marine populations or environmental ideals fare under the various decommissioning alternatives. It is this last group that is most likely to use ecological information in making decisions regarding platform decommissioning. A decommissioning option that involves reefing may be supported if a substantial net benefit to the marine environment can be demonstrated (Chabot 1999). Others support complete removal because this option is the only one which promotes a wilderness ideal, that is, a marine environment which fails to retain a visible mark of human activities. If there is a lack of scientific evidence regarding ecological consequences, or if they are unaware of such consequences, these stakeholders may use another social value, such as community membership, in choosing a preferred decommissioning alternative (Chabot 1999).

Economic incentives interact and overlap with social values. In past rigs-to-reefs activities, industry and state entities have equally shared the cost-savings resulting from partial removal or toppling alternatives. Partial removal of deep water platforms will generate estimated savings of one to two orders of magnitude greater than the amount saved in decommissioning smaller platforms. The cost of maintaining navigational equipment (if any is needed) at these reefed platforms will not increase in the same proportion as the increase in cost-savings, and may actually decrease. These additional financial resources may be used to develop or enhance projects of interest to stakeholders, and may be a sufficient incentive to alter the preferred decommissioning option for some groups.

The Interaction of Science, Scale, and Social Values

State and federal regulatory agencies involved in the decommissioning process are required to protect the public interest when managing natural resources. In the face of strongly conflicting viewpoints among stakeholder groups, resource managers may try to convert a controversial issue into a technical one. For instance, they may give preference to the protection of marine life resources, thereby avoiding the appearance of favoring one group's economic concerns over another's. Additionally, legislation such as the Endangered Species Act and the Marine Mammal Protection Act, among others, often give environmental concerns priority over social and economic concerns. In combination, these issues give ecological information a prominent role in the decommissioning process.

Impacts to the environment may be measured at short or long time scales, or within a local or regional context. As time and space scales increase, so does scientific uncertainty about predicting consequences of various management alternatives (due to an increasing number of unknown variables and propagation of error associated with imprecise assumptions or model parameters). When there is greater scientific uncertainty, social values and political or economic factors often become more important in the decision-making process. This phenomenon may result in stakeholders advocating that ecological performance of reefed platforms be evaluated at scales which enhance the possibility of their preferred decommissioning alternative, even if ecological data are irrelevant to their concerns.

For example, proponents of regional ecological assessment at long time intervals may be individuals who oppose the local presence of the oil industry. Since regional assessment is difficult and expensive to accomplish, social values (e.g., antagonistic views of oil industry) will increase in importance. Significantly, these same individuals have not stipulated that other artificial reefs which are similar to reefed platforms, such as steel hulled ships, undergo the same rigorous ecological assessment. Further, the assured instantaneous and lethal effects of explosives are not considered in arguments about marine life effects.

Proponents of small scale ecological assessment tend to be recreational anglers, who often state their support for rigs-to-reef programs in terms of benefits to the environment. They maintain that the local presence of abundant marine life at a platform is sufficient evidence of satisfactory ecological performance. But this support for a rigs-to-reef alternative often evaporates if artificial reefs are designated no-take areas.

Ecological information greatly aids the decision-making process if explicit management goals are specified. The rebuilding of depleted fish stocks might be one goal, the preservation and expansion of marine wilderness might be another. Determination and ranking of ecological goals reflects cultural values. Thus, controversies surrounding platform decommissioning cannot easily be translated into technical issues by giving priority to ecological goals because we lack agreement on the space and time scales in which ecological impacts should be measured. Therefore, the scale at which ecological impacts are measured (local or regional) and considered (short or long term) becomes paramount in the decommissioning process. To date, such specific space and time scales have not been designated by any state or federal government agency.

Decommissioning Activities in the Gulf of Mexico

To date, almost all platform decommissioning and reefing in the world has occurred in the Gulf of Mexico. Because large-scale offshore drilling first took place in the Gulf of Mexico, it was in this region that the issue of what to do with unwanted platforms first arose. Below, we give a brief summary of the history of decommissioning in the Gulf of Mexico; additional details are found in Lukens (1997), Kasprzak (1998), and Dauterive (2000).

Kerr-McGee erected the first offshore oil and gas platform in the Gulf of Mexico off Louisiana in 1947. Despite its primitive structure and placement in waters only 6 m (18 ft.) deep, oil was struck 22 days after drilling began, presaging a veritable tidal wave of offshore drilling. In 2001, there were over 4,000 platforms in the Gulf of Mexico, the vast majority occurring off Louisiana, followed by Texas, Mississippi and Alabama (Lukens 1997; Moritis 1997; Kasprzak 1998, 1999; Dauterive 2000). Platforms provide a considerable amount of the hard substrate in the north-central Gulf of Mexico, and surveys indicate that 20%–50% more fish live around platforms than on surrounding soft seafloors (Gallaway and Lewbel 1982; Driesen 1985). Because recreational and commercial fishers target fish residing near these structures, they are of considerable economic value (Dimitroff 1982; Reggio 1987; Kasprzak 1998).

By the late 1970s, it was apparent that the economic life span of many of these structures was nearing an end. During that decade, about 150 platforms were removed to shore and scrapped. The first reefing of an oil and gas structure occurred in 1979 when a subsea production system was towed from Louisiana to an artificial reef site off the Panhandle of Florida. In 1982, an obsolete platform jacket was moved from Louisiana to a Dade County, Florida site and over the next few years several additional structures were moved to various artificial reef sites.

Responding to this new activity, Congress passed the National Fishing Enhancement Act (NFEA) in 1984 (33 U.S.C. § 2101 *et seq.*). The NFEA mandated the creation of a "long-term plan for siting, constructing, permitting, installing, monitoring, managing, and maintaining artificial reefs within and seaward of state jurisdictions" (Kasprzak 1998). This document, later called the National Artificial Reef Plan, was published in 1985. In response to NFEA, several Gulf of Mexico states have now passed laws to take advantage of platform decommissioning to help preserve complex habitat in the northern Gulf of Mexico, for example, the Louisiana Fishing Enhancement Act of 1986 (La. Rev. Stat. § 56:639.1 *et seq.*) [Act 100] and the Texas Artificial Reef Act of 1989 (Tex. Parks & Wildlife Code § 89.001 *et seq.*). As an example, Act 100 created a process by which ownership of and liability for uneconomical platforms could be transferred from operators to the state of Louisiana. As noted by Kasprzak (1998), "Act 100 established the State of Louisiana as the permittee for artificial reefs developed under the program's jurisdiction and appointed the Department of Wildlife and Fisheries as agent for the state. The state assumes responsibility for the reefs upon placement within the established reef permit area…Act 100 does not authorize state general funds for the artificial reef program but does establish the Louisiana Artificial Reef Trust Fund. Oil and gas companies that donate structures to the program are asked to contribute half of the disposal savings realized through program participation to the trust fund." A similar program exists in Texas (Texas Parks and Recreation 1999).

A significant amount of money has been collected in rigs-to-reef programs in both Louisiana and Texas. As of 2001, there was about $15 million in the Louisiana fund and at least $4 million in Texas. Contrary to what has been reported (McGinnis et al. 2001), major artificial reef programs of several states, including Louisiana and Texas, receive neither state nor federal funding, they are fully underwritten by the interest paid on their respective rigs-to-reef accounts (J. Culbertson, personal communication; R. Kasprzak, personal communication). The Louisiana Department of Wildlife and Fisheries and Texas Parks and Wildlife Department describe their rigs-to-reefs programs at http://www.wlf.state.la.us (under "Marine Fisheries") and http://www.tpwd.state.tx.us/fish/reef/artreef.htm, respectively.

Since 1942, over 188 Gulf of Mexico platforms have been reefed, primarily off Louisiana and Texas. This represents about 8.4% of all decommissioned platforms (L. Dauterive, personal communication). The reasons for this early low reefing rate were economic. Most of the platforms thus far decommissioned were in shallow water, and it was more cost effective to haul them onshore for salvage or reuse rather then tow them to reefing sites. In the future, it is likely that a higher proportion of platforms will be reefed as more offshore structures become obsolete. Of the platforms that have been reefed, about 60% have been removed from a site and towed to a new location. Contrary to what was stated by Krop (1998), some decommissioned platform structures have been left in place. Thus far, 30% have been toppled in place and the remainder have been partially removed and left standing (Dauterive 2000). As larger platforms in deeper waters are decommissioned, L. Dauterive (personal communication) has noted a trend towards partial removal, rather than towing or toppling. In all but a few instances, only the platform jacket has been used as reef material.

The Future: Ecological Consequences of Offshore Platform Decommissioning in California

Complete Removal (Total Removal) of Platform

The immediate impact of removing and hauling an entire platform to shore is that all attached animals die. If some of the platform structure is hauled to a reef area and replaced in the water, some of these animals may survive, depending on water depth and the length of time the structure is exposed to the air.

Using explosives to separate the jacket from the seafloor kills large numbers of fishes, although limited research makes it difficult to predict how many deaths will occur. Marine mammals and sea turtles may also be indirectly killed by damage to the auditory system. In a study in the Gulf of Mexico (Bull and Kendall 1994), explosives were placed 5 m (15 ft.) below the seafloor to sever the well conductors, platform anchor pilings and support legs, of a platform in about 30 m (100 ft.) of water. All of the fishes on or near the bottom and most of the adult fishes around the entire platform suffered lethal concussion.

Some shallow-water platforms can be removed without explosives. However, "The oil and gas industry has attempted to find alternatives to the use of explosives, such as cryogenic cutting, hydraulic abrasive cutting, mechanical cutting, and torch cutting. Most of these techniques either have proven to be ineffective or are successful only in limited situations. At present, the industry maintains that the use of explosives is by far the safest, most reliable, and most cost-effective method of platform removal" (Kasprzak 1998). A recent assessment of techniques for removing platforms (NRC 1996) found that it is unlikely that any techniques or devices now known will significantly reduce fish kills during removal operations that use explosives.

Shell Mounds at the Base of Platform

The jackets and conductors of all platforms off southern and central California are heavily encrusted with invertebrates, including mussels, barnacles, seastars, rock scallops, rock oysters and jingle shells, sea anemones, caprellid amphipods, rock crabs, limpets, gooseneck barnacles, and sessile tunicates. An extremely thick layer of mussels extends from the intertidal zone to depths of at least 30 m (100 ft.) (and deeper on some platforms). The seafloor surrounding the platforms is covered with mussel shells. This "shell mound" or "mussel mound" is created when mussels, and other invertebrates, are dislodged during platform cleaning or heavy swells. Our observations show that, depending on bottom depth, a number of species of invertebrates, including many species of seastars, brittle stars, and rock crabs, as well as king crabs, opisthobranchs, shrimps, octopi, and sea anemones are abundant on the shell mounds. Substantial number of fishes, primarily the juvenile stages of various rockfishes, adult stages of dwarf rockfish species, as well as lingcod, poachers, painted greenling, and other benthic species also inhabit shell mounds.

Around four platforms in shallow water locations (+/- about 33 m, 109 ft., water depth), the shell mounds were found to be many meters thick, and were found to cover accumulations of drilling muds and cuttings. Investigations of the shell mounds around deep-water platforms have not been completed. Nevertheless, because of the potential for environmental harm, this issue must be addressed for all platforms regardless of the decommissioning option pursued. The level of contamination, while localized, has been shown to vary from platform to platform. Therefore, any remedial actions taken during the decommissioning process will likely be determined on a case-by-case basis. Although the regulatory requirements are still evolving, the alternatives being discussed include leaving the shell mounds undisturbed, smoothing and shaping them to allow for trawling, capping the shell mounds with an impervious material, adding material to the mounds for enhancement, or completely removing the shell mounds.

The removal of shell mounds may have a number of consequences to marine life by (1) removing habitat and (2) the potential for releasing toxins into the water column during the removal process. The biological consequences of either removing, altering, or leaving the shell mounds in-place must be given appropriate attention in the decommissioning process.

Partial Removal of Platform

Since partial removal reduces or eliminates shallow water habitat from the platform structure, this alternative would likely result in lower species composition and diversity than at the start of decommissioning process. Response of biotic communities will depend upon how much of the upper portion is removed. Depending on the platform, fewer nearshore reef fishes, such as surfperches, basses, and damselfishes may occur. Invertebrates that only reside or recruit to shallow water habitat would also be absent. Since the majority of mussels are located at shallow depths, shell mound replenishment will be reduced or absent, and affect the persistence of that community.

Since partial removal does not require the use of explosives, there is relatively little marine mammal, sea turtle, fish and invertebrate mortality compared to complete removal. Vertebrate and invertebrate assemblages associated with the remaining platform structure are assumed to be minimally affected.

A number of misunderstandings surround predictions regarding the potential ecological consequences of partial removal.

(1) Some stakeholders and policy analysts have erroneously assumed that Coast Guard regulations require a minimum depth below the ocean surface to which a reefed platform must be reduced. However, as noted earlier, the decision on how much of the jacket and conductors is left in place is based on both a Coast Guard assessment and the willingness of the liability holder to pay for the requisite navigational aids. As mussels become rare below 30 m (100 ft.) on most platforms, the mistaken assumption that all topped platforms must be cut to 24–30 m (80–100 ft.) below the surface has led some to conclude that partial removal will inevitably lead to a severe reduction in the amount of mussels that fall to the bottom and, thus, to a change in or end to the shell mound community. This is not necessarily the case.

(2) Some reports suggest that partial removal will lead to a large decrease in juvenile rockfish densities; our research does not support this supposition. On the offshore platforms in the Santa Barbara Channel region, the juveniles of most rockfish species (particularly blue, bocaccio, halfbanded, olive, pygmy, squarespot, starry, widow, and yellowtail) are uncommon in waters shallower than 26 m (85 ft.). Partial removal could reduce fish densities if pelagic juvenile stages of these rockfishes first encounter a platform in shallow surface waters, then swim downwards below the 26 m range, causing pelagic juveniles to "miss" a platform. However, young-of-the-year rockfishes of many of these species recruit from the plankton in large numbers both to natural outcrops in nearshore waters and to those coming out of deeper waters that have crests in about 30 m (100 ft.) of water. This indicates that emergent structure is not necessary for these juveniles to locate suitable habitat.

On the other hand, the pelagic stage of a few rockfish species, particularly copper, gopher, black-and-yellow, and kelp may prefer to recruit shallower portions of the platform than other rockfish species (Holbrook et al. 2000; this report). These species recruit to nearshore rocky outcrops and kelp beds and do not appear to settle in deeper waters (Larson 2002a,b). For these species, partial removal of a platform would probably decrease juvenile recruitment, depending on the uppermost depth of the remaining structure.

(3) Errors regarding factors affecting juvenile fish mortality have also lead to confusion. McGinnis et al. (2001), in describing the history of artificial reef research in California, states that "Research has shown that high relief, open structures serve best to attract fish, and better enable fishery exploitation, while low relief, complex structured reefs provide better nurseries and afford more diverse assemblages of fish and other organisms". McGinnis et al. (2001) also cite an anonymous California Department of Fish and Game biologist who notes that "a drawback to rigs as reefs is that they are high relief, which works against survival of young-of-the-year fish, suggesting they may not be a source of production but rather simply an attraction site."

We know of no research that can support the above claims, and the authors do not cite any specific studies. Predators are the main source of juvenile fish mortality in marine systems; death due to starvation or exposure is rare. Thus, variation in habitat structure would modify juvenile fish survivorship by modifying the success rate of predators. Presently, no studies have assessed comparative performance in survivorship rates between platforms and natural habitats. Alternatively, we may begin to infer potential predator vulnerability between habitats by examining the ratio of juvenile fishes to piscivorous fishes. In the shallow portion of Platform Irene, the ratio of juvenile rockfishes to piscivorous fish is about 25:1 and at nearby Tarantula Reef it is 3:1 (Appendix 2; Schroeder, unpublished data). Conversely, in the east Santa Barbara Channel, at Platform Gina the ratio is 1:5, and at Portuguese Rock, Anacapa Island it is 1:1.4.

Toppling of Platform

Toppling would produce reefs with somewhat different fish assemblages than what has been observed around intact platforms. Consequences of removal of shallow water habitat would be similar to that of partial removal. In California, because most platforms reside in fairly deep water, toppled platforms would also harbor fewer young-of-the-year rockfishes, just as the reefs adjacent to Platform Hidalgo harbor fewer of these animals. Depending on the characteristics of the platform, a toppled structure, with twisted and deformed pilings and beams, might have more complexity than an upright one. This might increase the number of such crevice dwelling fishes as pygmy rockfishes.

No Removal (Leave-in-Place) of Platform

The no-removal option would allow the platform and shell mound to continue to function as they had when the structure was occupied. Decommissioning activities would result in small mortality impacts to resident marine populations.

What is the Life Span of a Reefed Platform?

How long can a decommissioned steel platform survive in the marine environment before rusting away? Operating steel platforms are protected by sacrificial anodes, often made of aluminum or zinc, which preferentially corrode before steel, thus preserving the jackets' integrity. This cathodic protection lasts as long as the anodes are intact, usually for a number of decades. It is assumed that, once a platform is reefed, there will be no additional replacement of the sacrificial anodes, although the issue has yet to be addressed for platforms off California. While corrosion rates vary in seawater, depending on water temperature, biofouling and other factors, it is estimated that the life span of a cathodically unprotected platform will range from a minimum of 100 to more than 300 years (Quigle and Thorton 1989; Mishael 1997; Voskanian and Byrd 1998).

Pipelines Associated with Platforms

Pipelines run from all platforms either to shore or to other platforms that collect the oil or gas and then ship it to shore. McGinnis et al. (2001), note that "Both Federal and California regulations allow decommissioned OCS pipelines to be abandoned in place so long as they do not constitute a hazard to navigation, commercial fishing or unduly interfere with other uses of the OCS." (See also 30 C.F.R. § 250.1750; CA. PUB. RES. CODE § 6873.) In the Gulf of Mexico, few pipelines have been completely removed in the course of decommissioning (Breaux et al. 1997).

In 2001, using the research submersible *Delta*, we conducted pilot surveys of a pipeline between Platforms Gail and Grace. We found this pipe to be heavily encrusted with such invertebrates as anemones, crinoids, basket stars, and seastars. We also noted relatively large numbers of fishes, particularly juvenile or dwarf fishes, including cowcod, flag, blackgill, striped, and vermilion rockfishes, along with poachers and flatfishes. Both fish and invertebrate densities were much higher than found on the surrounding mud bottom.

Resource Management Issues Associated with Decommissioning

Habitat Enhancement of Reefed Platform Structure

The California Department of Fish and Game has issued guidelines for rigs-to-reef projects that call for enhancing the remaining structure using quarry rocks or other material (Parker 1998). Adding such material would increase the number of crevices and hiding places suitable for smaller sized fish. Thus, species which are rare or absent from observed platform fish assemblages, such as pygmy rockfish, may then occur. The ecological community response may depend on the type of habitat enhancement and has not been examined.

Marine Protected Areas

To a certain extent, the platforms in the Santa Barbara Channel and Santa Maria Basin currently act as de facto marine protected areas (Schroeder and Love 2002). Fishing pressure around many of these platforms is relatively low because (1) some platforms are relatively far from harbors and thus from fishing vessels, (2) four platforms (Irene, Hidalgo, Harvest, and Hermosa) are located near Point Conception in waters that are extremely rough for much of the year, and (3) it is difficult to fish close to operating platforms because tying up to these structures is discouraged by platform operators.

Clearly, many reefed platforms would be a target for recreational anglers or commercial fishermen because platforms often host sizable local populations of sought-after fish species. Off Florida, Shinn and Wicklund (1989) suggest that patterns of large fish at Tenneco platforms may be in part determined by fishing activities. Thus, in California, it has been proposed that reefed structures be designated as no-take areas (California senate bill introduced by D. Alpert). In addition, it may be possible to modify the architecture of reefed platforms to make them difficult to fish. For instance, because most of the target species are found inside the bottom of platform any structure above the bottom would prevent gear from reaching the seafloor, thus inhibiting the capture of many fishes.

Decommissioning Alternatives in Relation to National Marine Fishery Service's Fishery Rebuilding Plans

The use of explosives to remove or topple a platform may compromise fishery-rebuilding programs. Cowcod provide one example. This species has been declared overfished by NOAA Fisheries (formerly known as the National Marine Fisheries Service) and is the subject of a federal rebuilding plan. The Pacific Fisheries Management Council has approved a cowcod rebuilding plan that limits fishery impacts to 1% per year (about 2.4 metric tons for 2001), as part of a 95-year rebuilding period, and the use of spatial closures south of Point Conception to reduce bycatch mortality. As noted earlier, our observations around Platform Gail indicate it has the highest density of adult cowcod and bocaccio of any natural or artificial structure surveyed. We can make an estimate of the number of cowcod at the bottom of Gail by multiplying the density of cowcod observed by the area of the platform's footprint (the area underneath the platform). For instance, in the last two years of the survey, 1999 and 2000, observed cowcod densities were 0.015 and 0.0183 fish per m^2, respectively. As Gail's footprint is 5,327 m^2 (Holbrook et al. 2000), extrapolation for 1999 and 2000 gives estimates of 79 and 97 individuals respectively. This conservative estimate does not include juveniles we have observed living on the shell mound or on the adjacent pipeline. The current rebuilding plan calls for both a quota on commercial and recreational fisheries combined of 2.4 metric tons, equal to about 600 fish (T. Barnes, personal communication). Assuming that Platform Gail has 75 or more cowcod living under it, and if, as seems likely from all known research, explosives used to remove or topple a platform will kill all of them, that loss may be sufficiently large to complicate the rebuilding plan (T. Barnes, personal communication).

LOVELAB, UC SANTA BARBARA

Spotted ratfish on shell mound at Platform Gail.

CHAPTER 5

RESEARCH AND MONITORING RECOMMENDATIONS

When Governor Davis vetoed SB 1, a bill that would have allotted some of the savings derived from reefing platforms to California, he wrote, "There is no conclusive evidence that converted platforms enhance marine species or produce net benefits to the environment…it is premature to establish this program until the environmental benefits of such conversions are widely accepted by the scientific and environmental communities." And, with respect to assessing the effect of different decommissioning options on marine populations, Holbrook et al. (2000) state that the key marine ecological question is, "What is the effect of each decommissioning alternative on regional stocks of reef-associated species in general, or of particular targeted species?" Clearly, in the decommissioning process, there is a need for additional information.

Below we list examples of research that would be useful in addressing these issues. Many of these examples have been suggested by various resource managers. The first two tasks are necessary to resolve issues regarding attraction or production of platform and natural habitats as well as helping to define essential fish habitat. In addition to aiding in the platform decommissioning process, these three tasks will also aid in future coastal zoning and mapping that would occur in any future boundary expansion of the Channel Islands Marine Sanctuary.

Compare ecological performance between oil platforms and natural outcrops and determine if any oil platforms serve as Essential Fish Habitat for focal species.

What fishes live around platforms and nearby natural reefs?

In order to assess the relative importance of a platform to its region, it is essential to conduct basic surveys not only around the platform, but also at nearby reefs. A majority of platforms have not been well surveyed or have not been surveyed at all. Both scuba and submersible surveys must be conducted.

How does fish production around platforms compare to that at natural outcrops?

Fish production can be assessed and compared between habitats by examining a number of ecological yardsticks. These include (1) fish growth rates, (2) mortality rates, and (3) reproductive output. As an example, we conducted a pilot study comparing the growth rates of young-of-the-year blue rockfish at Platform Gilda and Naples Reef. More research needs to be conducted in all of these areas. For instance, mortality rates can be estimated by sequential surveys of the densities of young fishes at a specific platform or natural outcrop. Reproductive output (larval production in the case of rockfishes) can be quantified by first estimating the size frequency and density of a species at a platform or natural outcrop. Then, using size-fecundity relationships from the literature, the potential annual larval production for that species can be calculated.

How does trophic structure around platforms compare to that at natural outcrops?

How do platforms and natural outcrops compare in terms of habitat value?

A relatively new measure called Habitat Value (HV) allows comparisons between habitats, incorporating fish density, fish length, and fish regularity of occurrence. In Stephens et al. (1999), we presented a preliminary analysis of nine platforms and found that platform HVs tended to be much higher than those for open coastal soft substrate, higher than low relief deep rock outcrop and in the same range as wetlands and kelp/rock natural outcrops. An analysis of all of the platforms and as many outcrops as possible should be conducted.

Can we identify areas that are Essential Fish Habitat?

All of the above studies contribute to answering this question.

Define the spatial distribution of economically important species (all life history stages) within the region of interest and define connectivity of habitats within this region.

What is the relative contribution of platforms in supplying hard substrate and fishes to the region?

This research would put in perspective the relative contribution of platforms in supplying hard substrate and reef fishes to their environment.

First, this requires an assessment of the rocky outcrops in the vicinity of each platform; this is derived from seafloor mapping. Much of the seafloor in the vicinity of platforms remains to be characterized. Once the mapping is complete, visual surveys of the outcrops, using a research submersible, will determine the fish assemblages and species densities in these habitats. Knowing the areal extent of both natural and platforms habitats and the densities of each species in both of these habitats, it is then possible to assess the total contribution of each platform to the fish populations and hard substrate in that region.

How long do fishes reside at platforms?

It remains unclear how long fishes are resident around a platform. For instance, do the large numbers of fishes, such as the overfished bocaccio and cowcod, remain around the platforms for extended periods? One settled on a platform, how long do young-of-the-year fishes remain there? A knowledge of the residence time of these species would allow for a more accurate determination if platforms form optimal habitat for these species and if they are indeed acting as long-term marine reserves. Residence time can be determined through the use of both tagging studies and observations of a year class through time.

Acoustic tags are one way to determine fish residency. In a pilot study, Dr. Christopher Lowe, at California State University, Long Beach, captured and acoustically tagged rockfishes at Platform Gail and, after one year has determined that all have remained around the platform. Broader studies, covering additional platforms, outcrops, and species are needed.

What are the effects of platform retention or removal on fish populations within a region?

As an example, what effect would platform retention or removal have on fish recruitment? For instance, would the young rockfishes that settle out at a platform survive in the absence of that platform? Our surveys demonstrate that planktonic juvenile fishes, particularly rockfishes, often settle out of the plankton to a platform in substantial numbers. If that platform did not exist, would these young fishes have found, and settled upon, natural outcrops? In a pilot project, we are using radar-derived (CODAR) current data to estimate where the young rockfishes that settled at Platform Irene would have gone if Irene had not existed. We identify the direction and distance of pathways from the platform to natural outcrops. A directional histogram of radar-derived trajectories will show the degree to which surface currents potentially carry larvae in any given direction from the platform site. Knowing how long it would take rockfish larvae to reach suitable natural outcrops, and what percent of these larvae would likely die before reaching these outcrops, will give a sense of the importance of a platform as a nursery ground. Similarly, using a synthesis of oceanographic information, it is possible to model the drift direction of larvae produced by fishes living at a platform.

It would be useful to understand the natal origins of fishes residing at platforms and natural outcrops. Both genetic and otolith microchemistry techniques might aid in determining the degree of dispersal of fishes produced at platforms and natural outcrops.

Understand how habitat modification of platform environment (e.g., removal of upper portion or addition of bottom structure) changes associated assemblages of marine life at offshore platforms.

All decommissioning options except leave-in-place involve modification of the current physical structure of offshore platforms. Is it possible to increase fish diversity and density by altering the seafloor or the platform itself? For instance, it would be useful to add complexity, in the form of quarry rock or other structure, to the shell mound around a platform, and follow the changes in fish assemblages.

Descriptive information such as depth distribution and life history information is also useful in determining how decommissioning options affect the environment. Experimental research, using a BACI design or similar approach, can aid in predicting how the biotic community will respond to such structural changes.

ACKNOWLEDGEMENTS

This research was funded by the Biological Resources Division, U. S. Geological Survey (National Offshore Environmental Studies Program 1445-CA-0995-0386) based on an information need identified by the Minerals Management Service's Pacific OCS Region, as well as by the Minerals Management Service and the California Artificial Reef Enhancement Program (CARE). We would like to thank Lyman Thorsteinson for his unflagging support for this research. Ann Bull and Lyman Thorsteinson carefully reviewed the first draft and we wish to express our sincerest thanks. George Steinbach reviewed our discussion of the platform decommissioning process and options and made very constructive comments.

We greatly appreciate the efforts of Roberta Bloom, UCSB Artworks, who was responsible for the layout and many of the graphics. Also, we would like to thank the following companies for granting us permission to survey their platforms: Arguello Associates, Chevron Texaco, Nuevo Energy Company, Pacific Operators Offshore, Torch Operating Company, and Venoco Incorporated.

We thank the pilots of the submersible *Delta*, Chris Ijames and Dave Slater, for their very professional handling of the technical aspects of that survey, as well as the crews of the R/V *Cavalier*, R/V *McGaw* and R/V *Valero*. Linda Snook managed the deep-water survey data. We thank Craig Syms for his masterful analyses of the deep-water survey data. Frank Donohue, skipper of the F/V *Gus D*, was an essential part of our pelagic fish surveys. Dr. Edward Brothers compared daily growth rates of blue rockfish. Dr. Mark Carr provided advice and field assistance early in the research program. Dr. Libe Washburn assisted us in planning the biological oceanographic surveys and in subsequently interpreting data from those surveys. Many thanks to the scuba divers who helped us collect data, including Arnold Ammann, Scott Clark, Becky Frodsham, Lise Goddard, William Golden, Jeff Harding, Eric Hessell, Janine Kido, Laird MacDonald, Scott Mau, Melissa Meeker, Michelle Paddack, Chris Thompson, and Jordan Watson. We thank Edwin Beckenbach, Christy Herren, Matt Knope, Elan Love, Kurt McClure, Karina Mendiola, Martin Moreti, Dawn Outram, Maria Petueli, Toni Ross, David Salazar, Clara Svedlund, Melinda Simmons, Eric Simons and others for all manners of assistance in the field and laboratory. Frank Manago and Fred Piltz were always very supportive of our research. We received much useful information about platforms and platform decommissioning from Lee Bafalon, Rob Campbell-Taylor, John Deacon, Tom Dunoway, Rod Eason, Mike Edwards, Jim Galloway, David Gebauer, Jeff Goddard, Rick Kasprzak, Herb Leidy, Jim Lima, Michael Mitchell, Greg Pelka, Karen Robertson-Fall, David Rose, George Steinbach, and Marina Voskanian. Glenn Shackell provided the ROV platform inspection tapes. Linda Nelson drew one of the cowcod images for one of the figures. The California Department of Fish and Game provided the net for the midwater trawling surveys. Finally, we offer apologies to anyone we may have inadvertently forgotten to acknowledge.

PERSONAL COMMUNICATIONS

Tom Barnes, California Department of Fish and Game, La Jolla, California.

TABLES

TABLE 1. Common and scientific names of fishes observed in these studies.

Common Name	Scientific Name
Bank rockfish	*Sebastes rufus*
Barred sand bass	*Paralabrax nebulifer*
Barred surfperch	*Amphistichus argenteus*
Bat ray	*Myliobatis californica*
Bearded eelpout	*Lyconema barbatum*
Big skate	*Raja binoculata*
Black-and-yellow rockfish	*Sebastes chrysomelas*
Blackeye goby	*Rhinogobius nicholsi*
Blackgill rockfish	*Sebastes melanostomus*
Black rockfish	*Sebastes melanops*
Blacksmith	*Chromis punctipinnis*
Black perch	*Embiotoca jacksoni*
Bluebanded goby	*Lythrypnus dalli*
Bluebarred prickleback	*Plectobranchus evides*
Blue rockfish	*Sebastes mystinus*
Bluntnose sixgill shark	*Hexanchus griseus*
Bocaccio	*Sebastes paucispinis*
Brown rockfish	*Sebastes auriculatus*
Bull sculpin	*Enophrys taurina*
Cabezon	*Scorpaenichthys marmoratus*
Calico rockfish	*Sebastes dalli*
California halibut	*Paralichthys californicus*
California lizardfish	*Synodus lucioceps*
California scorpionfish	*Scorpaena guttata*
California sheephead	*Semicossyphus pulcher*
California smoothtongue	*Leuroglossus stilbius*
California tonguefish	*Symphurus atricauda*
Canary rockfish	*Sebastes pinniger*
Chilipepper	*Sebastes goodei*
C-O turbot	*Pleuronichthys coenosus*
Copper rockfish	*Sebastes caurinus*
Cowcod	*Sebastes levis*
Darkblotched rockfish	*Sebastes crameri*
Dover sole	*Microstomus pacificus*
Dwarf perch	*Micrometrus minimus*
Embiotoca sp.	Black perch, *Embiotoca jacksoni* or striped perch, *E. lateralis*
Fantail sole	*Xystreurys liolepis*
Flag rockfish	*Sebastes rubrivinctus*
Freckled rockfish	*Sebastes lentiginosus*
Garibaldi	*Hypsypops rubicunda*
Giant kelpfish	*Heterostichus rostratus*
Gopher rockfish	*Sebastes carnatus*
Grass rockfish	*Sebastes rastrelliger*
Gray smoothhound	*Mustelus californicus*
Greenblotched rockfish	*Sebastes rosenblatti*
Greenspotted rockfish	*Sebastes chlorostictus*
Greenstriped rockfish	*Sebastes elongatus*
Halfbanded rockfish	*Sebastes semicinctus*
Halfblind goby	*Lethops connectens*
Halfmoon	*Medialuna californiensis*
Honeycomb rockfish	*Sebastes umbrosus*
Hornshark	*Heterodontus francisci*
Hornyhead turbot	*Pleuronicthys verticalis*
Island kelpfish	*Alloclinus holderi*
Jack mackerel	*Trachurus symmetricus*
Kelp bass	*Paralabrax clathratus*
Kelp goby	*Lethops connectens*
Kelp greenling	*Hexagrammos decagrammus*
Kelp gunnel	*Ulvicola sanctaerosae*
Kelp rockfish	*Sebastes atrovirens*
Kelp perch	*Brachyistius frenatus*
Lavender sculpin	*Leiocottus hirundo*
Leopard shark	*Triakis semifasciata*
Lingcod	*Ophiodon elongatus*
Longnose skate	*Raja rhina*
Mexican rockfish	*Sebastes macdonaldi*
Mola	*Mola mola*
Mussel blenny	*Hypsoblennius jenkinsi*
Northern anchovy	*Engraulis mordax*
Ocean sunfish	*Mola mola*
Ocean whitefish	*Caulolatilus princeps*
Olive rockfish	*Sebastes serranoides*
Opaleye	*Girella nigricans*
Pacific argentine	*Argentina sialis*
Pacific barracuda	*Sphyraena argentea*
Pacific electric ray	*Torpedo californica*
Pacific hagfish	*Eptatretus stouti*
Pacific hake	*Merluccius productus*
Pacific mackerel	*Scomber japonicus*
Pacific pompano	*Peprilus simillimus*
Pacific sanddab	*Citharichthys pacificus*
Pacific sardine	*Sardinops sagax*
Painted greenling	*Oxylebius pictus*
Phanerodon sp.	White seaperch, *Phanerodon furcatus* or sharpnose seaperch, *P. atripes*
Pile perch	*Rhacochilus vaca*
Pink rockfish	*Sebastes eos*
Pink seaperch	*Zalembius rosaceus*
Pinkrose rockfish	*Sebastes simulator*
Plainfin midshipman	*Porichthys notatus*
Pygmy rockfish	*Sebastes wilsoni*

TABLE 1. (cont.) Common and scientific names of fishes observed in these studies.

Common Name	Scientific Name
Rainbow surfperch	*Hypsurus caryi*
Rathbunella sp.	Unidentified ronquil
Redbanded rockfish	*Sebastes babcocki*
Rex sole	*Glyptocephalus zachirus*
Rock wrasse	*Halichoeres semicinctus*
Rosy rockfish	*Sebastes rosaceus*
Roughback sculpin	*Chitonotus pugetensis*
Rubberlip seaperch	*Rhacochilus toxotes*
Sarcastic fringehead	*Neoclinus blanchardi*
Sargo	*Anisotremus davidsoni*
Sebastomus sp.	Unidentified member of rockfish subgenus *Sebastomus*
Senorita	*Oxyjulis californica*
Sharpchin rockfish	*Sebastes zacentrus*
Sharpnose seaperch	*Phanerodon atripes*
Shiner perch	*Cymatogaster aggregata*
Shortbelly rockfish	*Sebastes jordani*
Shortspine combfish	*Zaniolepis frenata*
Shortspine thornyhead	*Sebastolobus alascanus*
Silver surfperch	*Hyperprosopon ellipticum*
Slender sole	*Eopsetta exilis*
Speckled sanddab	*Citharichthys stigmaeus*
Spotted cuskeel	*Chilara taylori*
Spotted ratfish	*Hydrolagus colliei*
Spotted sand bass	*Paralabrax maculatofasciatus*
Squarespot rockfish	*Sebastes hopkinsi*
Starry rockfish	*Sebastes constellatus*
Striped seaperch	*Embiotoca lateralis*
Stripetail rockfish	*Sebastes saxicola*
Swell shark	*Cephaloscyllium ventriosum*
Swordspine rockfish	*Sebastes ensifer*
Thornback	*Platyrhinoidis triseriata*
Threadfin bass	*Pronotogrammus multifasciatus*
Treefish	*Sebastes serriceps*
Tube-snout	*Aulorhynchus flavidus*
Vermilion rockfish	*Sebastes miniatus*
Walleye surfperch	*Hyperprosopon argenteum*
White seabass	*Atractoscion nobilis*
White surfperch	*Phanerodon furcatus*
Whitespeckled rockfish	*Sebastes moseri*
Widow rockfish	*Sebastes entomelas*
Wolf-eel	*Anarrhichthys ocellatus*
Yelloweye rockfish	*Sebastes ruberrimus*
Yellowtail	*Seriola lalandi*
Yellowtail rockfish	*Sebastes flavidus*
Zebra goby	*Lythrypnus zebra*
Zebraperch	*Hermosilla azurea*
Unidentified blennies	Family Blenniidae
Unidentified gunnel	Family Pholidae
Unidentified kelpfishes	Family Clinidae
Unidentified pipefishes	*Syngnathus* spp.
Unidentified poachers	Family Agonidae
Unidentified rockfish juveniles	*Sebastes* spp.
Unidentified ronquils	Family Bathymasteridae
Unidentified sanddabs	*Citharichthys* spp.
Unidentified sculpins	Family Cottidae
Unidentified silversides	Family Atherinidae
Unidentified fish species	

TABLE 2. Mean length of selected species at platform bottoms and shell mounds, 1996–2001.

TABLE 3. Total numbers and densities (fishes per 100m²) of all fishes observed at Platform Hidalgo and North Reef, 1996–2001.

PLATFORM HIDALGO

Species	Total	Density
Unidentified rockfish YOY	13,462	103
Halfbanded rockfish	13,194	101
Widow rockfish YOY	828	6
Greenspotted rockfish	617	5
Flag rockfish	266	2
Lingcod	224	2
Painted greenling	218	2
Widow rockfish	95	<1
Bocaccio YOY	91	<1
Greenstriped rockfish	84	<1
Greenblotched rockfish	69	<1
Bocaccio	56	<1
Rosy rockfish	56	<1
Vermilion rockfish	44	<1
Canary rockfish	41	<1
Squarespot rockfish	33	<1
Swordspine rockfish	27	<1
Sebastomus sp.	27	<1
Pacific sanddab	17	<1
Pygmy rockfish	16	<1
Sharpchin rockfish	16	<1
Unidentified combfish	14	<1
Cowcod	12	<1
Yelloweye rockfish	12	<1
Kelp greenling	10	<1
Unidentified rockfish	9	<1
Unidentified sanddab	7	<1
Starry rockfish	7	<1
Shortspine combfish	6	<1
Unidentified poacher	5	<1
Yellowtail rockfish	5	<1
Unidentified fishes	5	<1
Pink surfperch	4	<1
Bank rockfish	2	<1
Unidentified ronquil	2	<1
Unidentified sculpin	1	<1
Ratfish	1	<1
Copper rockfish	1	<1
Stripetail rockfish	1	<1
California scorpionfish	1	<1
Longspine combfish	1	<1
TOTAL	**29,587**	**226**
Minimum number of species	34	
Total rockfish YOY	14,381	109
Total rockfishes	29,071	217

Rockfish YOY comprised 48.6% of all fishes surveyed.
All rockfishes comprised 98.3% of all fishes surveyed.

NORTH REEF

Species	Total	Density
Unidentified rockfish YOY	4,786	54
Pygmy rockfish	1,684	19
Widow rockfish YOY	886	10
Halfbanded rockfish	575	7
Greenspotted rockfish	370	4
Sebastomus group	187	2
Yellowtail rockfish	118	1
Vermilion rockfish	100	1
Squarespot rockfish	72	<1
Shortspine combfish	69	<1
Greenstriped rockfish	61	<1
Unidentified rockfish	52	<1
Lingcod	49	<1
Blackeye goby	43	<1
Unidentified fish	40	<1
Pink surfperch	39	<1
Starry rockfish	38	<1
Canary rockfish	38	<1
Greenblotched rockfish	38	<1
Rosy rockfish	34	<1
Unidentified combfish	27	<1
Pacific argentine	23	<1
Swordspine rockfish	19	<1
Flag rockfish	18	<1
Bocaccio	16	<1
Cowcod	12	<1
Widow rockfish	10	<1
Unidentified flatfishes	10	<1
Unidentified ronquils	5	<1
Speckled rockfish	4	<1
Yelloweye rockfish	4	<1
Unidentified sanddab	3	<1
Bank rockfish	3	<1
Unidentified poacher	2	<1
Ratfish	2	<1
Olive rockfish	2	<1
Unidentified Cusk-eel	1	<1
Kelp greenling	1	<1
Painted greenling	1	<1
Bluebarred prickleback	1	<1
Sharpchin rockfish	1	<1
Longspine combfish	1	<1
TOTAL	**9,445**	**108**
Minimum number of species	34	
Total rockfish YOY	5,672	65
Total rockfishes	9,128	99

Rockfish YOY comprised 60% of all fishes surveyed.
All rockfishes comprised 96.6% of all fishes surveyed.

Species observed only at Platform Hidalgo: California scorpionfish, copper and stripetail rockfishes.
Species observed only at North Reef: Blackeye goby, bluebarred prickleback Pacific argentine, speckled sanddab.

TABLE 4. Total numbers of all fishes observed at the deeper, below 30 m, depths at seven platforms and 80 natural outcrops, 1996–2001.

ALL PLATFORMS

Species	Total	Species	Total	Species	Total
Unident. rockfish YOY	47,973	Pile perch	235	Splitnose rockfish	22
Halfbanded rockfish	46,831	Blackeye goby	222	Gopher rockfish	19
Widow rockfish YOY	10,902	Pacific sanddab	215	Pygmy rockfish	17
Shortbelly rockfish	7,443	Unidentified combfish	210	Yelloweye rockfish	16
Squarespot rockfish	3,834	Yellowtail rockfish	198	C-O turbot	15
Pacific sardine	3,308	Whitespeckled rockfish	196	Senorita	14

GRAND TOTAL 298,379
Minimum number of species 94
Total rockfishes 276,034
All rockfishes comprised 92.5% of all fishes surveyed.

TABLE 5. Twenty highest densities of rockfish young-of-the-year juveniles, 1996–2001 as observed from the *Delta* submersible. Platforms are listed in blue, natural outcrops in red.

Site	Year	Habitat Type	Density of Rockfish YOY (fish per 100m^2)
Hidden Reef	1999	Natural	1249.2
Platform Hermosa	1999	Midwater	993. 6
Platform Irene	1998	Midwater	935.4
Platform Harvest	1999	Midwater	555.1
Platform Irene	1999	Midwater	524.3
San Miguel Island	1995	Natural	520.5
Platform Grace	2001	Midwater	486.5
Platform Hidalgo	1997	Midwater	385.2
Potato Bank	1996	Natural	367.7
Platform Irene	1997	Bottom	363.8
Platform Grace	2000	Midwater	346.2
Platform Irene	1997	Midwater	344.1
North Reef	1995	Natural	338.7
Platform Holly	1999	Bottom	326.1
Platform Hidalgo	1999	Midwater	314.6
Platform Irene	2001	Midwater	306.2
San Nicolas Island	1996	Natural	302.9
San Miguel Island	1995	Natural	262.1
Santa Rosa Island	1995	Natural	227.1
Platform Harvest	1997	Midwater	225.6

TABLE 6. Fish species observed as young-of-the-year juveniles at California oil/gas platforms.

Common Name	Common Name
Bank rockfish	Kelp bass*
Black rockfish	Kelp greenling*
Blackeye goby*	Kelp rockfish*
Blackgill rockfish	Lingcod*
Blacksmith*	Olive rockfish
Blue rockfish*	Pacific hake
Bluebanded goby*	Painted greenling*
Bocaccio*	Pinkrose rockfish*
Brown rockfish*	Pygmy rockfish*
Cabezon*	Rosy rockfish*
Calico rockfish*	Sharpchin rockfish
Canary rockfish*	Shortbelly rockfish*
Copper rockfish*	Splitnose rockfish
Cowcod*	Squarespot rockfish*
Flag rockfish*	Starry rockfish*
Garibaldi*	Stripetail rockfish*
Gopher/Black-and-Yellow rockfish*	Treefish
Greenblotched rockfish*	Vermilion rockfish*
Greenspotted rockfish*	Widow rockfish*
Greenstriped rockfish*	Yelloweye rockfish*
Halfbanded rockfish*	Yellowtail rockfish
Halfmoon*	Unidentified combfishes (*Zaniolepis* spp.)*

We also observed adult sarcastic fringehead, as well as unidentified blennies (*Hypsoblennius* spp.) and sculpins. Given the cryptic and sedentary nature of these species, we believe they arrived at platforms via larval recruitment.

In addition, Carlisle et al. (1964) observed young-of-the-year black perch, pile perch, rubberlip seaperch, and white surfperch at Platform Hazel (removed in 1996).

*These species were observed as both newly settled juveniles and adults at platforms.

APPENDICES

APPENDIX 1. Platform Synopses

In this section, we give a brief summary of each of the California platforms. The platforms are listed from the most northwest, Irene, off Point Arguello, to Emmy in the southeast off Long Beach.

Wherever possible, we have included the following information on each platform: (1) the original operator; (2) the current operator of record; (3) the date the platform was installed; (4) the first production date; (5) the platform's distance from shore (including whether it is in state or outer continental shelf [OCS] waters); (6) the bottom depth of the platform; (7) the number of wells; (8) what the platform produces (oil and/or gas); (9) the platform jacket dimensions (generally at the seafloor [bottom]); (10) the size of the shell mound surrounding the platform; (11) the size of the platform's footprint. This data was taken from California Resources Agency (1971), Manago and Williamson (1998), Holbrook et al. (2000), and Sea Surveyor Inc. (2001). We have also included a photograph of most of the platforms and their locations including latitude and longitude.

We follow this with a synopsis of the fish assemblages around each platform. When these summaries are based on our scuba and submersible surveys we include the years these surveys were conducted. Scuba surveys are midwater surveys except at the shallow water Platform Gina. Because of funding limitations, a number of platforms were surveyed only once and in a number of instances poor water visibility prevented complete coverage. Neither ExxonMobil nor Aera gave us permission to survey their platforms. In some instances, we were able to review videos that were taken during mandatory platform inspections. From these, we made a qualitative estimate of platform bottom fish assemblages for those platforms we were unable to survey.

IRENE

Original operator: Union; current operator of record: Nuevo Energy; date installed: 1985; first production: 1987; distance from shore (miles): 4.7 (OCS); water depth: 73 m (242 ft.); number of well slots 72; produces: oil and gas; platform jacket dimensions: 47 x 56 m (155 x 185 ft.) (bottom); platform footprint (m^2): 2,633; location: 120°43.45'N, 34°36.37'W.

Dates and types of surveys:

Scuba: 1995–2000

Submersible:

	Midwater	Bottom	Shell Mound
1995	x		
1996	x	x	x
1997	x	x	x
1998	x	x	x
1999	x	x	x
2000	x	x	x
2001	x	x	x

Platform Irene's midwaters consistently harbored large numbers of YOY (young-of-the-year) and older juvenile rockfishes. Bocaccio, blue, shortbelly, squarespot, treefish, and widow rockfishes, and the complex comprised of young black-and-yellow, copper, gopher, and kelp rockfishes, were abundant. Densities of these fishes were usually among the highest we observed around either platforms or natural outcrops. Young painted greenling, living on the jacket, were also quite abundant. During the 1998 El Niño, YOY blacksmith settled on the platform in large numbers. However, they were gone by the following year. Kelp greenling recruited as young-of-the-year in 1999; they swam to the platform bottom during the next year and were there through 2001. Two pelagic species, jack mackerel and Pacific sardine, were also occasionally seen in high numbers. The platform bottom had particularly high densities of halfbanded rockfish and YOY rockfishes, as well as subadult and adult copper, vermilion, calico, and brown rockfishes. Juvenile lingcod, pile perch and painted greenling were also very abundant and Pacific sanddab, canary and yellowtail rockfishes were frequently seen. On the shell mound, halfbanded and copper rockfish, as well as young lingcod were very common. Platform Irene is particularly noteworthy as it harbored far higher densities of young lingcod than did any other site (platform or natural outcrop) that we surveyed.

Opposite: Vermilion rockfish and assorted invertebrates at the bottom of Platform Grace. (Photograph by Donna Schroeder)

HIDALGO

Original operator: Chevron; current operator of record: Arguello Inc.; date installed: 1986; first production: 1991; distance from shore (miles): 5.9 (OCS); water depth: 130 m (430 ft.); number of well slots: 56; produces: oil and gas; platform jacket dimensions: 78 x 53 m (257 x 176 ft.) (bottom); platform footprint (m^2): 4,154; location: 34°29'N, 120°42'W.

Dates and types of surveys:
Scuba: 1996–2000
Submersible:

	Midwater	Bottom	Shell Mound
1996	x	x	x
1997	x	x	x
1998	x	x	x
1999	x	x	x
2000	x	x	x
2001	x	x	x

We observed high densities of YOY and older juvenile rockfishes in the midwaters of Platform Hidalgo. A number of rockfishes, including blue, copper, gopher, kelp, olive, rosy, squarespot, and widow rockfishes and bocaccio were abundant. Halfmoon and young painted greenling were also common. Large numbers of YOY blacksmith recruited to the platform during 1998 and remained there through 2001. Similarly, kelp greenling young settled during 1999, and some remained through 2001. Jack mackerel and northern anchovy were occasional visitors. The bottom of this platform was dominated by halfbanded, greenspotted, and flag rockfishes, YOY rockfishes, and lingcod. Flag rockfish density was higher than at any natural outcrop or other platform. Other important species included canary, greenstriped, vermilion, and widow rockfishes and painted greenling. On the shell mounds, we noted extremely large numbers of halfbanded rockfish. Both juvenile and adult lingcod were also abundant.

HARVEST

Original operator: Texaco; current operator of record: Arguello Inc.; date installed: 1985; first production: 1991; distance from shore (miles): 6.7 (OCS); water depth: 205 m (675 ft.); number of well slots: 50; produces: oil and gas; platform jacket dimensions: 61 x 97 m (200 x 319 ft.) (bottom); platform footprint (m^2): 5,859; location: 34°28'N, 120°40'W.

Dates and types of surveys:
Scuba: 1996–2000
Submersible:

	Midwater	Bottom	Shell Mound
1996	x		
1997	x	x	x
1998	x	x	x
1999	x	x	x
2000	x	x	x
2001			

As on most of the other platforms we surveyed, YOY and somewhat older rockfishes characterized the midwaters of Platform Harvest. Of these, bocaccio, as well as blue, olive, squarespot, and widow rockfishes were most abundant. Young painted greenling , as well as halfmoon, also were seen frequently. Blacksmith were abundant, they had recruited in 1998 as YOY and remained at the platform through 2001. Large numbers of kelp greenling settled from the plankton in 1999. Pelagic species, such as northern anchovy and Pacific sardine, were occasional visitors. In the deeper midwaters, we saw many sharpchin and whitespeckled rockfishes. Stripetail, greenstriped, greenspotted, and greenblotched rockfishes and lingcod were commonly seen on the bottom. Stripetail, greenstriped and sharpchin rockfishes were most abundant on the shell mounds.

HERMOSA

Original operator: Chevron; current operator of record: Arguello Inc.; date installed: 1985; first production: 1991; distance from shore (miles): 6.8 (OCS); water depth: 183 m (603 ft.); number of well slots: 48; produces: oil and gas; platform jacket dimensions: 61 x 85 m (200 x 280 ft.) (bottom); platform footprint (m^2): 5,142; location: 34°27'N, 120°38'W.

Dates and types of surveys:
Scuba: 1996–2000
Submersible:

	Midwater	Bottom	Shell Mound
1996	x	x	
1997	x	x	x
1998	x	x	x
1999	x	x	x
2000	x	x	x
2001			

Platform Hermosa's midwaters are noteworthy as rockfish nursery grounds. They harbored the second highest densities of YOY rockfishes of any site we surveyed (second only to Hidden Reef) (Table 5). Bocaccio, blue, olive, squarespot, widow, and whitespeckled rockfishes, as well as painted greenling were very abundant. Blacksmith and halfmoon were also typical species. As at many other platforms, in 1999 kelp greenling settled out of the plankton at Platform Hermosa. Jack mackerel and northern anchovy were also common. While halfbanded rockfish dominated the bottom assemblage, greenspotted rockfish were also abundant. Halfbanded rockfish also were the most abundant species on the shell mound.

HONDO

Original operator: Exxon; current operator of record: ExxonMobil; date installed: 1976; first production: 1981; distance from shore (miles): 5.1 (OCS); water depth: 255 m (842 ft.); number of well slots: 28; produces: oil and gas; platform jacket dimensions: 68 x 68 m (225 x 225 ft.) (bottom); platform footprint (m^2): 4,649; location: 34°23'N, 120°07'W.

Exxon and ExxonMobil did not allow us to survey this platform. However, we were able to review part of an inspection tape made at and near the bottom of Platform Hondo (Divecon International, 3 August 2002). Based on this, a number of rockfishes, including bank, darkblotched, pinkrose, widow and probably blackgill, live around the bottom of Platform Hondo. Darkblotched rockfish appeared to be particularly abundant.

HARMONY

Original operator: Exxon; current operator of record: ExxonMobil; date installed: 1989; first production: 1993; distance from shore (miles): 6.4 (OCS); water depth: 363 m (1,198 ft.); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 91 x 117 m (300 x 385 ft.) (bottom); platform footprint (m^2): 10,606; location: 34°22'N, 120°10'W.

Exxon and ExxonMobil did not allow us to survey this platform.

HERITAGE

Original operator: Exxon; current operator of record: ExxonMobil; distance from shore (miles): 8.2 (OCS); water depth: 326 m (1,075 ft.); number of well slots: 60; produces: oil and gas; location: 34°21'N, 120°16'W.

Exxon and ExxonMobil did not allow us to survey this platform. We reviewed part of an ROV inspection of this platform (Divecon International, 2 August 2002) and noted blackgill, darkblotch, pinkrose, and widow rockfish at or near the bottom.

HOLLY

Original operator: Atlantic Richfield, current operator of record: Venoco, date installed: 1966; first production: 1966; distance from shore (miles): 1.8 (state); water depth: 64 m (211 ft.); number of well slots: 30; produces: oil and gas; platform jacket dimensions: 18 x 30 m (60 by 100 ft.) (surface), 36 x 48 m (119 by 158 ft.) (bottom); location: 34°22'N, 119° 52'W.

Dates and types of surveys:
Scuba: 1995–2000
Submersible:

	Midwater	Bottom	Shell Mound
1995	x		
1996	x	x	
1997	x	x	x
1998	x	x	x
1999		x	
2000			
2001	x	x	x

The midwaters around Platform Holly were populated by large numbers of blue, copper, kelp, olive, squarespot, and widow rockfishes and bocaccio. With the exception of kelp rockfishes, most of these fishes were juveniles. Blacksmith, halfmoon, kelp bass, painted greenling, pile perch, and sharpnose seaperch were also abundant. Schools of jack mackerel and Pacific sardines were also noted. The platform bottom fish assemblage was characterized by YOY widow rockfish, calico, vermilion, halfbanded, and copper rockfishes, sharpnose seaperch and blackeye goby. Most of the vermilion and copper rockfishes were juveniles and subadults. Calico, vermilion, and copper rockfishes were the most abundant species on the shell mound.

C

Original operator: Union Oil; current operator of record: Nuevo Energy; date installed: 1977; first production: 1977; distance from shore (miles): 5.7 (OCS); water depth: 58 m (192 ft); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 40 x 48 m (133 x 158 ft.) (bottom); platform footprint (m^2): 1,930; location: 34°19'N, 119°37'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
2000	x (partial)		x

Only part of the platform midwater was surveyed and olive rockfish were most abundant. On the shell mound, vermilion, halfbanded, and calico rockfishes were most common, and blackeye goby, copper rockfish and painted greenling were also frequently encountered. A platform inspection video made on 23 September 1999 (Stolt Comex Seaway) around the platform bottom showed large numbers of juvenile blue, brown, copper, olive, vermilion, and widow rockfishes and lingcod. Both juvenile and adult calico, gopher, halfbanded and kelp rockfishes and painted greenling were also present.

B

Original operator: Union Oil; current operator of record: Nuevo Energy; date installed: 1968; first production: 1969; distance from shore (miles): 5.7 (OCS); water depth: 58 m (190 ft.); number of well slots: 63; produces: oil and gas; platform jacket dimensions: 40 x 48 m (133 x 158 ft.) (bottom); platform footprint (m^2): 1,930; location: 34°19'N, 119°37'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Juvenile widow rockfish, which had probably settled from the plankton in 1999, were abundant in the platform midwaters in 2000. Blacksmith, young blue, olive and kelp rockfishes, senorita and painted greenling were also common. We reviewed a video of a platform inspection (Stolt Comex Seaway, 21 September 1999) and noted large numbers of juvenile lingcod, blue, flag, and vermilion rockfishes as well as many juvenile and adult calico, gopher, halfbanded, kelp and rosy rockfishes and painted greenling.

A

Original operator: Union Oil; current operator of record: Nuevo Energy; date installed: 1968; first production: 1969; distance from shore (miles): 5.8 (OCS); water depth: 57 m (188 ft.); number of well slots: 57; produces: oil and gas; platform jacket dimensions: 40 x 48 m (133 x 158 ft.) (bottom); platform footprint (m^2): 1,930; location: 34°19'N, 119°36'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Blacksmith, blue and olive rockfishes were most abundant in the platform midwaters during 2000. Halfmoon, kelp bass and painted greenling were also common. Due to poor visibility, we were unable to survey the bottom and shell mound of Platform A during 2000. However, we reviewed a 2001 platform inspection video tape (Divecon International 2001) conducted with a remotely operated vehicle. That tape showed that there were large numbers of fishes, primarily rockfishes, around the platform bottom. These included many subadult vermilion and copper rockfishes, as well as blue, calico, gopher, kelp, and juvenile widow rockfishes, lingcod and painted greenling.

HILLHOUSE

Original operator: Sun Oil; current operator of record: Nuevo Energy; date installed: 1969; first production: 1970; distance from shore (miles): 5.5 (OCS); water depth: 58 m (190 ft.); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 49 x 40 m (163 x 133 ft.) (bottom); location: 34°19'N, 119°36'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Blacksmith and painted greenling were the most abundant species in the platform midwaters. Poor water visibility prevented us from surveying the platform bottom and shell mound. We reviewed a videotape made during an ROV platform inspection survey (Divecon International, 26 August 2001) and, although this too was conducted during poor visibility, noted juvenile copper, flag, and vermilion rockfishes, as well as painted greenling and pile perch.

HENRY

Current operator of record: Nuevo Energy; date installed: 1979; first production: 1980; distance from shore (miles): 4.3 (OCS); water depth: 52 m (173 ft.); number of well slots: 24; produces: oil and gas; platform jacket dimensions: 45 x 33 m (149 x 110 ft.) (bottom); size of shell mound: 9 m (19 ft) high, circular and 76 m (250 ft.) in diameter; platform footprint (m^2): 1,505; location: 34°19'N, 119°33'W.

Dates and types of surveys:

Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Halfmoon, blacksmith and kelp bass were common in the midwaters of Platform Henry.

HOUCHIN

Original operator: Phillips Petroleum/Continental Oil/Cities Services Oil; current operator of record: Pacific Operators Offshore; date installed: 1968; first production: 1969; distance from shore (miles): 4.1 (OCS); water depth: 49 m (163 ft.); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 38 x 38 m (125 x 125 ft.) (bottom); size of shell mound: 6 m (21 ft.) high, circular and 85 m (280 ft.) in diameter; 1,435; location: 34°20'N, 119°33'W.

Dates and types of surveys:

Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Painted greenling and halfmoon were the most abundant species in the platform midwaters.

HOGAN

Original operator: Phillips Petroleum/Continental Oil/Cities Services Oil; current operator of record: Pacific Operators Offshore; date installed: 1967; first production: 1968; distance from shore (miles): 3.7 (OCS); water depth: 47 m (154 ft.); number of well slots: 66; produces: oil and gas; platform jacket dimensions: 38 x 38 m (125 x 125 ft.) (bottom); platform footprint (m^2): 1,435; location: 34°20'N, 119°32'W.

Dates and types of surveys:

Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

The midwaters around Platform Hogan were important habitat for a diverse fish assemblage. Blacksmith, blue and olive rockfishes, painted greenling, sharpnose seaperch, pile perch and California sheephead were all common species.

HABITAT

Original operator: Texaco; current operator of record: Nuevo Energy; date installed: 1981; first production: 1993; distance from shore (miles): 7.8 (OCS); water depth: 88 m (290 ft.); number of well slots: 24; produces: gas; platform jacket dimensions: 60 x 38 m (199 x 125 ft.) (bottom); platform footprint (m^2): 2,284; location: 34°17'N, 119°35'W.

Dates and types of surveys:

Submersible:

	Midwater	Bottom	Shell Mound
1995	x (partial)		
2000	x		

YOY widow rockfish, blacksmith, and one-year-old widow rockfish dominated the midwater at Platform Habitat. Blue and kelp rockfishes and painted greenling were also common species.

GRACE

Original operator: Standard Oil; current operator of record: Venoco; date installed: 1979; first production: 1980; distance from shore (miles): 10.5 (OCS); water depth: 96 m (318 ft.); number of well slots: 48; produces: Grace is a non-producing platform; platform jacket dimensions (at surface and at bottom): 27 x 44 m (90 by 145 ft.) (surface), 48 x 65 m (158 x 213 ft.) (bottom); size of shell mound: 4 m (13 ft.) high, oval, 61 x 118 m (200 x 390 ft.), oriented in a northwest-southeast direction; platform footprint (m^2): 3,090; location: 34°10'N, 119°28'W.

Dates and types of surveys:

Scuba: 1996–2000

Submersible:

	Midwater	Bottom	Shell Mound
1996	x	x	
1997	x	x	x
1998	x		x
1999	x	x	x
2000	x	x	x
2001	x	x	x

The midwaters around Platform Grace contained very large numbers of young rockfishes. Most of these rockfishes recruited between 1999 and 2001.YOY widow rockfish and bocaccio, juvenile squarespot, blue and widow rockfishes, bocaccio and juvenile and adult blacksmith were very common. Painted greenling, sharpnose seaperch, jack mackerel and young flag rockfish were also frequently encountered. Halfbanded rockfish were the most abundant species around the platform bottom. Juvenile widow, vermilion, and flag rockfishes and bocaccio were also abundant. Many of these individuals had settled out of the plankton at the platform in 1999 and had remained there. Squarespot and greenspotted rockfishes, young lingcod, and sanddabs were also common. Over the shell mounds, halfbanded rockfish and shiner perch were the most abundant species. Pink seaperch, sanddabs, YOY bocaccio, young lingcod, juvenile greenspotted, flag and vermilion rockfishes were also characteristic species.

GILDA

Original operator: Union Oil; Current operator of record: Nuevo Energy; date installed: 1981; first production: 1981; distance from shore (miles): 8.8 (OCS); water depth: 62 m (205 ft.); number of well slots: 96; produces: oil and gas; platform jacket dimensions: 45 x 52 m (150 x 170 ft.) (bottom); platform footprint (m^2): 2,342.location: 34°10'N, 119°25'W.

Dates and types of surveys:
Scuba: 1995–2000
Submersible:

	Midwater	Bottom	Shell Mound
2000	x		

Blacksmith, halfmoon, kelp bass, opaleye, senorita, as well as YOY and juvenile blue, olive, squarespot and widow rockfishes and bocaccio were abundant in the midwater of this platform. Many of these rockfishes recruited from the plankton as YOYs during 1999. Due to poor visibility, we were unable to survey the bottom and shell mound of Platform Gilda during 2000. However, we reviewed a 2001 platform inspection video tape (Divecon International 2001) conducted with a remotely operated vehicle. That tape showed high densities of calico and juvenile vermilion rockfishes, as well as blue, brown, copper, halfbanded, olive, and widow rockfishes. Kelp greenling, lingcod, Pacific sanddab, and painted greenling were also noted.

GAIL

Original operator: Standard Oil; current operator of record: Venoco; date installed: 1987; first production: 1988; distance from shore (miles): 9.9 (OCS); water depth: 224 m (739 ft.); number of well slots: 36; produces: oil and gas; platform jacket dimensions: 21 x 52 m (70 x 170 ft.) (surface), 60 x 90 m (197 x 297 ft.) (bottom); platform footprint (m^2): 5,327; location: 34°07'N, 119°24'W.

Dates and types of surveys:
Scuba: 1996–2000
Submersible:

	Midwater	Bottom	Shell Mound
1996	x	x	
1997	x	x	x
1998	x		
1999	x	x	x
2000	x	x	x
2001	x	x	x

Blacksmith, halfmoon, kelp bass and a variety of young rockfishes, including bocaccio, blue, flag, olive, and widow, characterized the midwaters of this platform. Most of the young rockfishes settled from the plankton in 1999. The platform bottom fish assemblage was dominated by adult bocaccio, greenblotched, greenspotted, stripetail and pinkrose rockfishes. Of particular interest, we observed higher densities of both adult cowcod and bocaccio at the bottom of Platform Gail than at any natural outcrop or other platform. The shell mound at Platform Gail was characterized by stripetail, pinkrose, greenblotched and greenstriped rockfishes. On one occasion, large numbers of juvenile hake were observed, on another northern anchovies were abundant.

GINA

Original operator: Union Oil; current operator of record: Nuevo Energy; date installed:1980; first production: 1982; distance from shore (miles): 3.7 (OCS); water depth: 29 m (95 ft.); number of well slots: 15; produces: oil and gas; platform jacket dimensions: 28 x 20 m (94 x 65 ft.) (bottom); shell mound: 4 m (13 ft.) high, oval, 45 x 64 m (150 x 210 ft.), oriented in a northwest-southeast direction; platform footprint (m^2): 561; location: 34°07'N, 119°16'W.

Dates and types of surveys:
Scuba: 1995–2000

Platform Gina had the highest species richness (47) of any platform surveyed using scuba. Blacksmith dominated the assemblage, comprising 38% of all fishes observed. A close second was kelp bass, which counted for 31% of all fishes observed. Platform Gina had the highest number and density of surfperches of any platform, and was the only site where rubberlip surfperch formed part of the assemblage. The shell mound habitat at this platform provided excellent habitat for many species of recruiting rockfishes, where 13 species were observed. However, despite being present at every other surveyed platform, no widow or bocaccio juveniles were observed at Platform Gina. Pelagic species that characterized this assemblage include yellowtail, barracuda, and jackmackerel.

EDITH

Original operator: Standard Oil; current operator of record: Nuevo Energy; date installed: 1983; first production: 1984; distance from shore (miles): 8.5 (OCS); water depth: 49 m (161 ft.); number of well slots: 72; produces: oil and gas; platform jacket dimensions: 58 x 50 m (190 x 165 ft.) (bottom); platform footprint (m^2): 2,879; location: 33°35'N, 118°08'W.

Dates and types of surveys:
Submersible:

	Midwater	Bottom	Shell Mound
1998	x	x	x

Blacksmith, halfmoon, opaleye, sheephead and garibaldi characterized the midwater fish assemblage at Platform Edith. Very high densities of California scorpionfish, along with sharpnose seaperch, blacksmith and blackeye goby were found at the platform bottom. California scorpionfish were also extremely abundant on the shell mound.

ELLEN

Original operator: Shell Oil; current operator of record: Aera Energy; date installed: 1980; first production: 1981; distance from shore (miles): 8.6 (OCS); water depth: 80 m (265 ft.); number of well slots: 80; produces: oil and gas; platform jacket dimensions: 45 x 56 m (147 x 186 ft.) (bottom); platform footprint (m^2): 2,511; location: 33°34'N, 118°07'W.

Aera did not allow us to survey this platform. We reviewed a tape of a platform inspection carried out with a remotely operated vehicle (Divecon International, 7 September 2001) and observed very high densities of flag, halfbanded, squarespot and honeycomb rockfishes. We also saw a number of young vermilion rockfish. In the platform midwater, from about 61 m (200 ft) and deeper, there were very large numbers of young rockfishes, including both squarespots and widows.

ELLY

Original operator: Shell Oil; current operator of record: Aera Energy; date installed: 1980; first production: n/a; distance from shore (miles): 8.6 (OCS); water depth: 77 m (255 ft.); number of well slots: n/a; produces: Elly is a processing facility for Ellen and Eureka; platform jacket dimensions: 48 x 61 m (159 x 202 ft.) (bottom); platform footprint (m^2): 2,949; location: 33°35'N, 118°07'W.

Aera did not allow us to survey this platform. We reviewed a tape of a platform inspection carried out with a remotely operated vehicle (Divecon International, 9 September 2001) and observed high densities of young vermilion and young widow rockfishes, as well as many flag, honeycomb, olive, and squarespot rockfishes, and lingcod.

EUREKA

Original operator: Shell Oil; current operator of record: Aera Energy; date installed: 1984; first production: 1985; distance from shore (miles): 9.0 (OCS); water depth: 212 m (700 ft.); number of well slots: 60; produces: oil and gas; platform jacket dimensions: 54 x 85 m (179 x 282 ft.) (bottom); platform footprint (m^2): 4,635; location: 33°33'N, 118°06'W.

Aera did not allow us to survey this platform. We reviewed a tape of a platform inspection carried out with a remotely operated vehicle (Divecon International, 5 September 2001) and observed large numbers of pink-rose and juvenile darkblotched rockfishes, as well as juvenile and subadult bocaccio and widow rockfish. Also present were flag, greenblotched and greenspotted, and perhaps speckled, rockfishes and lingcod.

EVA

Original operator: Union Oil Company; current operator of record: Nuevo Energy; date installed: 1964; first production: 1966; distance from shore (miles): 1.8 (state); water depth: 17 m (57 ft.); number of well slots: 39; produces: oil and gas; location: 33°39'N, 118°03'W.

EMMY

Original operator: Signal Oil and Gas Company; current operator of record: Aera Energy; date installed: 1963; first production: 1963; distance from shore (miles): 1.2 (state); water depth: 14 m (47 ft.); number of well slots: 53; produces: oil and gas; location: 33°39N, 118°02'W.

Aera did not allow us to survey this platform.

APPENDIX 2

Density of fishes observed during the oil/gas platform scuba surveys off central and southern California. Platforms are listed from northwest to southeast. Density is in fish per 100 m^2, "<" means "less than."

DAN DUGAN

Cabezon in the midwater of Platform Holly.

APPENDIX 3

Number and density of fishes observed in the midwaters, bottoms and shell mounds of oil/gas platforms off central and southern California. Platforms are listed geographically, from northwest to southeast. Species are ranked by number observed. YOY means "young-of-the-year", those are fish that are less than one year old. Density is in fish per 100 m^2, "<" means "less than".

PLATFORM MIDWATERS

Because we could not estimate the lengths of the transects around Platforms Habitat and Gilda, no fish densities are presented.

PLATFORM IRENE (Surveyed 1995–2001)

Species	Number	Density
Shortbelly rockfish YOY	7,300	378
Unidentified rockfish YOY	4,133	214
Widow rockfish YOY	2,310	120
Pacific sardine	1,600	83

1. PROJECT DESCRIPTION

In 1995, the USGS/BRD initiated cooperative research with the University of California at Santa Barbara (UCSB) to conduct research to address a critical marine resource management issue defined by the Minerals Management Service (MMS). MMS requested that the DOI's National Biological Survey (now U. S. Geological Survey/Biological Resources Division, USGS/BRD) conduct a study to address the need to understand how offshore oil/gas platforms contributed to the fish populations and fishery productivity in the Santa Maria Basin and Santa Barbara Channel. In 2000, the California Artificial Reef Enhancement (CARE) program began to contribute a substantial portion of the research funds devoted to this project.

The on-going research has involved broad scale sampling at numerous oil/gas platforms and natural reefs. The research has been coordinated with researchers and managers of the National Oceanic and Atmospheric Administration's National Ocean Service (Channel Island Marine Sanctuary), National Marine Fisheries Service, California Sea Grant Program, California Department of Fish and Game, and various other state agencies involved in fisheries management and conservation biology.

During the course of this study, much of our research has focused on: 1) characterizing the fish assemblages around platforms and natural reefs; 2) examining how oceanography affects patterns of recruitment and community structure of reef fishes; 3) describing the spatial and temporal patterns of fish diversity, abundance and size distribution among habitat types (e. g., platforms and natural reefs).

From these studies, it is clear that platforms harbor a wide range of fishes and fish assemblages. However, as noted in "Ecological Issues Related to Decommissioning of California's Offshore Production Platforms" (Holbrook et al. 2000) "to best evaluate decommissioning alternatives one would need several other types of information that address (1) spatial and temporal patterns of distribution and abundance of reef-associated species in different parts of the Southern California Bight, including on natural reefs and associated with platforms, (2) distribution, abundance and quality of natural hard substrate in the area, and (3) physical oceanographic data to identify patterns of water

Subject: Comments on the “Pacific Coast Groundfish Fishery Management Plan - Essential Fish Habitat Designation and Minimization of Adverse Impacts” Draft EIS Support of Modified Alternatives of Collaborative Efforts between Environmental Non-Governmental Organizations and Fishermen and Protection and Consideration of Impacts to Coastal Communities

Dear Mr. Robert Lohn:

We appreciate this opportunity to comment on the "Groundfish Essential Fish Habitat Designation and Minimization of Adverse Impacts Draft Environmental Impact Statement (DEIS)." We support the Pacific Fisheries Management Council and National Marine Fisheries Service’s efforts to assess the environmental and socioeconomic effects of the alternatives presented in the Draft EIS. Our review of the Draft EIS document and discussions we have had with NMFS staff, including Dr. Rebecca Lent and Mr. Steve Copps, provided us with a good understanding of the intent and variables of the Essential Fish Habitat program. Our comments are broad with respect to the fisheries issues but are focused on the effects of the Essential Fish Habitat program on local coastal communities and fishing dependent harbors.

The Magnuson-Stevens Act and a 2000 court order require the preparation of this DEIS. The purpose of this DEIS is to evaluate the effects of fishing on essential fish habitat and to identify measures that will minimize those impacts to the extent practical. The project will also designate “Habitat Areas of Particular Concern” and identify other actions that encourage the conservation and enhancement of Essential Fish Habitat (source: DEIS). The Pacific Coast Groundfish Management Plan (FMP) will ultimately be amended to incorporate the alternatives selected by the Pacific Fisheries Management Council (PFMC) and as may be approved by the National Marine Fisheries Service (NMFS).

Fisheries and Non-Governmental Organizations

There are an estimated 4-6 permit holders that we believe regularly bottom trawl in the San Luis Obispo central California region. These commercial fishermen have historically moored and offloaded seafood product at Avila Beach/Port San Luis Harbor. We strongly support the environmental non-governmental organizations (NGO's) and these 4-6 commercial fishermen's (and their associated representatives) efforts to agree on designating zones in the study area (such as Alternative C.12 as may be modified) as no-bottom trawl zones. Of course, other areas would remain available for trawling and other types of fishing, both sport and commercial use. As we understand it, the NGO's, individuals and Fishing Associations (local Fishermen's Associations, FMA, PCFFA and others) are working to identify areas they think should be kept open to bottom trawl fishing and those remaining areas that should be closed to bottom trawlers. Again, we strongly support these efforts and recommend that whatever collaborative proposals are eventually submitted to the Pacific Fisheries Management Council be taken seriously and adopted by NMFS and the Commerce Department. We believe that the collaborative efforts of the NGO's and the commercial fishermen will result in the best alternative for the central California coast area regarding designations of the Essential Fish Habitat, while also meeting the requirements of the court order and the Magnuson-Stevens Act, et seq.

Port San Luis Harbor staff is working with the NGO's and some of the fishermen to educate and encourage the development of information for the GIS mapping of the Alternatives in the draft EFH EIS. The outcome, which is subject to modification, may also include some of the local trawl permits and vessels being purchased with private funds.

We respectfully request both the PFMC and NMFS allow the NGO's to continue working with the trawl fishermen, the group most greatly impacted by this process, in order to prepare recommendations on open trawl areas and trawl closed zones within the central California coast study region. We expect these groups to present a preliminary zoning plan at the PFMC meeting in June 2005. We support any alternative submitted by a collaborative effort of NGO's and commercial fishermen.

In addition, we respectfully request that both the Pacific Fisheries Marine Council and the National Fisheries Marine Service accept and support any Alternative submitted by these groups in a joint effort as one of the preferred alternatives in the EFH EIS. We believe that the fishermen and NGO's should be allowed, if not encouraged, to continue their collaborative work to identify essential fish habitat, to designate habitat areas of particular concern, to minimize, to the extent practical, the adverse effects of fishing on the essential fish habitat, and to identify other actions that will encourage the conservation and enhancement of the essential fish habitats within any modified Alternative for the central California coastal region.

Ports, Harbors and Coastal Communities

There are many small ports and harbors that have a symbiotic relationship with the fisheries industries, both sport and commercial, within the EIS study region. These small craft harbors rely on the fisheries to provide steady jobs and act as an economic engine, keeping the community vibrant. In the case of central California harbors, the past few years of increased regulatory actions have had a drastic effect on the ability of the fishing fleets to continue making a profit. This decline, in turn, has a direct effect on the coastal host community (harbors and marinas). The implementation of regulatory closures or restrictions will have a deleterious economic effect on these local coastal communities. We ask that both the PFMC and the NMFS carefully consider the socioeconomic effects of any designation of essential fish habitat in the central California region.

We understand that it is very difficult to quantify the exact social and economic effects of the proposed closures and cannot offer, at this time, solid evidence of those effects, other than our past experience and day-to-day observation of the fishing industry and the benefits it provides to our communities. There is a synergy that occurs which is un-measurable in terms of cash value that also needs to be considered in the development of fishing regulations, including the designation of essential fish habitats on the west coast. The public visits the ports and harbors and loves to get their fresh seafood while watching the boats offload their catch. Without community interest, these small craft harbors become stagnant and turn into yacht harbors for the wealthy, or marine malls selling plastic sharks and T-shirts. The small independent business persons (fishermen) are forced out and the working harbors cease to exist. We have seen this in southern California harbors and hope that that does not happen here. With this in mind, please use care in implementing the EFH's and HACP's and take our comments into consideration.

We have attached our specific comments to this letter for your consideration in preparing the final "Environmental Impact Statement for the Essential Fish Habitat Plan on the West Coast for the Pacific Fisheries Management Council." In advance, we appreciate your consideration of these comments and observations.

Again, we thank the Council and Fisheries Service for your attention to this alternative. We are available for future discussions on this issue. Should you require additional information please contact me by phone at (805) 595-5409, ext. 14, or by email at jaye@portsanluis.com.

Sincerely,

Jay K. Elder
Harbor Manager

Re: Comments on the “Pacific Coast Groundfish Fisheries Management Plan - Essential Fish Habitat Designation and Minimization of Adverse Impacts” Draft EIS

The following are comments offered for consideration with regard to the “Draft Environmental Impact Statement on Pacific Coast Groundfish Fisheries Management Plan Essential Fish Habitat Designation and Minimization of Adverse Impacts.” The Proposed Action is to amend the “Pacific Coast Groundfish Fishery Management Plan (“FMP”) pursuant to section 303(a)(7) of the Magnuson-Stevens Act, to (**1**) describe and identify essential fish habitat (EFH) for the fishery, (**2**) designate Habitat Areas of Particular Concern, (**3**) minimize to the extent practicable the adverse effects of fishing on EFH, and (**4**) identify other actions to encourage the conservation and enhancement of EFH. The project area for this action extends from the seaward boundary of the Pacific Coast Exclusive Economic Zone shoreward to the inland extent of estuaries.

We appreciate the opportunity to offer these comments, which focus on the possible effects of the proposed action on coastal fishing communities in the central California coast study area (Port San Luis/Avila Beach to Pillar Point - Princeton).

There are numerous alternatives offered and considered in the Draft EIS that would have distinct effects on the coastal fishing communities. We are also aware that the socioeconomic effects of the proposed action are difficult to calculate due to the lack of available hard data for both the fisheries biomass and onshore activities related to the fishing industry. The fisheries models and economic models are models and, as such, are subject to a margin of error. We appreciate the efforts of the NMFS staff economists who have worked hard to develop these economic models and are not being critical of the work presented here. However, we believe there is much to be learned about the socioeconomics of any essential fish habitat designation that may be adopted. We urge the Council and NMFS to proceed with caution as we are dealing with a very tender social community which is on the verge of collapse. As we all agree, the estimates of the rockfish biomass is still uncertain and we support the continued funding of monitoring and research to improve the science of rockfish biomass determination to continue the sustainability of these important fisheries.

In general, the calculations that use the "Habitat Suitability Probability" ("HSP") are acceptable and raise the question of "What is the definition of Essential Fish Habitat?" We believe that the entire ocean is an essential fish habitat and, therefore, any human use would have an impact to its protection designation. We also understand that essential fish habitat is defined in the statutes, but in reality, we must make a reasonable determination that allows human interaction with the habitat as long as the final effect of the human factor does not reduce the species (in this case, rockfish) below the sustainability levels set by the NMFS and PFMC. We request that you continue to allow human use of the resources to the greatest extent feasible for the benefit of both fishing and harbors. We believe that we can co-exist in the environment by properly designating some areas for the protection of the essential fish habitat and other areas for resource harvest and harbor functions.

Alternatives to Designate and Describe Essential Fish Habitat ("EFH")

This Draft EIS states that the "Actions taken by a Council to minimize adverse effects of fishing on EFH may include fishing equipment restrictions, time or area closures, harvest limits, or other measures. Any such measures would be designed to reduce ongoing effects to fish habitats and/or promote recovery of disturbed habitats. <u>These measures may result in socioeconomic effects for the affected sectors of the fishing industry</u>, but would be designed to promote sustainable fisheries and long-term socioeconomic benefits. The environmental consequences of proposed actions would be evaluated in applicable NEPA documents before they are implemented." The designation of EFH's is a good idea but should only be adopted if the socioeconomics and historic uses (specifically fisheries and harbors) of those areas are seriously considered, understood and protected in the final EIS. We do not believe that the long-term cumulative socioeconomic effects on harbors in the designation of EFH's were fully explored, identified or mitigated in this draft EIS. More work is required to identify and mitigate the long-term socioeconomic impacts of any designation of EFH's on coastal harbors and the fishing industry.

A.1: The no action plan or status quo encompasses 317,690 sq. miles. We do not support this alternative for obvious reasons.

A.2: Designate the entire region west of the 3,500 meter as EFH (100% of HSP is greater than zero); encompasses 187,741 sq. miles. We do not support this alternative as it could have severe effects on the existing fishing and harbor industries that rely on the resources in that designated area.

A.3: Designate the region as EFH (100% of HSP is greater than zero); encompasses 87,160 sq. miles. Same comment as A.2 above.

A.4: Designate the region as EFH (60-90% of HSP overfished areas, precautionary areas, all other ground fish and all seamounts); encompasses 79,481 sq. miles. May support if some areas were opened to all gear types for continued fishing.

A.5: Designate the region as EFH (70% of HSP is greater than zero); encompasses 78,569 sq. miles. May support if adequate areas were opened to all gear types for continued fishing and limited effects to coastal communities.

A.6: Designate the region as EFH (30% of HSP is greater than zero); encompasses 66,589 sq. miles. May support if adequate areas were opened to all gear types for continued fishing and limited effects to coastal communities.

With regard to the matter of the errors on some of the essential fish habitat maps generated from information collected on the managed species, we wish to reserve the right to comment further if there are substantial differences in those maps from what is represented in the Draft EIS.

Alternatives to Designate Habitat Areas of Particular Concern ("HAPC")

This Draft EIS states that the "Designation of HAPC's, like designation of EFH generally, does not have any direct environmental or socioeconomic affect, but may result in indirect effects greater than those associated with EFH because resource managers and regulators are likely to place a high priority on protecting areas that have been designated as HAPC's." The designation of HAPC's is a good idea but should be adopted only if the socioeconomics and historic uses of those areas are seriously considered by the PFMC and NMFS in the final EIS. The long-term effects of designation of HAPC's must be further considered in the final EIS with a focus on the probability of further regulation restricting the fisheries and possibly the functions of ports and harbors in these designated zones. We do not believe that the long term cumulative effects of the designation of HAPC's were fully explored and identified in this draft EIS. More work is required to establish the long-term impacts of any designation of HAPC's.

B.1: The no action plan or status quo. We do not support this alternative as we understand that HAPC's must be identified and designated.

B.2: Estuaries designation: This alternative is understandably an important one and is supported. However, many estuaries also include harbors and marinas and the effects of a HAPC on any of these coastal dependent harbors could have an effect on the basic functions of harbors and marinas and should be seriously considered in the process. We do not believe that this Draft EIS fully explores the possible effects of such a designation on ports, harbors and marinas located in or near estuaries. More work needs to be done with regard to the continued ability of harbors to perform basic maintenance functions such as dredging and repairs to facilities.

B.3: Canopy Kelp: This alternative is also an important one and is supported. Again, however, we urge the consideration that a 100% designation of all kelp forest (current and historic) could have an effect on some commercial harvest operations and, of course, some harbors and marinas. Excluding some areas should be considered, which might have a negative effect on the harvesters and or coastal communities with facilities in or near kelp forest.

B.4: Sea Grass: See our comments on B.3. Clearly an important species, but must consider the impacts to ports, harbors and marinas and their continued ability to continue in maintaining their facilities and providing services.

B.5: Core Habitat (upper 10% of overfished and precautionary species): Clearly an important alternative and is supported. However, there may be some areas which should be excluded to allow continued fishing and harbor functions, as may be historic and established by past or current use. Additional consideration on the effect to historic and existing use by fishermen and harbors is required.

B.6: Rocky Reefs: Again, this is an important alternative and is supported. However, there may be some areas that should be excluded to allow continued fishing and harbor functions, as may be historic and established by past or current use. Additional consideration on the effect to historic and existing use by fishermen and harbors is required.

B.7: Areas of Interest: This is an important alternative and is supported. However, there may be some areas that should be excluded to allow continued fishing and harbor functions, as may be historic and established by past or current use. Additional consideration on the effect to historic and existing use by fishermen and harbors is required.

B.8: Oil Production Platforms: The artificial reef alternative is not supported. Also consideration of existing lease sales, (Mineral Management Service) especially in the Santa Maria Basin should be discussed. Designation of EFH and HAPC's of those existing Outer Continental Shelf (OCS) lease sites should be done to protect the habitat from future oil exploration and production on the central coast.

B.9: Process for New HAPC Designations: Great idea, but another process also needs to be developed. The "Process to Un-Designate HAPC's" should be designed for the possibility of future re-designation or changes to this HAPC program. Please add the decommissioning of HAPC process to this alternative.

Alternatives to Minimize Adverse Impacts to EFH

This Draft EIS states that the "Federal and state agency actions that may adversely affect EFH trigger consultation and/or recommendations under sections 305(b)(2)-(4) of the Act. Under section 305(b)(4)(A) of the Act, NMFS must provide EFH Conservation Recommendations to federal and state agencies regarding any action that would adversely affect EFH."

"EFH recommendations from NMFS or a Council to federal or state agencies are non-binding. Nevertheless, as a result of EFH coordination, consultations, and recommendations, Federal or state agencies may decide to restrict various activities to avoid or minimize adverse effects to EFH. Such restrictions could result in project modifications that lead to higher costs for the applicants for federal or state permits, licenses, or funding."

"Costs associated with consultations will likely vary depending on the number of species associated with an EFH designation, and the amount of habitat designated as EFH. If an entity chooses not to participate in consultations, then the EFH designation will ultimately have no effect on that entity. If consultations result in conservation recommendations, then there are likely to be increased costs in the short-term and possibly in the long-term depending on the amount of offsetting benefits realized from enhanced habitat productivity resulting from EFH designation."

This Draft EIS fails to fully consider the probable effects of the EFH designation on coastal communities, especially ports, harbors and marinas. The final EIS should detail what the effects might be to these coastal facilities if designation of EFH's are adopted and include the community's facilities. The increase in costs to mitigate an EFH in a harbor location may have an adverse socioeconomic effect and/or close down existing facilities which support coastal access, commerce, recreational uses and marine transportation corridors.

C.1: No Action: No comment.

C.2: Depth-based Gear –specific Restriction:

C.2.1: For the central California region, we believe that this action is already in place and, if so, would support the status quo, with some exceptions that might open up some historic trawl zones to allow some take with bottom gear.

C.2.2: For the central California region, we believe that this action is already in place and, if so, would support the status quo. We would object to the prohibition of all fixed gear shoreward of 150 fathoms and request that some fixed gear be allowed in the region, specifically in areas of historic take.

C.2.3: We would not support this alternative option as it would have a significant impact on the historic fisheries and harbor functions.

Consideration of the effects of all the C.2 options should be analyzed for the economic and social impacts to the coastal communities.

C.3: Close Sensitive Habitat:

C.3.1: "Greater than or equal to the recovery index where the value is greater than one. Closed to all gear types."(?) We would support this option if the pelagic fisheries and other less invasive bottom gear fisheries would still be allowed in the EFH zones.

C.3.2: "Greater than or equal to the recovery index where the value is greater than one. Closed to all gear types."(?) We would support this option if the pelagic fisheries and other less invasive bottom gear fisheries would still be allowed in the EFH zones.

C.3.3: Same comment as above.

C.3.4: Same comment as above.

Consideration of the effects of all the C.3 options should be analyzed for the economic and social impacts to the coastal communities. The use of the 100 hours rule and the limited time period (i.e., 2000-2002) is not reasonable. We strongly suggest that the period be expanded to include at least the past ten - if not the past twenty - years of trawling. The one hundred hour rule may be sufficient, but we would request that the NMFS and PFMC take into consideration the trawl fleet reply for this central coast area on this matter. There is a limited fleet here and the time periods (hours and years) used may not be applicable for our small fleet.

C.4: <u>Prohibit the Geographic Expansion of Fishing</u>: Areas that have not been fished recently (2000-2002) would be closed to fishing to protect areas that are potentially pristine.

<u>C.4.1</u>: Trawl fisheries would be prohibited from fishing in areas that were untrawled during 2000-2002.

<u>C.4.2</u>: Apply the expansion limit to all bottom-tending gear types. The closure would extend west from a line approximating the 2,000 m (1,094 fm) depth contour to the seaward margin of the EEZ.

Consideration of the effects of all the C.3 options should be analyzed for the economic and social impacts to the coastal communities. The use of the 100 hours rule and the limited time period (i.e., 2000-2002) is not reasonable. We strongly suggest that the period be expanded to include at least the past ten - if not the past twenty - years of trawling. The one hundred hour rule may be sufficient, but we would request that the NMFS and PFMC take into consideration the trawl fleet reply for this central coast area on this matter. There is a limited fleet here and the time periods (hours and years) used may not be applicable for our small fleet.

C.5: <u>Prohibit a Krill Fishery</u>: We support as long as other fisheries and the harbor functions are not impacted and continue to be allowed.

C.6: <u>Close Hotspots:</u> Prohibits trawling in hotspot areas, where – in this case – hotspots are defined as habitat that has high probability of being EFH for a large number of groundfish. Areas that are associated with 50 or more species/lifestage combinations would be closed to bottom trawling.

We support this as long as other types of non-trawling fisheries are allowed in the "Hotspot" areas.

C.7: <u>Close Areas of Interest</u>: Closes any combination of the areas of interest HAPC's designated under Alternative B.7 to fishing by specified gear types. (The 21 areas of interest listed under Alternative B.7 are underwater features, such as seamounts and submarine areas, or are currently under some form of protection.) Closures affect the following activities:

<u>Option C.7.1</u>: Close areas of interest to bottom trawling.

<u>Option C.7.2</u>: Close areas of interest to all bottom-contacting fishing activities.

This is an important alternative and is supported. However, there may be some areas that should be excluded to allow continued fishing and harbor functions, as may be historic and established by past or current use. Additional consideration on effect to historic and existing use by fishermen and harbors is required.

C.8: <u>Zoning Fishing Activities:</u> Limits the use of bottom-tending fishing gear to specified zones.

First, all areas deeper than the 2,000 m (1,094 fm) contour along the continental slope extending to the maximum westward range of groundfish EFH are closed to certain bottom-tending fishing gear types, according to the options described below.

Second, a five-year transition period to gear specific zones is established for the remaining area inside the 2,000 m contour, which remains open to these activities, subject to any other restrictions, for the five years from implementation (e.g., 2007-2011). Third, during this five-year period, NMFS conducts the research necessary to delineate zones where specified fishing activities would be permitted. At the end of the five-year transition period, the gear-specific zones come into effect and any remaining unzoned area is closed to affected gear types, according to the options described below. (Restrictions applied outside 2,000 m remain in effect.)

In identifying fishing zones, NMFS must demonstrate that any unavoidable adverse impacts would be minimal and temporary, based on the best scientific information available.

<u>Option C.8.1</u>: Fishing zones are established for bottom-contact trawls, dredges, and similar bottom-tending mobile fishing gear. Other bottom-contacting gear types are unaffected by the zoning system, including the prohibition outside 2,000 m.

We support as long as some bottom trawl and bottom-contact fishing is allowed and that all other types of fisheries are not impacted (i.e., pelagic and mid-water trawl/net).

<u>Option C.8.2</u>: Fishing zones are established for all bottom-contacting gear types, including bottom longlines, traps, and pots. The immediate closure outside of 2,000 m applies to all bottom-contacting gear types. In addition to establishing the zoning system, NMFS will conduct a gear substitution and modification research program, intended to redesign bottom fishing gear to reduce damage to habitat. This program will have a significant cooperative research element by employing fishermen in the design and testing of new gear.

We support as long as some bottom trawl and bottom-contact fishing is allowed and that all other types of fisheries are not impacted (i.e. pelagic and mid-water trawl/net).

The zoning system will be regularly modified to incorporate new information about habitat sensitivity and recovery factors, gear impacts on habitat, and to accommodate use of newly developed or modified gear.

This is an important statement that requires a follow up mitigation measure and policy to insure it is implemented.

C.9: Gear Restrictions: Specific gear modifications and prohibitions that are based on that interaction. The following gear restrictions would be implemented in areas identified as EFH for groundfish:

C.9.1: Prohibit roller gear larger than 15 inches on bottom trawls.
C.9.2: Prohibit the use of flat trawl doors (i.e., require cambered doors).
C.9.3: Limit the length of a single longline groundline to 3 nm.
C.9.4: Employ Habitat-Friendly Anchoring System.
C.9.5: Prohibit dredge gear.
C.9.6: Prohibit beam-trawl gear.
C.9.7: Prohibit set-gillnets in waters deeper than 60 fm.
C.9.8: Prohibit dingle bar gear (troll groundfish gear).

We support these mitigation measures and policies.

C.10: Central California No-trawl Zones: Based on a project being undertaken by two environmental advocacy organizations, The Nature Conservancy (TNC) and Environmental Defense Fund (EDF). Involves private funds used to purchase groundfish limited entry trawl licenses and vessels in concert with the designation of no-trawl zones off the central California coast. The project area extends from Point Conception to Davenport, California, and includes adjacent offshore seamounts (Gumdrop, Guide, Pioneer, Davidson, and Rodriguez).

TNC/ED have identified 23 permit holders they believe regularly trawl inside the project area. Most home port in Morro Bay, Moss Landing, Monterey, or Half Moon Bay. TNC/EDF intend to purchase a significant majority of the bottom trawling permits and vessels in this region if the Council/NMFS designates a significant portion of the project area as no-bottom-trawl zones.

TNC/ED will identify areas they think should be designated no-trawl zones using the GIS data developed as part of this EIS in combination with a participatory process involving trawl fishermen in the project area. If this alternative is adopted as an FMP and regulatory amendment, these areas will be closed to bottom trawling by NMFS once TNC/EDF have negotiated purchase contracts or options for at least half of the limited trawl permit holders they have identified as operating in the project area.

We generally support this Alternative only if a majority of the limited entry permit holders of local bottom trawl fishermen and other impacted fishermen cooperate with the NGO's in establishing the open trawl areas and agree with the closed areas. We suggest that a modified alternative be considered which allows for the collaboration of the NGO's and the bottom trawl fishermen to present a pilot project in the southern area of this Alternative study area (Pt. Conception to Pt. Sur) and then expand to the northern boundary of this Alternative study area in the nine months allocated for final action by the Pacific Fisheries Management Council. Consideration of the buy out program and unintended effects to the local harbors should be considered and offset with mitigation measures to insure the continued infrastructure is in place, new markets are explored, funding for new shore side fisheries support facilities are provided and the economic synergy is maintained for the shore side businesses in the local coastal communities. The Final EIS should also implement mitigation measures to prevent the buy back program from becoming a burden to the local coastal communities and harbors if the subject vessels are abandoned and fall into disrepair, creating a nuisance.

C.11: Relax Gear Endorsement Requirements: Vessels holding a groundfish limited entry permit account for a large portion of groundfish landings. Currently, limited entry permits include a gear endorsement specifying the type of gear the permit holder may use. These endorsements identify three gear categories: trawl, longline, and pot. In addition, longline and pot gear permit holders may also have a sablefish endorsement. Permit holders with this species-specific endorsement may participate in the high-value primary sablefish fishery and are allocated vessel-specific catch quotas, known as tier limits because the endorsements fall into one of several categories, or tiers, with different catch quotas. Under this alternative, gear endorsements are relaxed but the sablefish endorsement is not. This would allow permit holders to switch gear types, providing fishermen greater flexibility in changing strategies based on prevailing conditions in the fishery.

We support this Alternative.

C.12: Close Ecologically Important Areas to Bottom Trawl: This alternative was proposed by the environmental group Oceana. The alternative would close a network of areas to bottom trawling; set a maximum footrope size of eight inches on bottom trawl gear within open area; require Vessel Monitoring Systems on all bottom trawl vessels with positions recorded every 5 minutes; increase onboard observer coverage on bottom trawl vessels to a level determined to be necessary by NOAA to estimate annual bycatch of habitat-forming invertebrates; establish a process for setting a limit on the bycatch of habitat-forming invertebrates; require ongoing research including comprehensive benthic mapping.

We would support this Alternative only if a majority of regional limited entry bottom trawl fishermen cooperate with this NGO in establishing the open trawl areas and agree with the closed areas and if all other fishing gear types would continue to be allowed in the EFH designated in the Alternative.

C.13: Close Ecologically Important Areas to Bottom-contacting Gear: The areas identified in Alternative C.12 would be closed to all bottom-contacting gear types, defined as both fixed gear (longlines, pots, and traps) and bottom trawl.

We oppose this alternative.

C.14: Close Ecologically Important Areas to Fishing: The areas identified in Alternative C.12 (see Figure 2-28) are closed to all fishing.

We oppose this alternative.

The Draft EIS fails to take into consideration or explain the current regulations and restrictions that are in place and should prepare a map with overlays in the Final EIS. The PFMC and NMFS should seriously consider these existing and possible future (such as the California State Blue Ribbon committee studying MPA's) actions that may overlap any designations being considered in this EIS.

This EIS includes the following statement: ***6.1.7*** *EO 12866 (Regulatory Impact Review)* EO 12866, Regulatory Planning and Review was signed on September 30, 1993, and established guidelines for promulgating new regulations and reviewing existing regulations. The EO covers a variety of regulatory policy considerations and establishes procedural requirements for analysis of the benefits and costs of regulatory actions. Section 1 of the EO deals with the regulatory philosophy and principles that are to guide agency development of regulations. It stresses that in deciding whether and how to regulate, agencies should assess all of the costs and benefits across all regulatory alternatives. Based on this analysis, NMFS should choose those approaches that maximize net benefits to society, unless a statute requires another regulatory approach. The information and analyses in Chapter 4 of this EIS would be relevant to a Regulatory Impact Review (RIR) analysis of future regulations developed from this process. If proposed regulations are promulgated, an RIR would be prepared as part of a proposed regulatory package.

The question here is whether the Draft EIS sufficiently meets this requirement of an analysis of the benefits and costs of regulatory actions with regard to the designation of EFH and or HAPC. We would request that the NMFS expand the discussion on this EO and provide additional analysis of the proposed regulations on both the fishing fleets and the harbors and marinas within the study area.

We appreciate your consideration on this very important matter and look forward to the Final EIS including a response to our questions. Overall, we believe that the contents meet the minimum requirements of NEPA but the document must be expanded in the areas identified in our comments. We are available for consultation on our comments if you wish to discuss them further. Again, thank you for the opportunity to comment on this EIS.

circulation off the coast of California, coupled with estimates of populations connectivity for species of interest."

Beginning in 2003, we have integrated this report's recommendations, along with the needs expressed by both BRD and MMS, into our research plans. This year's research, described in Sections 4 and 5, will compliment and build upon our previous studies.

2. ACHIEVEMENTS IN 2004

A. Scientific Research

1) Platform and Natural Reef Surveys – In September 2004, with funding from MMS and CARE, we were able to survey the largest number of platforms since 1999. Complete surveys, including mussel mounds, were conducted at platforms Irene, Hidalgo, Harvest, Hermosa, Hondo (first time), Heritage (first time), Holly, Gail, Grace, and Gilda. Due to poor water visibility, only midwater surveys were conducted at platforms C, B, A, Hillhouse, Henry, and Habitat. In addition, we surveyed a number of natural reefs (some first mapped in spring 2004) in the Santa Barbara Channel and (with additional funding from the Channel Islands National Marine Sanctuary) around the northern Channel Islands.

Once again, we have found that many platforms harbor higher densities of both juvenile and adult fishes than do most natural reefs. In particular, the new seafloor maps produced by the USGS (see 3A) and partially ground-truthed by us demonstrated that the seafloor of much of the Santa Barbara Channel is composed of mud and sand. Thus, our research continues to demonstrate the importance of the Santa Barbara Channel platforms as providers of habitat for reef fishes.

2) Research on Recruitment of Young-of-the-Year Rockfishes to Platforms – In the spring and summer of 2004 (funded by MMS and CARE), we conducted intensive diver surveys of platforms Gail and Gilda, documenting the young fishes that recruited out of the plankton to these structures. At the same time, we determined both surface and midwater current patterns, to determine the current patterns that lead to the large numbers of young rockfishes we saw. In this way, we are attempting to understand why platforms are often so heavily populated by young rockfishes.

B. Scientific Publications Submitted, In Press, Or In Preparation

1) *The Unexpected Utility of Offshore Marine Structures in Rebuilding an Overfished Species*

The bocaccio (*Sebastes paucispinis*) is an historically important rockfish species, found on the West Coast of North America, that through overfishing has been reduced to about 7.4% of its unfished population. Based on our surveys, we estimated that there was a minimum of 433,682 juvenile bocaccio around the six platforms we surveyed in the Santa Barbara Channel. With assistance from NOAA Fisheries, we determined that this number of juvenile bocaccio is about 20% of the average number of juvenile bocaccio that survive in a year for the species' entire range (over 4,000 km of North American coastline) and, when adults, will contribute about one percent of the additional amount of fish needed to rebuild the Pacific Coast population. This research demonstrates, for the first time, that a small amount of artificial nursery habitat placed in the ocean may be quite valuable in rebuilding an overfished species.

Status: We submitted this important research to the biological journal Canadian Journal of Fisheries and Aquatic Sciences. The findings in this paper were sufficiently surprising that we been asked to rewrite the paper, adding additional data to bolster our case. This paper is being revised and will be resubmitted to that journal.

2) *Comparing Potential Larval Production of Bocaccio* (Sebastes paucispinis*) and Cowcod* (Sebastes levis*) around Oil Platforms and Natural Outcrops off California*

There is increasing evidence that some central and southern California oil platforms form important habitats for a number of economically important fishes. Given the overfished status of several of these species, we asked to what extent might platforms be important as producers of larvae of these species on a local, or even regional, basis. We conducted a pilot study that focused on bocaccio (*Sebastes paucispinis* Ayres, 1854) and cowcod (*S. levis* Eigenmann and Eigenmann, 1889), two overfished species, comparing adult densities and potential larval export of these species at platforms and natural outcrops in central and southern California. Densities of mature bocaccio and cowcod were highly variable among survey sites, but were generally very low at both natural reefs and platform habitats. However, the mean densities for both species around platforms were higher than at natural reefs. In addition, two of the three platforms (Gail and Hidalgo) that harbored mature bocaccio had larger mature individuals than did any natural reef. Platform Gail had by far the highest densities of both mature bocaccio and cowcod of any natural or human-made habitat. Because of these very high densities, the potential larval production of both species at Platform Gail was much higher than at any other site surveyed. We estimated that for bocaccio one hectare of sea floor at that platform was equivalent to 68 hectares at an average natural reef and for cowcod one platform hectare was equivalent to 26 at the average natural reef.

Status: Submitted to Bulletin of Marine Science

3) *A comparison of the Fish Assemblages Associated with an Oil/Gas Pipeline and Adjacent Seafloor in the Santa Barbara Channel, Southern California Bight.*

This paper summarizes our comparisons of the fishes that live on the platform Gail-Grace pipeline and the surrounding seafloor. Based on differences in fish assemblages, we found there were four habitats (shallow and deep pipeline and shallow and deep seafloor). Fish densities along the shallow portion of the pipeline were about seven times higher than on the adjacent seafloor and densities along the deep pipeline portion were nearly six times that of the deeper seafloor. Along the pipeline, rockfishes comprised 84% of the fishes and included 22 species. Unidentified sanddabs (probably most or all *Citharichthys sordidus*), forming 33.2%, and combfishes (*Zaniolepis frenata* and *Z. latipinnis*), comprising 19% of the total, were most often observed on the seafloor. Most of the fishes living on the pipeline were either juveniles of such larger species, such as blackgill, flag, and vermilion rockfishes, cowcod, and lingcod or dwarf species such as halfbanded and stripetail rockfishes, combfishes, and poachers (Family Agonidae), Of particular interest were the relatively high densities of juvenile cowcod along the deeper parts of the pipeline, densities that were far higher than any seen at over 80 natural outcrops and at ten platforms.

Status: Bulletin of Marine Science, in press.

4) *Do Oil and Gas Platforms off California Affect the Fate of Recruiting Bocaccio* (Sebastes paucispinis)*? An Analysis Based On High Frequency Radar Derived Surface Trajectories*.

Among some environmentalists, there is a concern that recruitment of high densities of many species of juvenile rockfishes (*Sebastes* spp.) from the plankton to some oil and gas platforms off southern and central California may reduce recruitment at natural nursery habitat. To investigate the likelihood of a platform interfering with the transport of recruiting pelagic juvenile fishes to natural nursery habitat, we estimated the proportion of fish recruiting to a platform that would arrive at natural juvenile habitat in the absence of that platform. In this study, we simulated the surface current movements originating at Platform Irene, located west of Point Conception, during the bocaccio (*Sebastes paucispinis*) recruiting seasons, May through August, of 1999 and 2002 using high frequency radar current measurements. Our results from 1999 and 2002 indicate that 7% and 23%, respectively, of the young fishes would have survived to shallow water natural nursery habitat. Thus, we predict that the vast majority of the juvenile bocaccio settling on the platform during the recruitment season would have perished if that structure did not exist. If this is correct, the platform helped produce bocaccio.

Status: Submitted to Fishery Bulletin

5) *The Role of Bottom Crossbeam Complexity in Influencing the Fish Assemblages at California Oil and Gas Platforms*

In this paper, we documented that many of the overfished and economically important fishes that live around oil platforms, such as bocaccio, cowcod, copper, greenblotched and vermilion rockfishes, were found most often where the bottom-most crossbeam (located at the seafloor) was present. In particular, a group of fishes (e. g., bocaccio, cowcod, blue and vermilion rockfishes) lived primarily where the crossbeam was undercut and formed a long crevice. This research suggests that enhancing the seafloor in and around decommissioned platforms with materials such as quarry rock or concrete will likely lead to higher densities of many economically important species.

Status: Submitted to Fishery Bulletin

6) *Growth Rates of Blue Rockfish at Three Platforms and Three Natural Reefs off California*

One of the issues confronting decommissioning authorities is the question of the “ecological performance” of the fishes living at platforms compared to the same species living on natural reefs. In other words, how “healthy” are fishes living at these human-made structures? In this study, we compared the daily growth rates of young blue rockfish (*Sebastes mystinus*) living around three platforms (Irene, Holly, and Gilda) and at three natural reefs in the same areas. In all instances, the fishes at the platforms grew faster than the fishes at the paired reefs.

Status: Report being prepared.

C. Presentations Regarding Platform Fish Ecology

Between March 2004 and January 2005, we gave presentations on fishes and platforms at the following meetings and to the following organizations: Centro de Investigacion Cientifica y de Educacion Superior Ensenada (CICESE), Ensenada, Mexico; Friends of Moss Landing, Moss Landing, California; University of Alaska, Juneau; Plains Oil Company.

3. CONCURRENT PLATFORM RESEARCH in 2004

Along with MMS and CARE-sponsored fish assemblage characterizations, we participated in the following platform-related research.

A. Sea floor mapping and characterization of the Santa Barbara Channel and Santa Maria Basin by USGS (MMS-Sponsored)

In 2004, Guy Cochrane of the U. S. Geological Survey conducted sea floor mapping of previously uncharacterized areas in the eastern Santa Barbara Channel. This research established that much of the sea floor in the Santa Barbara Channel is composed of soft sediments and bolsters the contention that platforms provide some of the only reef structure in the area.

B. Ecological Performance of OCS Platforms as Fish Habitat off California (MMS-Sponsored).

This MMS-funded program included the following tasks. 1) Estimating the potential annual production of larvae from reproductively mature cowcod and bocaccio at Platform Gail versus natural reefs (see paper #2 above). 2) Determining the growth rate of YOY rockfish that settle at platforms versus nearby natural reefs. 3) Estimating the survival and mortality rates of juvenile rockfish at platforms versus natural reefs.

C. Residence Time At Oil and Gas Offshore Platforms by Characteristic Fish Species (CARE and MMS-Sponsored)

This research, funded by MMS and CARE, will build on a pilot program conducted in 2002-2003. Dr. Chris Lowe, of Long Beach State University, will tag fishes with acoustic tags around Platform Gail and monitor their movements.

D. Fish Recruitment Processes at Platforms (MMS and CARE-sponsored)

In this study, funded by both MMS and CARE, we explored the processes that lead to successful settlement of rockfishes on platforms Gail and Gilda (see 2A2).

4. CONCURRENT PLATFORM RESEARCH 2005-2007

In addition to the CARE and MMS-sponsored surveys, the following platform-related research will occur in 2005.

A. Sea floor mapping and characterization of the Santa Barbara Channel and Santa Maria Basin (MMS-Sponsored)

In 2005, Guy Cochrane of the U. S. Geological Survey will continue to conduct sea floor mapping of previously uncharacterized areas in the eastern Santa Barbara Channel.

B. Investigation of Otolith Microchemical Signatures Specific to Fishes at Platforms (MMS-Sponsored).

This research, to be conducted between 2005 and 2007, will examine whether fishes living around platforms have a characteristic elemental “signature” in their ear bones. If a platform-dwelling fish does have this signature, it would remain in place even if that fish moved away from the platform to a natural reef. In essence, part of that fish’s ear bone would have a permanent “tag”, allowing researchers to trace the fish back to living around the platform.

C. Pollutant Body Burden of Fishes at Platforms and Natural Habitats (MMS-Sponsored)

A concern in the decommissioning process is the question of whether fishes living around platforms have higher levels of pollutants than those living in natural habitats. This research, to be conducted between 2005 and 2007, is intended to compare pollutant levels in fishes living around platforms and both over natural reefs and on soft sea floors.

D. Residence Time At Oil and Gas Offshore Platforms by Characteristic Fish Species

This research, funded by MMS and CARE, continues research begun in 2004. Dr. Chris Lowe, of Long Beach State University, intends to tag fishes with acoustic tags around platforms Grace and Gilda, monitor their movements and transfer some tagged fishes to natural reefs.

5. PROPOSED CARE-FUNDED RESEARCH FOR 2004-2005

This year, some of our most important platform-related work will center on several questions of direct importance to the issue of decommissioning.

A. What is the Relative Contribution of Platforms in Supplying Hard Substrate and Fishes to Regional Fish Populations?

Clearly, platforms harbor large numbers of both adults and juvenile fishes. But what is the relative importance of these platform fish communities in the context of their regions?

The most accurate way to gauge this contribution is to understand 1) the quantity of natural hard features and 2) the fish assemblages on these features, in the region around a platform. To accurately assess this, we have to have a good understanding of the amount of natural reefs in our area and, until 2004, this information was mostly lacking. However, as noted previously, in 2004 and continuing into 2005, Dr. Guy Cochrane of the USGS will map and characterize the sea floor habitat of much of the Santa Barbara Channel.

We will use this data to pinpoint new reefs for our fish surveys. These techniques will allow us to more accurately understand the contribution of a platform to the overall amount of rocky outcrops in the vicinity of the platform. In addition, this data will allow us to vastly expand our estimates of the contributions of platforms to the reproductive capacity of fishes in the region.

B. What is the fate of the 1999 rockfish year class at platforms and natural reefs in the Santa Barbara Channel and Santa Maria Basin using the *Delta* submersible?

In central and southern California, the La Nina conditions of 1999 lead to good survival of the larvae and young juveniles of a number of rockfish species. Specifically, using the *Delta* submersible, we saw large numbers of young bocaccio, flag, blue, olive, and widow rockfishes at some platforms. Densities of these rockfishes, particularly bocaccio and flag and widow rockfishes, were higher at some platforms than at any natural reef surveyed. From 2000 through 2003, we have revisited these platforms and observed high densities of 1999 year class fishes of the same species. Clearly, many of those rockfishes settling on the platforms in 1999 survived and were present through 2002. Some, such as bocaccio, have now spent all of their juvenile and parts of their adult lives around platforms, a good indication that some platforms are producing fish, rather than only attracting them.

By continuing our platform and natural reef surveys, we will learn more about the fate of these fishes. Will they remain around the platforms, ultimately maturing and reproducing? Will they move onto adjacent reefs? If either occurs, this will provide additional evidence that platforms produce fishes.

The Minerals Management Service is providing some funds for this research. However, as we have noted in the past, this is complex research and requires a considerable amount of data to arrive at defensible answers. In particular, it requires a relatively large number of surveys and, hence, a large number of submersible dive days. The MMS funding, while extremely useful, will not provide adequate funding for the needed dive days and personnel time. Thus, we are requesting funding from CARE to help us with these efforts.

6. BUDGET FY 2005-2006

A detailed budget is attached.

Executive Summary

The Pacific OCS Region (POCSR) Offshore Facility Decommissioning Cost Team (OFDC) was formed to develop cost estimates for decommissioning offshore oil and gas facilities in the POCSR. This OFDC cost report covers operator compliance with OCS oil and gas regulations (30 CFR 250 and 256) for permanent plugging of wells; removal of well conductors and platform jackets to 15 feet below the mudline; decommissioning and removal of platform decks; decommissioning and removal of pipelines and powercables as appropriate; site clearance; and other lease and permit requirements. The report is one of the inputs used by the POCSR to determine if a Supplemental Bond is required from a lessee.

This report assumes that POCSR platforms will be completely removed and transported to shore for disposal. The decommissioning cost estimates for individual platforms are based on a decommissioning scenario that was developed by the OFDC for the 23 Pacific OCS oil and gas platforms. The scenario assumes six decommissioning projects will be conducted during the 2010-2025 period, and that 2-6 platforms will be removed during each project to minimize the high cost of mobilizing/demobilizing a heavy lift vessel from the Gulf of Mexico, North Sea, or Asia. The decommissioning scenario and methodology assumptions are described in detail in Section 2 of this report.

The decommissioning costs were developed by the OFDC based on information obtained from MMS files, oil and gas operators, consultants, and technical decommissioning studies funded by the Minerals Management Service (MMS). The decommissioning scenario developed by the OFDC for this cost study represents MMS's best professional judgment regarding the sequence and timing of future platform decommissioning activities in the POCSR. The MMS is planning to conduct a detailed update of this report every five years to incorporate new information that results from advances in technology or changes in market conditions, and Federal, State and local regulatory requirements. More frequent updates may be required if unanticipated advances in technology occur or if there is a significant change in regulatory requirements.

The cost report estimates costs for each phase of the decommissioning process: Engineering and Planning, Permitting and Regulatory Compliance, Platform Preparation, Well Plugging and Abandonment, Conductor Removal, Mobilization and Demobilization of Heavy Lift Vessels, Platform Structure Removal, Pipeline and Powercable Decommissioning, Platform Transportation and Disposal, and Site Clearance.

Platform decommissioning costs can vary widely due to factors such as location and type (complexity) of the facility, number of structures to be removed, water depth and weight associated with the structure, the number and depth of wells and conductors, removal method, and transportation and disposal options. Although water depth and weight (size) are key variables in determining the decommissioning costs for any particular activity, other factors may have significant impact on the decommissioning cost. For example, the costs of plugging and abandoning a well with deviation greater than 60 degrees will be much greater than the cost of plugging and abandoning a well with no deviation. Similarly, the cost of decommissioning a pipeline that must be removed will be much greater than the cost of decommissioning a pipeline that is approved to be abandoned in-place.

The costs of mobilizing and demobilizing a heavy lift vessel can also vary widely depending on the origin of the derrick barge and the number of platforms that are being decommissioned as a group. This cost of mobilizing and demobilizing a heavy lift vessel will be very high in POCSR due to fact that such vessels are currently stationed in the North Sea, Gulf of Mexico, or Asia. It is very unlikely that heavy lift vessels would be stationed in the POCSR unless there was a strong and prolonged market demand for such vessels. This situation is not considered likely to change in the foreseeable future.

Table 1 shows the estimated decommissioning cost for each platform in the POCSR. Appendix B shows the total cost for decommissioning for each platform by cost category.

Table 1 Platform Decommissioning Costs (2004 Dollars)

Platform	Decommissioning Cost
Platform A	$21,533,000
Platform B	$22,579,000
Platform C	$19,401,000
Edith	$22,265,000
Ellen	$33,176,000
Elly	$19,946,000
Eureka	$73,569,000
Gail	$70,191,000
Gilda	$33,906,000
Gina	$10,291,000
Grace	$27,405,000
Habitat	$23,550,000
Harmony	$129,842,000
Harvest	$71,274,000
Henry	$15,755,000
Heritage	$128,654,000
Hermosa	$64,827,000
Hidalgo	$52,859,000
Hillhouse	$20,743,000
Hogan	$21,849,000
Hondo	$77,051,000
Houchin	$21,318,000
Irene	$25,715,000
Total POCSR	$1,007,699,000

Figure 1 is a map showing the location of the POCSR platforms and pipelines. Maps showing platforms included in each decommissioning project are included in Appendix A.

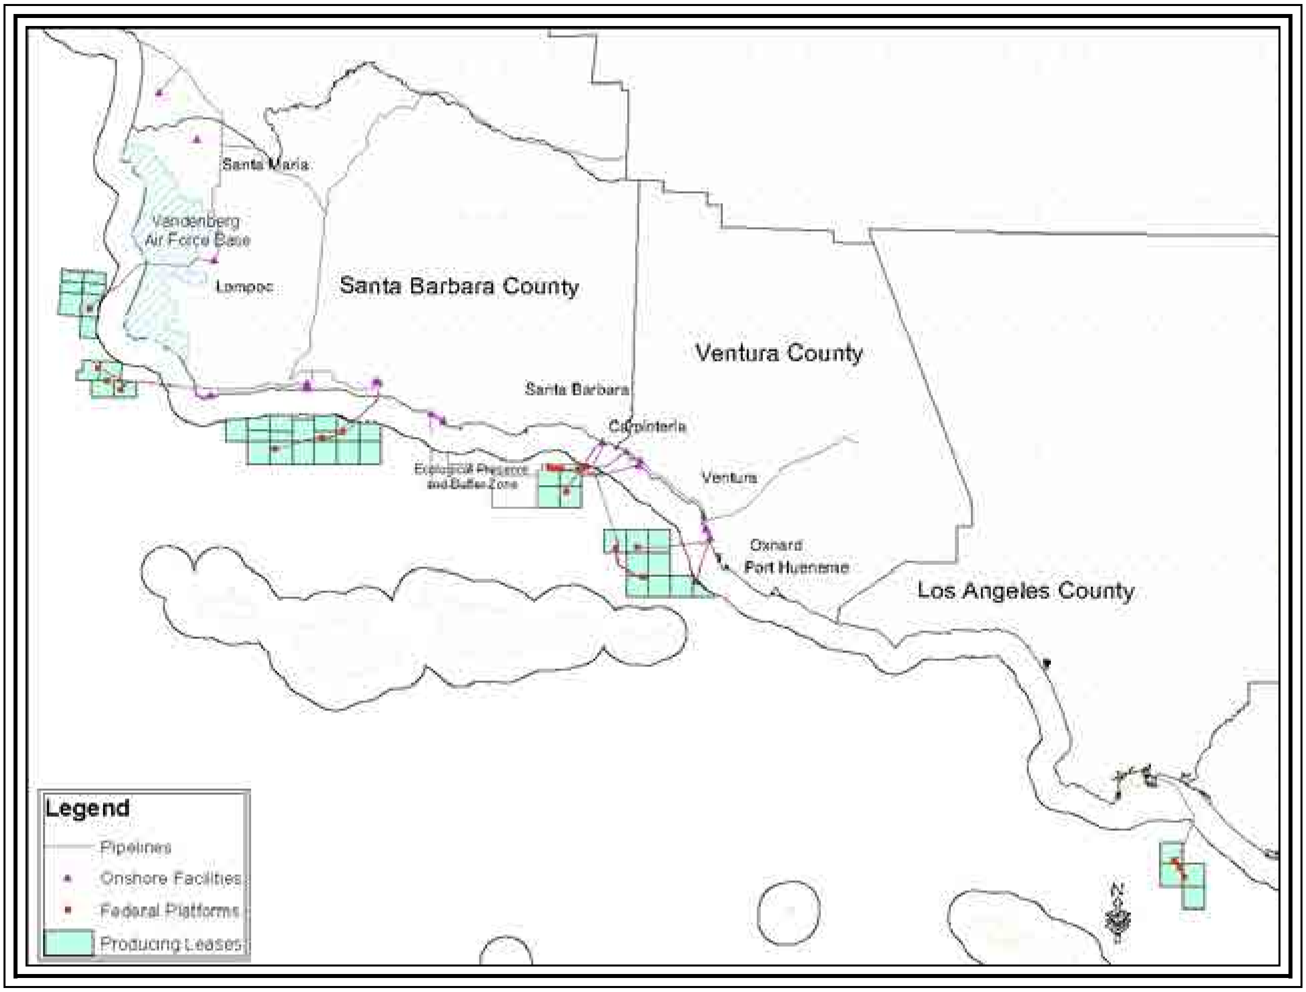

Figure 1 Federal Platforms and Pipelines in the Pacific OCS Region

Section 1: Introduction

The Pacific OCS Region (POCSR) Offshore Facility Decommissioning Cost Team (OFDC) was formed to develop cost estimates for decommissioning OCS oil and gas facilities in the POCSR. This cost study was prepared by the OFDC in accordance with Federal regulations (30 CFR 250 and 256) governing oil and gas operations decommissioning conducted on the OCS. The regulations specify requirements for plugging wells, decommissioning platforms and pipelines, and clearing a lease site. This report is one of the inputs used to determine if a lessee is required to post a Supplemental Bond to insure OCS lease decommissioning obligations are met. 30 CFR 256 and MMS Notice to Lessees No. 2003-N06 specify the requirements for Supplemental Bonds.

Development of the cost estimates required compilation of detailed and updated information on the offshore facilities in the POCSR, including: number of wells, number and weight of conductors, depth of productive interval, water depth, number of modules and weight of platform decks, depth and weight of platform jacket, location and size of pipelines, and location of powercables. The OFDC also conducted a literature review and collected cost data from industry sources. Much of the cost information presented in this report was obtained from technical decommissioning studies funded by the MMS, industry sources, and engineering and environmental consulting firms that have provided technical services to oil and gas companies in the POCSR and the Gulf of Mexico Region.

Decommissioning experience offshore California is very limited, as is information on costs. To date, only seven relatively small structures have been decommissioned; all were located in State waters. The most recent project occurred in 1996 when Chevron (now ChevronTexaco) removed Platforms Hope, Heidi, Hilda, and Hazel. These platforms were in water depths ranging from 100 to 140 feet and had an approximate total weight of 12,000 tons. In a news release dated April 17, 1996, Chevron reported that the cost of the final phase of dismantling and removing the four platforms was approximately $19 million. This cost did not include the costs to permanently plug 134 wells on the platforms. Local media coverage and industry journal articles reported that the total project cost ranged between $35 million and $40 million.

The private sector has compiled a significant amount of technical and cost data on platforms that have been decommissioned in the Gulf of Mexico. The majority of this data covers platforms that were located in water depths of less than 200 feet. From 200 to about 300 feet, there is less data available because fewer decommissioning projects have occurred in these water depths. Beyond a water depth of about 300 feet, the experience and data decline to the point where industry estimates and our cost estimates are based primarily on projections. It is clear, however, that decommissioning costs will rise steeply as decommissioning activities move from shallow water near shore to deeper water environments farther offshore.

Relative to the Gulf of Mexico, the POCSR has a high percentage of large deepwater structures. Of the 23 platforms, 14 (61%) are located in water depths exceeding 200 feet.

Moreover, 8 (35%) of OCS platforms are located in water depths that exceed 400 feet, which approximates the current worldwide water depth record for a platform removal project. The removal weight for individual platforms ranges from about 1,100 to nearly 70,000 tons. Table 1-1 provides information on water depth, weight, year installed, and field/unit for each of the 23 Pacific OCS platforms.

Each step in the decommissioning process is discussed individually in the sections that follow: Engineering and Planning, Permitting and Regulatory Compliance, Platform Preparation, Well Plugging and Abandonment, Conductor Removal, Mobilization and Demobilization, Platform and Structural Removal, Pipeline and Powercable Decommissioning, Platform Transportation and Disposal, and Site Clearance. Although water depth and weight (size) are key variables in determining the decommissioning costs for any particular activity, other factors may have significant impact on the decommissioning cost. These factors are addressed in the appropriate section.

The appendices include detailed specifications for the offshore facilities in the POCSR, estimated decommissioning cost by component for each platform, and detailed cost tables for selected decommissioning elements. Also included in the appendices are maps of the decommissioning projects used to determine the costs for this report.

The OFDC Team consisted of subject matter experts from several offices in the POCSR: Frederick L. White, Catherine Hoffman, John Smith, Michael Mitchell, Glenn Shackell, Eddie Lee Lim, and David Gebauer, with Rishi Tyagi as the team sponsor.

Table 1-1 Pacific OCS Region Platforms

Platform	Water Depth (in feet)	Estimated Removal* Weight (tons)	Year Installed**	Field/Unit
A	188	4,090	1968	Dos Cuadras
B	190	4,095	1968	Dos Cuadras
C	192	4,010	1977	Dos Cuadras

Elly	255	9,400	1980	Beta/Beta
Eureka	700	34,000	1984	Beta/Beta
Gail	739	31,320	1987	Sockeye/Santa Clara
Gilda	205	9,342	1981	Santa Clara/Santa Clara
Gina	95	1,102	1980	Hueneme/Pt. Hueneme
Grace	318	9,390	1979	Santa Clara/Santa Clara
Habitat	290	8,853	1981	Pitas Point/Pitas Point
Harmony	1,198	69,920	1989	Hondo/Santa Ynez
Harvest	675	30,190	1985	Pt. Arguello/Pt. Arguello
Henry	173	3,118	1979	Carpinteria
Heritage	1,075	60,556	1989	Pescado/Santa Ynez
Hermosa	603	28,131	1985	Pt. Arguello/Pt. Arguello
Hidalgo	430	21,421	1986	Pt. Arguello/Pt. Arguello
Hillhouse	190	3,738	1969	Dos Cuadras
Hogan	154	4,110	1967	Carpinteria
Hondo	842	27,250	1976	Hondo/Santa Ynez
Houchin	163	4,637	1968	Carpinteria
Irene	242	7,652	1985	Pt. Pedernales/Pt. Pedernales Tranquillon Ridge/Tranquillon Ridge

* Estimated Removal Weight includes the weight of the jacket, deck, piles, and conductors and assumes that they are removed to a depth of 15 feet below the mudline.

** Year Installed Date is the jacket installation launch date.

Section 2: Decommissioning Cost Assumptions and Scenario

This section provides a description of the decommissioning cost assumptions and scenario used in this report to estimate decommissioning costs for POCSR platforms and associated pipelines and powercables. The decommissioning scenario assumes that the platforms will be completely removed and the materials transported to shore for recycling or disposal. The decommissioning costs were developed by the OFDC based on information obtained from MMS files, oil and gas operators, consultants, and technical decommissioning studies funded by MMS and others. The decommissioning scenario represents MMS's best professional judgment regarding the sequence and timing of future platform decommissioning activities in the POCSR. The timing and scope of future decommissioning operations could differ markedly from this scenario, due to economic, technological, and other factors.

Decommissioning Cost Assumptions

- Costs are estimated in 2004 dollars.
- Conventional state-of-the-art technology (reverse installation using heavy lift vessels) will be used to remove platforms.
- A total of 6 OCS decommissioning projects are projected to be conducted during 2010-2025; all of the POCSR oil and gas platforms (23 facilities) will be removed during this period.
- During each project a total of 2-6 platforms will be decommissioned using heavy lift vessels mobilized from the Gulf of Mexico, North Sea or Asia.
- Platforms will be completely removed and transported to shore for disposal.
- Pipelines will be decommissioned in-place, partially removed, or completely removed from the OCS as appropriate (costs are estimated on a case-by-case basis).
- Powercables will be decommissioned in-place, partially removed, or completely removed from the OCS (costs are estimated on a case-by-case basis).

Scope of Cost Analysis

This section provides a listing of the items that are included in the cost estimates presented in this report. Also listed are items for which costs were not estimated. The cost estimates presented in this report were developed to support Federal bonding decisions to cover decommissioning obligations on Federal OCS leases. The report therefore does not include cost estimates for decommissioning oil and gas facilities and equipment located onshore or in State waters. The report also does not include certain other costs which could be individually and cumulatively significant if they happen to be included in an actual decommissioning project. These other costs include environmental mitigation costs imposed by other agencies, shell mound remediation, and the cost of retaining of a decommissioning agent (e.g., a civil engineering firm) having the specialized expertise to plan and manage a decommissioning project.

The decommissioning costs for platform structure removal and pipeline and powercables include a weather contingency of 10% or 20% . The 20% contingency factor has been applied only to Platforms Harvest, Hermosa, Hidalgo, Heritage, and Irene due to the harsher oceanographic conditions that exist in the areas where these platforms are located. In addition to the weather contingency, we have applied a 20% general contingency factor to cover unanticipated problems and potential cost overruns. The weather and general contingency factors were not applied to the mobilization and demobilization portion of the decommissioning costs.

Costs Included

- Engineering and Planning
- Permitting and Regulatory Compliance (including selected environmental mitigation costs typically required)
- Platform Preparation
- Well Plugging and Abandonment
- Conductor Removal
- Mobilization and Demobilization (Mob/Demob) of Heavy Lift Vessels
- Platform Structure Removal
- Pipeline and Powercable Decommissioning
- Platform Transportation and Disposal
- Site Clearance and Verification
- General and Weather Contingency Factors

Costs Not Included

- Decommissioning of pipelines and powercables located on State Tidelands (submerged lands located 0-3 miles offshore) or onshore.
- Decommissioning of onshore pipelines and powercables.
- Decommissioning of marine terminals, piers, and other associated equipment located on State Tidelands.
- Decommissioning of associated onshore oil and gas processing facilities.
- The costs of capping or removing shell mounds at OCS platforms, since this will be reviewed on a case-by-case basis.
- The cost of retaining a Decommissioning Agent.
- Special environmental mitigation costs (e.g., air emissions/vessel engine retrofit expenses, water quality, and habitat restoration) that are difficult to estimate due to their variability and case-by-case applicability.
- Non-MMS agency permit processing fees and reimbursable expenses.

Decommissioning Scenario

This section describes the 6 decommissioning projects that are projected to be conducted during 2010-2025 (see Table 2-1.) As noted above, a total of 2-6 platforms are expected to be removed during each project. For each project, a heavy lift vessel (HLV) is assumed to be mobilized from the Gulf of Mexico, North Sea, or Asia. The HLV's projected to be used have lift capabilities of 500 tons, 2,000 tons, and 4,400 tons. The type of HLV selected for each project was determined based on the size (total weight) of each individual platform included in the project, the projected maximum lift packages, and oceanographic considerations. A number of factors were considered in developing the projects, including the size, age and geographic location of the platforms, remaining oil and gas reserves, water depth, and company operators/ownership. For each project, the HLV mob/demob costs are allocated evenly among platforms.

Project I – Eastern Santa Barbara Channel

- Platforms Hogan and Houchin are projected to be removed during 2010-2015.
- An HLV with a lift capability of 500 tons will be mobilized from Asia.
- The estimated mob/demob time is 100 days.

Project II – South Coast (Los Angeles/Orange County)

- Platforms Eureka, Elly, Ellen and Edith are projected to be removed during 2010-2015.
- An HLV with a lift capability of 2,000 tons will be mobilized from Asia.
- The estimated mob/demob time is 100 days.

Project III – Eastern Santa Barbara Channel

- Platforms A, B, C, Henry, Hillhouse and Gina are projected to be removed during 2010-2015.
- An HLV with a lift capability of 2,000 tons will be mobilized from Asia.
- The estimated mob/demob time is 100 days.

Project IV – Eastern Santa Barbara Channel

- Platforms Gilda, Irene and Habitat are projected to be removed during 2010-2015.
- An HLV with a lift capability of 2,000 tons will be mobilized from Asia.
- The estimated mob/demob time is 100 days.

Project V – Southern Santa Barbara Channel/Santa Maria Basin

- Platforms Gail, Grace, Hermosa, Harvest, and Hidalgo are projected to be removed during 2015-2020.
- An HLV (dynamically positioned mono-hull) with a lift capability of 4,400 tons will be mobilized from the Gulf of Mexico or North Sea.
- The estimated mob/demob time is 200 days.

Project VI – Western Santa Barbara Channel

- Platforms Hondo, Harmony, and Heritage are projected to be removed during 2020-2025.
- An HLV (dynamically positioned mono-hull) with a lift capability of 4,400 tons will be mobilized from the Gulf of Mexico or North Sea.
- The estimated mob/demob time is 200 days.

Table 2-1 Projected Decommissioning Projects

Platform	Year Installed	Water Depth (feet)	Deck Weight (tons)	Jacket Weight* (tons)	Projected Removal Timeframe	Projected HLV Lift Capability (tons)
Project I – Eastern Santa Barbara Channel						
Hogan	1967	154	2,259	1,263	2010-2015	500
Houchin	1968	163	2,591	1,486	2010-2015	500
Project II – South Coast (Los Angeles/Orange County)						
Eureka	1984	700	8,000	19,000	2010-2015	2,000
Elly	1980	255	4,700	3,300	2010-2015	2,000
Ellen	1980	265	5,300	3,200	2010-2015	2,000
Edith	1983	161	4,134	3,454	2010-2015	2,000
Project III – Eastern Santa Barbara Channel						
A	1968	188	1,357	1,500	2010-2015	2,000
B	1968	190	1,357	1,500	2010-2015	2,000
C	1977	192	1,357	1,500	2010-2015	2,000
Henry	1979	173	1,371	1,311	2010-2015	2,000
Hillhouse	1969	190	1,200	1,500	2010-2015	2,000
Gina	1980	95	447	434	2010-2015	2,000
Project IV – Santa Barbara Channel/Southern Santa Maria Basin						
Gilda	1981	205	3,792	3,220	2010-2015	2,000
Irene	1985	242	2,500	3,100	2010-2015	2,000
Habitat	1981	290	3,514	2,550	2010-2015	2,000
Project V – Santa Barbara Channel/Southern Santa Maria Basin						
Gail	1987	739	7,693	18,300	2015-2020	4,400
Grace	1979	318	3,800	3,090	2015-2020	4,400
Hermosa	1985	603	7,830	17,000	2015-2020	4,400
Harvest	1985	675	9,024	16,633	2015-2020	4,400
Hildalgo	1986	430	8,100	10,950	2015-2020	4,400
Project VI – Western Santa Barbara Channel						
Hondo	1976	842	8,450	12,200	2020-2025	4,400
Harmony	1989	1,198	9,826	42,900	2020-2025	4,400
Heritage	1989	1,075	9,839	32,420	2020-2025	4,400

* Jacket Weight is the weight of the jacket only and does not include the weight of the deck, conductors or piles.

Section 3: Decommissioning Methodology

This section describes the methodology on which the decommissioning costs in this report are based. The methodology is consistent with the cost assumptions previously described and with MMS decommissioning requirements (30 CFR Parts 250 and 256) and standard industry practice.

Well Plugging and Abandonment

- All unplugged and temporarily abandoned wells will be permanently plugged and abandoned (P & A) consistent with MMS requirements.
- An existing platform rig or an acquired rig will be used to P & A wells (rigless methods will not be used except on Platform Grace).
- This work will be completed prior to arrival of the heavy lift vessel (HLV).

Conductor Removal

- All conductors will be removed to 15 feet below the original mudline.
- Mechanical cutting methods will be used to sever the conductors below the mudline.
- Casing jacks will used to make the initial lift to confirm that conductors have been completely severed below the mudline.
- The platforms drilling rig and crane or a combination of the rig and jacks or portable leapfrog cranes will be used to pull conductors.
- Mechanical cutting methods will be used to cut the conductors into 40-foot-long segments.
- The platform crane will place the cut sections on a workboat for transport to an onshore disposal site.
- This work will be completed prior to arrival of the HLV.

Platform Preparation

- A platform inspection, above and below the water line, will be conducted to determine the condition of the platform and identify potential problems with salvage. The inspection will be conducted by divers or by a combination of divers and remotely operated vehicles.
- All piping and equipment on the platform that contained hydrocarbons will be flushed and cleaned.
- All modules to be removed separately from the deck will be detached from the platform structure using oxygen-acetylene cutting torches.
- The piping, electrical, and instrumentation connections between modules will also be cut.
- Modules and captrusses (support frames) will be prepared for removal; new padeyes and lift supports will be installed; welds around bearing joints will be removed; and external equipment obstructing module lifts will be removed.
- It is assumed that 50% of the number of padeyes necessary for making the deck structure lifts must be fabricated and installed.

- Diving crews will use 10,000 psi water blasters to remove marine growth from the jacket to a water depth of approximately 100 feet; the dive spread will be set up on the platform; this work will be completed prior to the arrival of the HLV.
- The remaining marine growth attached to the deeper jacket sections will be removed after the HLV places the sections on the cargo barges; topside crews will use high-pressure water blasters to remove the marine growth.

Pipeline Decommissioning

- All pipelines will be flushed and cleaned
- Divers or an ROV will then expose the ends of the pipeline and cut the line above the riser bend and approximately 10 feet from the base of the jacket.
- Pipelines will be evaluated by MMS on a case-by-case basis during the permitting process, to determine whether they will be approved to be left in place or required to be partially or totally removed.
- Pipelines approved to be left in place will be required to be capped and their ends buried 3 feet below the mudline or covered with protective mats (e.g., articulated concrete mats).
- Pipelines or pipeline segments that have the potential to present an obstruction to other users will be removed.
- Pipeline segments that are removed will be transported to shore, cut into smaller segments, and transported to a disposal site.
- A small crane barge will be mobilized from the southern California area to remove pipelines if necessary.

Powercable Decommissioning

- Powercables that an operator has committed to removing will be removed (e.g., ExxonMobil's Santa Ynez Unit powercables).
- Other powercables will be evaluated on a case-by-case basis by MMS to determine whether they may be left in place or will be required to be partially or totally removed.
- Powercables or segments of powercable determined to have the potential to present an obstruction to other users will be removed.
- Powercable segments that are removed will be transported to shore, cut into segments, and transported to a disposal site.
- Powercables approved to be left in place will be required to have their ends capped and buried 3 feet below the mudline, or covered with protective coverings (e.g., articulated concrete mats).
- A special cable lay/retrieval vessel will be mobilized from the east coast of the U.S., Europe, or Asia to remove large segments of cable if necessary.

Mobilization and Demobilization of Vessels

- HLV's and their anchor handling tugs will be mobilized from the Gulf of Mexico, North Sea or Asia.
- Cargo barges will be mobilized from California or the Pacific Northwest

- Cargo barges will be outfitted at a fabrication yard with steel pads (load spreaders) to support the point loads of the deck modules and jacket sections.
- Support vessels and dive boats will be mobilized from southern California.
- Local crew boats and workboats will be utilized to the maximum extent practicable.

Topsides Removal

- Topside modules will be removed (reverse installation) and placed on cargo barges.
- The deck section or support frames (captrusses) will be removed by cutting the welded connections between the piles and the deck legs with oxygen-acetylene torches.
- Slings will be attached to the deck/captrusses lifting eyes and to the HLV crane.
- The HLV crane will lift the deck sections from the jacket and position the sections in load spreaders.
- The deck sections will be secured by welding steel pipe from the deck legs to the deck of the cargo barge.

Topsides Transport and Onshore Disposal

- Tugboats and cargo barges will transport the topside modules and deck structures to a scrap yard located in the United States, Mexico, or Asia.
- Possible U.S. west coast destinations are Los Angeles, Long Beach, San Diego, San Francisco, California and Portland, Oregon.
- The modules will be lifted off the cargo barges by dockside cranes or skidded off the barge.
- All of the structural components will be cut into small pieces and transported to a scrap yard.
- Non-metallic materials (cement, plastics, wood, etc.) will be transported to shore for disposal in a landfill.

Jacket Removal

- Jackets will be sectioned in situ (in place) and removed.
- Piles and skirt piles will be severed 15 feet below the original mudline by explosives or abrasive cutting tools.
- Divers will be deployed to sever structural members and section the jackets.
- Saturation diving techniques will be required below 150 foot water depths.

Jacket Transport and Onshore Disposal

- Tugboats and cargo barges will transport the jacket sections to an onshore scrap yard located on the west coast of the U.S., in Mexico, or in Asia.
- Possible U.S. west coast destinations are Los Angeles, Long Beach, San Diego, San Francisco, California and Portland, Oregon.
- The jacket sections will be lifted off the barges by dockside cranes or skidded off the barge.
- The jacket sections will be cut into small pieces and transported to a scrap yard.

Site Clearance

- The seafloor impacted as a result of oil and gas exploration, development, production, and decommissioning operations will be restored to a condition that ensures the area has been cleared of all obstructions to other activities.
- Site clearance procedures will include the following elements:
    1. Pre-decommissioning high resolution side-scan survey (SSS)
    2. Post-decommissioning high resolution SSS
    3. ROV/diver target identification and recovery of obstructions
    4. Test-trawling
- The pre-decommissioning SSS will cover all areas of the lease where operations occurred, including pipeline and powercable routes, and anchoring and mooring locations to identify any potential oil and gas related obstructions.
- The post-decommissioning SSS will cover all areas where decommissioning activities occurred to identify debris and obstructions resulting from decommissioning operations.
- A dive boat/ROV spread will be deployed to inspect and retrieve debris or obstructions identified during the SSS surveys.
- Test trawling will be conducted to verify that all potential obstructions have been cleared from the OCS lease(s).

Section 4: Engineering and Planning

The engineering and planning phase of the decommissioning process typically begins two to three years before production ceases and involves (1) a review of contractual obligations, (2) engineering analysis, (3) operational planning, and (4) contracting. The first step involves conducting a detailed review of all records and decommissioning requirements including lease, operating, production/unit, pipeline, and production sales agreements. A detailed engineering analysis is also conducted of drilling records, as-built drawings, construction reports, maintenance records and inspection reports. Field inspections are done to verify the structural integrity of the platform and examine the present condition of the wellheads and equipment. Based on this information, detailed engineering plans are developed for plugging and abandoning the wells, severing the conductors and piles, removing the topsides and jacket, and disposing of the materials. Concurrently, a comprehensive survey of decommissioning vessels and equipment is made to determine their availability and cost. Bids are then solicited and contractors selected.

Due to the limited availability of heavy lift vessels, contracting for such vessels is typically done two to three years in advance. Although some engineering functions can be conducted in-house if expertise exists, many steps in the decommissioning process require specialized expertise and the company must contract for this expertise. These steps include mechanical, abrasive, or explosive cutting services, civil engineering services to design and prefabricate the modules for individual lifts, and diving services. In addition, the services of firms having project management and engineering expertise specific to decommissioning are often secured to manage the complex logistics of the overall project.

Cost Assumptions

The costs of engineering and planning for decommissioning an offshore structure can vary widely, depending on the type of structure, its size and water depth, removal procedures, and transportation and disposal options. The costs can also vary widely depending on the degree to which costs can be internalized due to the availability of in-house engineering expertise. For this study, engineering and planning costs are estimated to be 8%, 10%, or 12% of the total structure removal cost which is calculated at $1,200 per ton (total platform removal weight). The percentage varies with platform water depth/size and is applied in the following manner: 0-200 foot water depths 12%, 201-450 foot water depths 10%, and >450 feet of water 8%. The $1,200 per ton cost figure was based on data obtained from a civil engineering company that compiles annual cost data on oil and gas platform decommissioning projects in the Gulf of Mexico. The cost figure represents the average cost of platform structure removal in 2002, the most recent year for which data was available.

Cost Estimates

The range of costs for the engineering and planning cost component is shown in Table 4-1. The costs range from a low of $159,000 to a high of $6.7 million. The tonnage figure is based on MMS's projection of the total weight to be removed during the dismantlement and removal phase of the project. The $1,200 per ton figure does not include well plugging and abandonment and conductor removal.

Table 4-1 Engineering and Planning Costs

Platform	Water Depth (feet)	Factor	Total Weight (tons)*	Total Costs
A	188	0.12	4,090	$589,000
B	190	0.12	4,095	$590,000
C	192	0.12	4,010	$578,000
Edith	161	0.12	8,298	$1,195,000
Ellen	265	0.10	11,300	$1,356,000
Elly	255	0.10	9,400	$1,128,000
Eureka	700	0.08	34,000	$3,264,000
Gail	739	0.08	31,320	$3,007,000
Gilda	205	0.10	9,342	$1,122,000
Gina	95	0.12	1,102	$159,000
Grace	318	0.10	9,390	$1,127,000
Habitat	290	0.10	8,853	$1,063,000
Harmony	1,198	0.08	69,920	$6,713,000
Harvest	675	0.08	30,190	$2,899,000
Henry	173	0.12	3,118	$449,000
Heritage	1,075	0.08	60,556	$5,814,000
Hermosa	603	0.08	28,131	$2,701,000
Hidalgo	430	0.10	21,421	$2,571,000
Hillhouse	190	0.12	3,738	$539,000
Hogan	154	0.12	4,110	$592,000
Hondo	842	0.08	27,250	$2,616,000
Houchin	163	0.12	4,637	$668,000
Irene	242	0.10	7,652	$919,000
Total	-	-	-	$41,659,000

* Total Weight is the estimated platform removal weight and includes the weights of the jacket, deck, piles, and conductors being removed to 15 feet below the mudline.

Section 5: Permitting and Regulatory Compliance

Permitting and regulatory compliance costs are incurred in obtaining the necessary Federal, State, and local permits required to conduct decommissioning operations and prepare the environmental documentation to satisfy the requirements of the California Environmental Quality Act (CEQA) and the National Environmental Policy Act (NEPA). The costs to satisfy special environmental mitigation requirements that typically are placed on the project by regulatory agencies are also included in this cost component. Examples include marine mammal protection measures, air emission mitigation measures, commercial fishermen preclusion agreements, and pre- and post-decommissioning biological surveys. For decommissioning projects offshore California, these costs can be significant.

Federal agencies that have regulatory authority over various aspects of decommissioning projects include the MMS, National Marine Fisheries Service, U.S. Army Corps of Engineers, U.S. Fish and Wildlife Service, U.S. Environmental Protection Agency, U.S. Coast Guard, and the U.S. Department of Transportation, Office of Pipeline Safety. State and local agencies having regulatory jurisdiction over decommissioning operations in California include the California Coastal Commission, California State Lands Commission, California Department of Fish and Game, California Division of Oil, Gas and Geothermal Resources, California State Fire Marshal, County Planning and Resource Management Departments, and local Air Pollution Control Districts. Due to the numerous permits required and the complexity of the process, companies that have decommissioned structures offshore California have typically contracted with local consulting firms to obtain technical, environmental and administrative support services.

Information on permitting and regulatory compliance costs for decommissioning projects is limited. To develop information on these costs, we surveyed public literature and contacted several local consulting firms that have provided technical, environmental, and administrative services for decommissioning projects in southern California. Based on this survey, we determined that the majority of the costs were for air emission mitigation measures, marine mammal mitigation measures, agency administrative fees, environmental consultants, and commercial fishermen preclusion agreements. Much of the information that is available pertains to the removal of Platforms Hope, Heidi, Hilda, and Hazel, commonly referred to as the Chevron 4-H Project, which was completed in 1996. Table 5-1 provides a perspective on some of the major permitting and regulatory compliance costs associated with this project:

Table 5-1 Chevron 4-H Permitting and Regulatory Compliance Costs

Permitting and Regulatory Cost Elements	Cost
Santa Barbara County Air Emission Offset Fees	$450,000
California State Lands Commission Administrative Fees	$450,000
Marine Mammal and Wildlife Protection Plan	$200,000
Environmental Consultants	$200,000
Commercial Fishermen Preclusion Agreements	not available

The costs of air emission offsets were obtained from the Chevron news release dated April 17, 1996. The California State Lands Commission (SLC), Marine Mammal and Wildlife Protection Plan, and environmental consultant cost estimates were provided by SLC, Chevron, and environmental consulting firms. The $450,000 paid by Chevron to SLC was required to cover the SLC's engineering and CEQA environmental document preparation fees and mitigation monitoring expenses. Chevron also developed and implemented a comprehensive marine mammal and wildlife protection plan for the project. Chevron estimated that it cost approximately $200,000 to develop and implement the plan, which equates to $50,000 per platform.

Companies conducting oil and gas projects offshore California typically provide compensation to commercial fishermen who are precluded from fishing in areas they commonly fish due to the presence of barges, workboats, and other construction related vessels. The cost of preclusion agreements is contingent upon the scope, location, and duration of the project. The costs are considered proprietary by the companies and fishermen.

Cost Assumptions

For this study, we have included costs for NEPA and CEQA environmental documentation, marine mammal observers, environmental consultants, pre- and post construction biological surveys, and compensating fishermen for being precluded from fishing in the area where decommissioning operations are conducted. The MMS estimates that it would cost $1.2 million dollars to prepare a NEPA Environmental Impact Statement for a decommissioning project that would involve removing two or more platforms. For the purposes of this study, we have assumed the costs of NEPA/CEQA environmental documentation will total $300,000 per platform. For marine mammal monitoring, we estimate that the costs will be $50,000 per platform. As noted earlier, explosives are likely to be used to sever the pilings of the structure. We have also assumed that this cost would be incurred even if explosives were not used, since marine mammal mitigation measures have been required for many recent offshore projects that did not involve the use of explosives. We have estimated the cost of environmental consultants to be $100,000 per platform, the cost of biological surveys to be $50,000 per platform and the cost of compensating fishermen to be $50,000 per platform. It should be noted that this report does not attempt to estimate costs for other potential environmental mitigation measures such as air emission/vessel engine retrofit expenses, and habitat restoration. Air emission offset fees were not considered applicable due to the fact that a state law was enacted subsequent to the Chevron 4-H Project that prohibits local Air Pollution Control Districts from imposing such fees.

Cost Estimates

Based on the above information, permitting and regulatory compliance costs are estimated to total $550,000 per platform. The costs are itemized in Table 5-2.

Table 5-2 Permitting and Regulatory Compliance Costs

Permitting and Regulatory Cost Elements	Cost
NEPA/CEQA costs	$300,000
Marine Mammal Monitoring	$50,000
Environmental Consultants	$100,000
Special Biological Surveys	$50,000
Commercial Fishing Preclusion Agreements	$50,000
Total Per Platform	$550,000

Section 6: Platform Preparation and Marine Growth Removal

Platform preparation includes the procedures associated with shutting down and preparing the facility for removal. Normally a crew paid on a day rate prepares the structure for decommissioning after the wells have been permanently plugged and abandoned. Above water and below water inspections are generally conducted to determine the condition of the structure and to identify any problems to removal. Divers and/or remotely operated vehicles (ROV's) assist in the inspections. On the surface, the work includes the flushing/cleaning and degassing/purging of tanks, processing equipment and piping, disposal of residual hydrocarbons, removal of platform equipment, cutting of piping and cables between deck modules, separation of modules into individual units, installation of padeyes for deck module lifting, removal of obstructions to lifting, and structural reinforcement. Below the water surface, the jacket can be prepared to aid in jacket facilities removal, including the removal of marine growth from the structure.

The key factors affecting the cost of platform preparation include structure size and complexity, topsides equipment (especially amount of processing equipment), and age of the facility. The costs can vary widely depending on the type of facility, removal procedures, and transportation and disposal options. The costs can also vary depending upon the degree to which costs can be internalized due to the availability of in-house manpower and expertise.

For this study, we assumed that marine growth will be removed from the structure, including the conductors and boat landings, by divers down to approximately 100 feet below the ocean surface. This will remove most of the heavy, hard marine growth. The balance of the marine growth will be removed using topside crews and high-pressure water blasters and/or fixed firewater monitors (nozzles) once the jacket or jacket section is on the deck of the barge. The in-water cleaning operations will be completed with the dive equipment set up on the platform to eliminate the need and added cost that would be incurred if the operations were conducted from a dedicated dive vessel.

Range of Costs and Assumptions

MMS has reviewed past Technology Assessment and Research Program studies, other studies conducted by various companies and contractors, and technical publications to assist us in estimating platform preparation costs. We also consulted with engineering firms that conduct such cost studies and a company that conducts marine growth cleaning operations. Table 6-1 shows our estimate of the number of days and platform preparation spread rate, marine growth removal cost, and total cost that would be required to prepare each of the 23 POCSR platforms for decommissioning as described above, including removing the marine growth from each structure. We assumed that a platform removal preparation spread would consist of a utility boat, helicopter use (1 trip/3 days), a preparation crew and materials and supplies. A higher spread rate and cost, due to a larger platform preparation crew and more equipment, was assumed for the larger, more complex topside structures based upon previous cost studies.

Table 6-1 Platform Preparation and Marine Growth Removal Costs

Platform	Platform Prep. Days	Prep. Spread Rate	Marine Growth Removal	Total Cost*
A	19	$19,000	$400,000	$761,000
B	19	$19,000	$400,000	$761,000
C	19	$19,000	$400,000	$761,000
Edith	18	$19,000	$600,000	$942,000

Houchin	19	$19,000	$400,000	$761,000
Irene	35	$19,000	$600,000	$1,265,000
Total	-	-	$14,800,000	$40,498,000

*Total Cost is the Platform Prep. Cost (Platform Prep. Days times Prep. Spread Rate) plus Marine Growth Removal Cost.

Section 7: Well Plugging and Abandonment

Requirements

One of the major cost components of a decommissioning project is the plugging and abandonment of platform wells. Regulations covering this area are contained in Subpart Q of 30 CFR 250 and are summarized below:

- All wells shall be abandoned in a manner to assure downhole isolation of hydrocarbon zones, protection of freshwater aquifers, clearance of sites so as to avoid conflict with other uses of the Outer Continental Shelf (OCS), and prevention of migration of formation fluids within the wellbore or to the seafloor.

Procedures

Planning and operations are two distinct phases in the well plugging process. The planning and actual abandonment process entails: data collection (including review of existing well design encompassing degree of deviation, maximum angles, and dog leg severities, past performance, and present geological and reservoir conditions), preliminary inspection (including inspection of wellhead and tree to verify that valves and gauges are operational, with repairs made as necessary), selection of abandonment methods(s) (including consideration of using either rig methods, rigless methods, or coiled tubing methods, or a combination of these three methods), and submittal of an application for MMS approval.

The actual well abandonment operation involves: well entry preparations (including skidding the rig to the appropriate well slot, installation of back pressure valve, and the nippling-up and testing of blowout prevention equipment), use of slickline unit (including confirmation of the presence or absence of wellbore obstructions, verification of measured depths, and the pulling of downhole safety valves), filling the well with fluid (including establishing an injection rate into open perforations, and pressuring-up the tubing and annulus to verify integrity), removal of downhole equipment (including the pulling of packers, pumps, and tubing strings), cleaning out the wellbore (utilizing casing scrapers and a variety of special purpose fluids), plugging open-hole and perforated intervals(s) at the bottom of the well (including squeeze cementing, setting cast-iron bridge plugs, or the placement of cement plugs), plugging casing stubs (where casing has been cut and recovered), plugging of annular space (using squeeze cementing techniques), placement of a surface plug, and placement of fluid between plugs. Figure 7-1 provides a schematic view of the typical wellbore configuration.

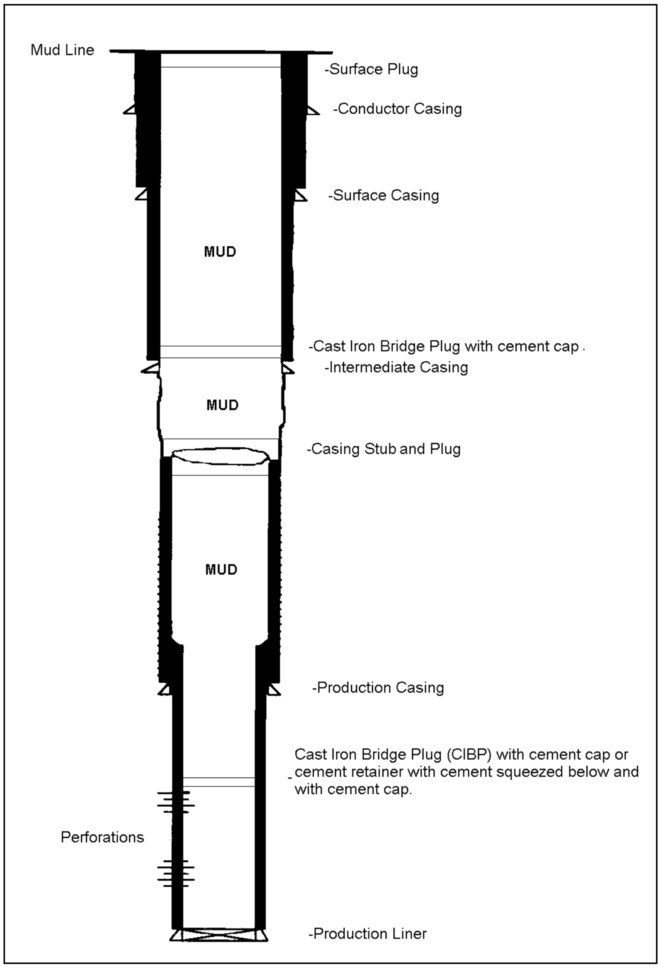

Figure 7-1 Schematic View of the Typical Wellbore Configuration

Cost Factors

The primary factor in determining costs to plug wells is the time required to complete the operation, which depends on the difficulty of each well. Table 7-1 shows the average daily cost for well plugging and abandonment.

Table 7-1 Average Daily Well Plugging and Abandonment Costs

Cost Item	Cost/Day
Workover rig and crew and supervision	$18,000
Mud/Mud Engineering	$2,000
Boat and helicopter support	$4,500
Cementing crew and cement	$3,000
Wireline unit and crew; perforations; rentals, tanks and other consumables	$7,500
Total	$35,000

The difficulty of each plugging and abandonment procedure is tied to the complexity of the well. For this study, four cost categories are used in estimating well plugging and abandonment costs.

- A low cost well will be a straightforward well without deviation problems or sustained annular pressures, and without pumps. A well of this type could be plugged in two to three days.
- A medium low cost well would be more complex with mid-range horizontal displacements with deviations less than 50° at the surface casing shoe. A medium low cost well could have minor complications such as stuck pipe or short-term milling or fishing operations. A medium low cost well can be plugged in three to four days.
- A medium high cost well could have high deviations between 50° and 60° at the surface casing shoe or extended reach wells. They may contain electric submersible pumps or sucker rod pumps. A medium high cost well would have greater operational difficulties and time delays due to hydrogen sulfide concerns, longer fishing or milling operations. A medium high cost well would take four to five days to plug.
- A high cost well could have high deviations with greater than 60° maximum angles, severe dog legs or extended reach. A high cost well can have operational difficulties including sustained annular pressures, parted casing, long term fishing or milling work, repeated trips in and out of the hole, etc. A high cost well would take six to ten days or longer to plug.

In all four cases it is assumed that a rig method would be used (most POCSR platforms have rigs on them that are capable of performing plugging and abandonment operations). Regardless of the technique used, plugs must be tagged to ensure proper placement and/or pressure-tested to verify integrity. Table 7-2 shows the average cost of plugging and abandoning a well for each cost category. Table 7-3 provides data regarding the number of wells, average well depth, number of conductors, and water depth for each platform in the POCSR. Total well plugging and abandonment costs by platform are shown in Table 7-4. There are 687 wellbores that require plugging and abandonment in the POCSR. The cost to plug and abandon these wells is estimated to total $89 million. Appendix C provides a detailed breakdown of well costs for each platform.

Table 7-2 Average Well Plugging and Abandonment Costs by Cost Category

Cost Category (Level of Complexity)	Cost/Well
Low cost well (2-3 days to plug and abandon)	$87,500
Med low cost well (3-4 days to plug and abandon)	$122,500
Med high cost well (4 – 6 days to plug and abandon)	$175,000
High cost well (6 – 10 days to plug and abandon)	$280,000

Table 7-3 Well and Conductor Details

Platform	Number of Wells to Plug	Average Well Depth (in Feet)	Number of Conductors to Remove	Water Depth (in Feet)	Conductor Length (in Feet)
A	52	2,500	55	188	268
B	57	2,500	55	190	270
C	38	2,500	43	192	272
Edith	18	4,500	23	161	241
Ellen	61	6,700	64	265	345
Elly	0	0	0	0	0
Eureka	50	6,500	60	700	780
Gail	21	8,400	22	739	819
Gilda	63	7,900	64	205	285
Gina	12	6,000	12	95	175
Grace	26	N/A	35	318	398
Habitat	20	12,000	20	290	370
Harmony	26	11,900	51	1,198	1,278
Harvest	19	10,000	21	675	755
Henry	23	2,500	24	173	253
Heritage	27	10,300	49	1,075	1,155
Hermosa	13	9,500	16	603	683
Hidalgo	10	10,700	10	430	510
Hillhouse	47	2,500	52	192	272
Hogan	40	5,400	40	154	234
Hondo	29	12,700	28	842	922
Houchin	36	5,100	36	163	243
Irene	24	9,800	24	242	322

Well depth is a less significant cost factor than plugging difficulty. Deeper wells involve longer tripping times and may include additional cement volumes. Measured depths of productive intervals for wells in the POCSR range from less than 1,000 feet to more than 17,000 feet.

Service and supply companies are highly competitive and offer substantial discounts (up to 35%) for multiple well packages. Costs associated with plugging of wells in all four well categories are based on multiple-well price packages, and represent the lowest daily unit costs for some goods and services.

There are 687 wellbores requiring plugging in the POCSR for a total abandonment cost of over $89 million. The average costs of plugging each well is $129,000. Table 7-3 shows the average cost for the different levels of complexity. Appendix C shows the detailed breakdown of well costs for each platform. Total well plugging and abandonment costs by platform are shown on Table 7-4.

Table 7-4 Well Costs

Platform	Total Well Cost
A	$5,005,000
B	$5,478,000
C	$3,710,000
Edith	$1,995,000
Ellen	$7,158,000
Eureka	$6,335,000
Elly	$0
Gail	$2,748,000
Gilda	$8,068,000
Gina	$1,435,000
Grace	$1,033,000
Habitat	$2,678,000
Harmony	$5,390,000
Harvest	$3,850,000
Henry	$2,328,000
Heritage	$5,565,000
Hermosa	$2,590,000
Hidalgo	$1,960,000
Hillhouse	$4,568,000
Hogan	$3,885,000
Hondo	$5,443,000
Houchin	$3,535,000
Irene	$4,305,000
Total	$89,062,000

Section 8: Conductor Removal

Requirements

Regulations for well plugging and abandonment are found in Subpart Q of 30 CFR 250, in subsections 250.1703 and 1728, and are summarized below.

- All platform components including conductor casings shall be removed by the lessee to a depth of at least 15 feet below the ocean floor or to a depth approved by the Regional Supervisor based upon the type of structure or ocean-bottom conditions.

Procedures

Conductor casing removal combines three distinct procedures: severing, pulling, and offloading. Severing of the conductor casings requires the use of explosive, mechanical, or abrasive cutting methods. Casing jacks are utilized to make the initial lift to confirm that conductors have been completely severed prior to pulling. Pulling the conductor casings entails utilization of the platform rig to pull the conductors which are unscrewed or cut into 40 feet-long segments. Offloading involves utilization of the platform crane to lay down each conductor casing segment in a platform staging area and then offloading to a boat.

Cost Factors

The primary factor in determining conductor casing removal costs is water depth. Water depths in the POCSR range from 95 feet to 1,198 feet. The number of conductors to be removed from each platform in the POCSR ranges from 10 to 64. Table 7-2 provides data regarding the number of wells, average well depth, number of conductors, and water depth for each platform in the POCSR.

Mechanical cutting methods are the most expensive of the three severing alternatives considered. This cost was used in our calculations because mechanical cutting is the most commonly used method. The cost to plug the wells and to remove the conductors is essentially the same regardless of whether all wells are plugged before any of the conductors are removed, or if individual conductors are removed immediately after each well is plugged. Because most POCSR platforms have derricks and cranes capable of performing conductor casing removal operations, we assumed that a derrick barge will not be used.

Conductor casings are assumed to be coated with marine growth which will be removed as they are pulled. Conductors extend approximately 65 feet above the water line to the wellhead on the platform. The average size and weight of conductors are assumed to be 24 inches outside diameter and 100 pounds per foot, respectively. Transportation and disposal costs are not included in these estimates but are included in the Transportation and Disposal Section. There have been well-documented studies that place the cost of conductor removal at $200 per linear foot. This study has verified that this cost continues to be accurate. Using $200/foot, conductor removal costs range from $35,000 to $255,600 per conductor. Table 8-1 shows total conductor removal costs by platform.

Table 8-1 Total Conductor Removal Costs

Platform	Conductor Removal Cost
A	$2,948,000
B	$2,970,000
C	$2,340,000
Edith	$1,109,000
Ellen	$4,416,000
Elly	$0
Eureka	$9,360,000
Gail	$3,604,000
Gilda	$3,648,000
Gina	$420,000
Grace	$2,786,000
Habitat	$1,480,000
Harmony	$13,036,000
Harvest	$3,171,000
Henry	$1,215,000
Heritage	$11,319,000
Hermosa	$2,186,000
Hidalgo	$1,020,000
Hillhouse	$2,829,000
Hogan	$1,872,000
Hondo	$5,164,000
Houchin	$1,750,000
Irene	$1,546,000
Total	$80,189,000

Section 9: Mobilization and Demobilization

Mobilization and demobilization (mob/demob) costs cover the transit time required to bring a heavy lift vessel (HLV) to the project site and return the HLV to its point of origin. In the POCSR, the infrastructure required to support decommissioning operations is severely lacking. There are currently no HLV's on the west coast capable of removing large deepwater platforms. The HLV's would be mobilized to southern California from the North Sea, Gulf of Mexico, Southeast Asia or other distant locations. It is very unlikely that HLV's would be stationed in the POCSR unless there was a strong and prolonged market demand for such vessels. This situation is not likely to change in the foreseeable future.

Cost Assumptions

This report assumes HLV's having 500, 2,000 and 4,400 ton lift capabilities will be mobilized from Southeast Asia, the North Sea, or the Gulf of Mexico (see Section 2). The mob/demob time for HLV's having lift capabilities of 500 and 2,000 tons is estimated to be 100 days. These HLV's would likely be mobilized from Southeast Asia. The mob/demob time for HLV's having 4,400 ton lift capabilities is estimated to be 200 days. These HLV's would likely be mobilized from the North Sea or Gulf of Mexico.

The current day rates for the HLV's that are projected to be used to remove POCSR platforms are: 500 ton lift capability - $80,000; 2,000 ton lift capability - $185,000; 4,400 ton lift capability - $225,000. This cost also covers the HLV's accompanying anchor handling tug. For cost estimating purposes, we have assumed that a rate of 90% of the day rate (rate charged during onsite operations) would be charged for mob/demob time.

Range of Costs

The mob/demob costs for the HLV's projected to be used to remove POCSR platforms are shown in Table 9-1. The costs range by project from $2.8 million to $13.5 million per platform. The calculation was made by taking 90% of the day rate of the HLV, multiplying that figure by the mob/demob time (100 or 200 days), and dividing by the number of platforms that would be removed during the project.

Table 9-1 Average Mob/Demob Cost by Project

Project	HLV Lift Capability	Mob/Demob Cost Calculation	Average Cost Per Platform
Project I	500 ton	$80,000 x 0.90 x 100 days ÷ 2 platforms	$3,600,000
Project II	2,000 ton	$185,000 x 0.90 x 100 days ÷ 4 platforms	$4,163,000
Project III	2,000 ton	$185,000 x 0.90 x 100 days ÷ 6 platforms	$2,775,000
Project IV	2,000 ton	$185,000 x 0.90 x 100 days ÷ 3 platforms	$5,550,000
Project V	4,400 ton	$225,000 x 0.90 x 200 days ÷ 5 platforms	$8,100,000
Project VI	4,400 ton	$225,000 x 0.90 x 200 days ÷ 3 platforms	$13,500,000

Section 10: Platform and Structural Removal

MMS regulations on the decommissioning of OCS platforms are covered in 30 CFR 250.1700 through 1754.

The depth of removal requirements for platforms and other facilities are at 30 CFR 250.1728 and are as follows:

(a) Unless the Regional Supervisor approves an alternate depth under (b) of this section, you must remove all platforms and other facilities (including templates and pilings) to at least 15 feet below the mudline.

(b) The Regional Supervisor may approve an alternative removal depth if:

  (1) The remaining structure would not become an obstruction to other users of the seafloor or area, and geotechnical and other information you provide demonstrate that erosional processes capable of exposing the obstructions are not expected; or

  (2) You determine, and MMS concurs, that you must use divers and the seafloor sediment stability poses safety concerns; or

  (3) The water depth is greater than 800 meters (2,624 feet).

In this report, we assume that platforms and other structures will be removed to a depth of 15 feet below the ocean floor (or mudline) and that sections will be removed in the reverse order in which they were installed. Figures 10-1 and 10-2 provide schematics representative of typical platform deck and jacket configurations.

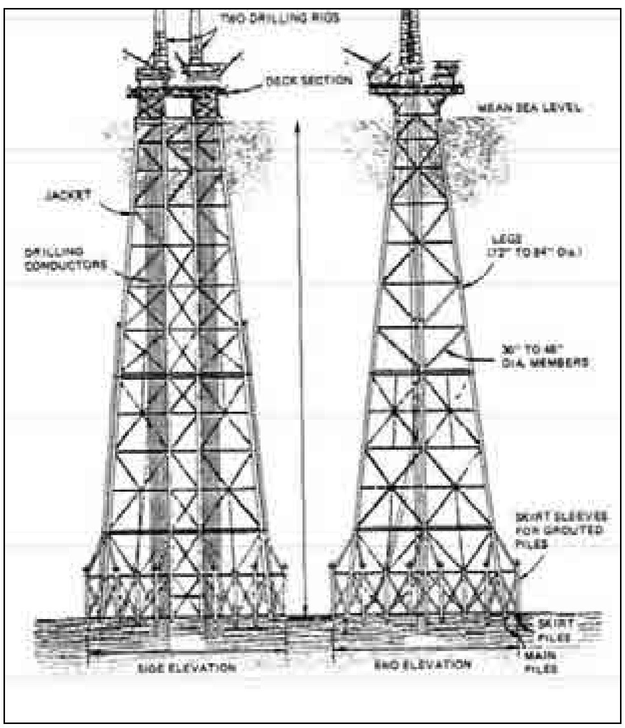

Figure 10-1 Deepwater Platform

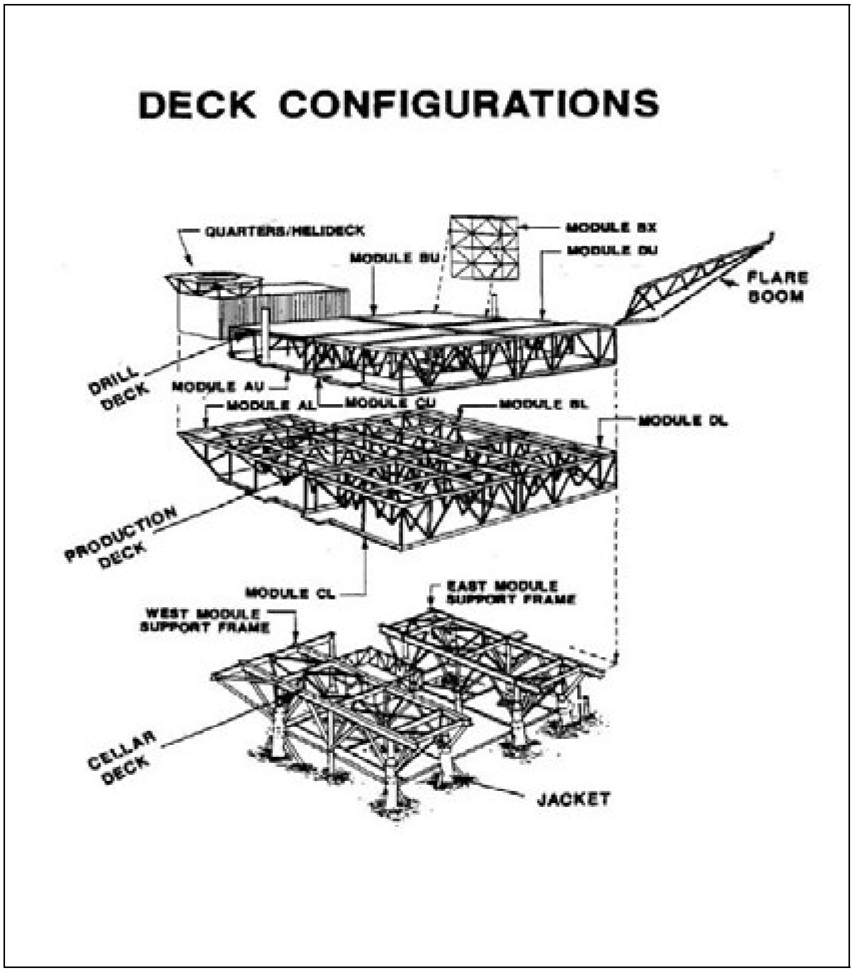

Figure 10-2 Deck Configurations

Deck/Topside Removal

The removal of topside facilities is one of the first steps in any decommissioning activity for an offshore platform. Topsides can vary significantly in size, functionality and complexity, so we have identified a range of decommissioning options. The diversity and range of complexity suggest that no one option is likely to be the most appropriate in all cases. In the POCSR, we have identified platforms that have topside facilities that range in weight from approximately 447 to almost 10,000 tons. Generally between 6 and 17 lifts were required to install these topsides. The largest lift for the modules or the modular support structures was approximately 2,000 tons.

Topsides may be integrated, modular, or hybrid in design. Integrated topside refers to a system where the process facilities are installed in the deck structure in the fabrication yard. Integrated facilities are usually installed by a single offshore lift. A modular design is used for larger topsides where the deck structure is subdivided into modules that can be lifted by the derrick barge. The modules are typically supported on the jacket by a modular support frame. Many of the very large topsides use a combined approach.

Topsides can be removed by any of the following methods:

- Removal in one piece
- Remove groups of modules together
- Removal in reverse order to installation
- Removal by small pieces

Removal of the entire topsides in one piece requires a heavy lift crane vessel (HLV) with sufficient lifting capacity, or a large specialized decommissioning vessel, or an alternative heavy lift technology such as the Versatruss lifting system, GM Heavy Lift Vessel, or other innovative lifting systems that are still in the developmental stage. One piece removal is more practical for small platforms. Major problems in removing large topsides this way are both how and where to offload the topsides onshore where crane lift capability is limited and how to dismantle these large structures once onshore.

The removal of combined modules is another method to remove the topsides. The advantage of this method is in reducing the time the heavy-lift vessels are required since fewer lifts are needed. Additional strengthening to allow for combined lifting will probably be needed. The position of the modules on the platform and their weight will dictate whether or not combined removal is possible and which modules may be lifted at one time.

Reverse installation is another method of topside removal. This involves dismantling the topsides in the reverse order in which they were installed. If the topsides were installed as modules, they would be removed as modules. If they were not installed as modules, topside structural components would be removed in the reverse order that they were installed. Discussions with civil engineering firms that work on many decommissioning projects indicate that reverse installation is the most likely method of platform removal on the west coast for the foreseeable future. For purposes of this study, we assume that topsides will be decommissioned using this method for this report.

Removal of the topsides by reducing them to small pieces is another method of removal. In this method the topsides are dismantled using mechanical and other cutting devices along with platform cranes, temporary deck mounted cranes or other cranes and a small HLV. The advantage of this method is that a smaller HLV would be required, and thus costs are substantially reduced.

Platform/Structural Removal
This aspect of platform decommissioning is the costliest operation in the field abandonment process, due to the large and expensive equipment that is required for the lifting and removal operations. Some of the major considerations that have to be made when evaluating the cost of removal are the weight and size of the structure, the oceanographic conditions of the area where the platforms are located, the heavy lifting method used, the method of cutting the main piles and skirt piles, piling access for the cutting operations, diving requirements, water depth, tie-down and transportation considerations of each removed component, and the planned disposition of the salvaged equipment and structure. Extensive saturation diving can add greatly to the cost of any

removal project. Jacket removal is initiated after bottom cuts have been made below the mudline on the piles. The entire jacket is removed in sections or as a single lift. Single lifting of the jacket is not likely except for the smaller structures located in less than 200 feet water depth.

In the POCSR, platform jacket weights range from approximately 400 tons to almost 43,000 tons. The platforms are located in 95 to 1,198 feet of water, respectively. In Appendix D we have listed the projected weight that will be required to be removed when the POCSR platforms are decommissioned. These numbers are only approximate as additional modifications (i.e., deck extensions, equipment additions or removals, etc.) have been made at many facilities. We have listed the jacket and deck weights and calculated roughly the weight of the piles and conductors that will have to be removed assuming that they will be removed to a depth of 15 feet below the mudline. Some of the weights are our best estimates, as detailed information was not readily available. We used the best sources that we had, such as the design, installation, load-out, or fabrication reports, installation manuals, operator correspondence, seismic analyses, etc. A deck and jacket specification table in Appendix E details the background information that we obtained from our records and used for this report. In some cases in this specification table, not all the information and numbers for every block in the table were available for each platform. We did however list which numbers that we were able to obtain for each of the 23 POCSR platforms to use as a source of background information. We used our best professional judgment concerning which numbers to use in the various sections of this decommissioning cost report.

Since the derrick barge is usually the highest cost item on location, the use of less expensive support equipment to minimize the heavy lifting equipment time is often justifiable. Reducing the derrick barge time is one of the best ways to reduce overall removal costs. Heavy lifting equipment must be evaluated for its lifting capability at the required working radius and oceanographic conditions in which it is to operate, and also for its height capability. Safety must always be the prime consideration in any removal project. Deepwater structures present much greater challenges for complete removal. The immense weight and extreme water depth of many of the structures on the west coast places a one step removal outside the limits of current proven and demonstrated technology.

A method known as progressive transport or jacket hopping was considered by some operators and engineering consultants at one time, but because of the difficulty of clearing large areas of the ocean floor to set down the jacket and reset the HLV anchors, this methods appears unlikely to be used on the west coast. Jacket hopping, however, would reduce the risk to divers as less diving time would be needed compared to in-situ dismantlement. In the hopping method, the structure would be rigged up and lifted after severing the piles. The jacket would be winched vertically off the bottom and moved into shallower water and set down. The upper portion of the jacket would then be cut and the rigging reattached underwater for another lift. The process is repeated until the structure is completely removed. In the future it may be possible to re-float the jacket or use additional buoyancy assist to remove some of the deepwater structures, but the technology is still in the developmental stage at this time.

Other alternative heavy lift vessels/systems are being considered for lifting the large jackets such as Offshore Shuttle, MPU, Pieter Schelte, Versatruss, and various buoyancy systems, such as the Control Variable Buoyancy System (CVBS). These approaches are currently undergoing test trials and may eventually be proposed to decommission these large structures.

The most common method of jacket removal is dismantlement in place (in-situ) in which the jacket is cut (with divers using cutting torches, diamond wire cutting tools, or other systems) into manageable pieces at the site and removed piece by piece with the HLV. The jacket can be cut up into small or large pieces. For this study, we assumed that the small piece (1,000 tons or less) removal method will be used for removing the very large structures in the POCSR, jackets located in deep water (water depth greater than 400 feet), as this method appears to be the most likely method to be used based on current information. In addition, smaller HLV's would be needed to do the work. Except for Platforms Hogan and Houchin, we are making the assumption that smaller jackets (1,500 tons or less) located in less than 200 feet water depth would be removed in a single lift with the 2,000 ton HLV after the topsides are removed. We are making the assumption that Platforms Hogan and Houchin would be removed using a 500 ton HLV, as the operator has only 2 platforms and it would be more costly to use a larger HLV. If a 500 ton HLV is used to remove these platforms, the jackets would be cut in-situ into lighter than 300 ton sections for removal.

Pile Severing

Piles can be cut using explosives, mechanical means, abrasive technology, or torches. Use of explosives has been the most reliable, most economical, and safest method for many years. The bottom cut required to remove the jacket must be clean to allow for a safe lift from the surface. A barge making such a lift at sea may exceed its lift capability if an incomplete cut left the load secured to the sea floor. The use of torches places divers at risk as piles are to be removed to at least 15 feet below the ocean floor. Abrasive and other similar technologies do not yet have a reliable means to verify that a complete pile cut has been made, but continue to evolve and may prove to be a preferred technique for cutting applications in the future. They are being used increasingly to sever piles in the Gulf of Mexico and other parts of the world. We assume that some of the piles would be cut using abrasives and others may require the use of explosives.

Range of Costs and Assumptions

Based upon the sizes and weights of the structures, the number of modules, the number of lifts needed and other factors, as described above, including the maximum weights of the lifts that will be needed, we believe all the POCSR platforms can be removed using HLV's with 500, 2,000, and 4,400 ton capabilities in groupings of platforms that we call projects. A number of other factors were also considered in developing the scenario that we are using including the age and oceanographic location of the platforms, remaining oil and gas reserves, water depth, and company operators/ownership. Our decommissioning scenario anticipates six decommissioning projects taking place between 2010 and 2025 (See Table 2-1). A total of 2 to 6 platforms are projected to be removed during each project. The HLV's needed for these projects will have the following lift capabilities: 500 tons (Project I), 2,000 tons (Projects II, III, & IV) and 4,400 tons (Projects V & VI). The costs and method of removal of the very large structures in deep water are very speculative and await further advances in technology as to the approach that would be needed for complete removal. We made cost projections for planning purposes only, assuming in-situ dismantlement of these jackets.

In addition to the barge and anchor-handling tug costs, we have included related diver support, survey and other related vessels and equipment, including ROV and severing equipment spread, which we estimate could be $40,000 per day for Platform Gina in 95 feet of water and $55,000 per day for Platforms Hogan and Houchin in 154 and 163 feet water depth, respectively. All other platforms would be in deeper water and we estimate $65,000 per day for all of their support services. We assumed that it would take 6 hours to cut and remove each platform main or skirt pile. We assumed that topside module removal would take approximately 1/2 day per module in most cases. Topsides that do not have modules would take longer and be cut up into manageable pieces for removal. Generally, we assumed approximately 1 day for each of these sections.

Table 10-1 details the formulas that were used to project platform decommissioning costs and contains an example of calculations for each of the projects. See Table 10-2 Platform Deck and Jacket Decommission Costs, for the projected costs for each of the 23 POCSR platforms. We have increased estimated costs by 10% to 20 % to allow for weather contingency depending on the area in which the platforms are located. We used 20% for Platforms Heritage, Harvest, Hermosa, Hidalgo, and Irene and 10% for all other platforms due to the harsher oceanographic conditions that these five platforms encounter. Appendix F shows the cost calculations for each platform by Decommissioning Project.

Table 10-1 Examples of Platform Deck and Jacket Decommissioning Cost Calculations

Project	Cost Calculation Formula	Cost Example
Project I -500 ton HLV	($80,000/day + $55,000/day + 10% weather contingency) x number of days	Platform Hogan Example: $135,000 x 1.1 x 28 days = $4,158,000
Projects II, III, & IV-2000 ton HLV	($185,000/day + $65,000/day + 10% weather contingency) x number of days	Platform Henry Example: $250,000 x 1.1 x 10 days = $2,750,000
Projects V & VI - 4400 ton HLV	($225,000/day + $65,000/day + 10% or 20% weather contingency) x number of days	Platform Heritage Example: $290,000 x 1.2 x 104 days = $ 36,192,000

Table 10-2 Platform, Deck and Jacket Decommissioning Costs

Platform	Platform, Deck, and Jacket Removal Costs
A	$3,025,000
B	$3,025,000
C	$3,025,000
Edith	$4,400,000
Ellen	$3,850,000
Elly	$4,125,000
Eureka	$20,075,000
Gail	$24,244,000
Gilda	$3,575,000
Gina	$1,485,000
Grace	$4,785,000
Habitat	$3,025,000
Harmony	$36,047,000
Harvest	$24,708,000
Henry	$2,750,000
Heritage	$36,192,000
Hermosa	$22,620,000
Hidalgo	$17,748,000
Hillhouse	$2,750,000
Hogan	$4,158,000
Hondo	$21,054,000
Houchin	$4,158,000
Irene	$3,600,000
Total	$254,424,000

Section 11: Pipeline and Powercable Decommissioning

Requirements

The MMS regulations at 30 CFR 250.1750 allow an operator to decommission a pipeline in place if the MMS determines that the "pipeline does not constitute a hazard (obstruction) to navigation and commercial fishing operations, unduly interfere with other uses of the OCS, or have adverse environmental effects." If the MMS determines that the pipeline is an obstruction, then the decommissioned pipeline must be removed per the regulations at 30 CFR 250.1752.

Procedures

Since 1990, the POCSR has required pipeline operators to conduct biennial ROV pipeline surveys to assess a pipeline's external integrity and to monitor 3rd party impacts. The surveys have verified that the pipelines historically have not been obstructions and could therefore be decommissioned in place. However, a decision on the final disposition of a specific pipeline cannot be made until a thorough technical and environmental review is conducted during the decommissioning permitting process.

To decommission a pipeline in place, the pipeline must first be cleaned by flushing water through the pipeline. The pipeline is then disconnected from the OCS platform, and filled with sea water. The cut end is plugged and buried at least 3 feet below the seafloor or covered with protective concrete mats. In addition to cutting and burying the ends, all pipeline valves/fittings, pipeline crossings and spanned areas that could unduly interfere with other uses of the OCS must be removed from the pipeline, and the cut ends plugged and covered or buried at least 3 feet below the seafloor.

Cost Factors

Appendix G shows the estimated pipeline and powercable decommissioning costs. The factors used to calculate the cost estimates are based on information provided by MMS and operator decommissioning studies, and contractors. There are three worksheets in Appendix G which are titled "Pipelines and Powercables," "Pipelines," and "Powercables," respectively.

"Pipelines and Powercables" and "Pipelines" Worksheets/Tables

The cost estimates for the "Pipelines" and the "Pipelines and Powercables" worksheets assume that all project vessels (small crane barge, dive boat, etc.) would be available locally. The costs incurred during the decommissioning operations reflect both fixed (e.g., mobilization/demobilization) and hourly rates for vessels (small crane barge and support vessels) and diver-related services. The two factors which have the greatest influence on the cost estimates are the water depth and the number of obstructions per pipeline that would have to be removed.

The estimated costs rely on data input values for: 1) mobilization/demobilization, 2) daily rate for on-site operations, 3) estimated time to complete the decommissioning activity, and 4) disposal costs. Below is a description of the type of work included in each of the data input values.

The mobilization/demobilization cost includes the mobilization/demobilization of the diving support vessel, diving system equipment, small crane barge(s), and any required third party equipment needed; planning and engineering; pigging and testing the pipeline(s); mooring installation/removal; and miscellaneous equipment or work needed.

The on-site daily rate includes 24-hour diving operations from a diving support vessel, 24-hour barge with crane, tug and construction crew, materials barge for transport and onshore support and project management.

The estimated time to complete a pipeline decommissioning is based on the number of risers and pipeline sections that would need to be cut out, rigged and lifted to a barge. The time is also dependent on the water depth in which the work is to take place. For this exercise, the amount of pipe that would be removed is based on Appendix A-4 of the 1999 Offshore Facility Decommissioning Costs Report. The Appendix provides information on the removal lengths for spans, pipeline crossings, and subsea tie-ins. With the exception of the Point Arguello Unit platforms, and Platforms Irene and Heritage, a 10% weather contingency was calculated into the estimated time. A 20% weather contingency was applied to the Point Arguello Unit platforms and Platforms Irene and Heritage due to the harsher oceanographic conditions in these areas.

The disposal costs include dockside wharfage fees and crane services, transportation of pipeline by truck to the disposal site, and disposal fees for cleaned pipe and hazardous materials. It is assumed for the purposes of these estimates that the removed pipelines and powercables could not be recycled.

"Beta and Santa Ynez Powercable Complete Removal" Worksheet/Table
The Beta Unit and Santa Ynez Unit (SYU) powercables will most likely be removed completely. The biennial ROV surveys of the Beta Unit show considerable evidence of third party impacts to the two powercables that run from Platforms Eureka to Ellen. There has been no evidence that the SYU powercables are interfering with other OCS users; however, ExxonMobil, operator of the SYU, has committed to the Santa Barbara County as part of a recent power system repair project that it will remove all powercables at the eventual end of the SYU development and production project life.

This table shows the estimated costs for completely removing the SYU and Beta Unit powercables using both local infrastructure and a cable removal vessel mobilized from outside the west coast. Using local infrastructure, the powercables would be cut into sections and lifted onto a barge. It is assumed that the cutting could be done using an ROV, and that divers will not be necessary. A cable removal vessel would simply pull the powercable up onto a reel. Although there is considerable time saved by using a cable removal vessel, the cost to mobilize a vessel from other areas is so great that it is far more economical to use equipment available locally and spend more time doing the work. Recycling of the powercable is highly unlikely and was therefore not taken into account.

Table 11-1 shows pipeline and powercable decommissioning costs by platform.

Table 11-1 Pipeline and Powercable Removal Costs

Platform	Pipelines	Powercables	Total Cost
A	$0	$44,165	$45,000
B	$364,537	$53,512	$419,000
C	$160,536	$53,512	$215,000
Edith	$340,245	$160,776	$502,000
Ellen	$0	$0	$0
Elly	$217,254	$1,100,345	$1,318,000
Eureka	$574,051	$0	$575,000
Gail	$441,523	$0	$442,000
Gilda	$316,307	$105,436	$422,000
Gina	$88,330	$44,165	$133,000
Grace	$210,871	$0	$211,000
Habitat	$133,813	$114,508	$249,000
Harmony	$490,573	$767,012	$1,258,000
Harvest	$231,355	$0	$232,000
Henry	$160,536	$53,512	$215,000
Heritage	$341,485	$6,447,317	$6,789,000
Hermosa	$212,041	$0	$213,000
Hidalgo	$231,355	$0	$232,000
Hillhouse	$107,024	$53,512	$161,000
Hogan	$577,861	$94,458	$673,000
Hondo	$330,073	$1,967,702	$2,298,000
Houchin	$311,415	$103,805	$416,000
Irene	$379,496	$106,021	$486,000
Total	$6,220,681	$11,269,758	$17,504,000

Section 12: Platform Transportation and Disposal

There are three primary methods of disposal for steel and other materials associated with dismantling a platform: refurbish and reuse, scrap and recycle, and dispose of in designated landfills. Opportunities for refurbishing and reusing facilities in the POCSR are very limited due to the age of many of the platforms, the current lack of additional oil and gas development in the POCSR, and inherent limitations associated with meeting the strict technical standards now required. Thus, it is assumed that the steel and other materials removed from platforms will be transported to shore for scrapping and recycling or disposal in landfills.

Due to the limited number of offshore decommissioning projects that have occurred in the POCSR, information pertaining to transportation and disposal costs is limited to that which was made available by Chevron in the 4-H Project. As noted earlier, the project involved the decommissioning of four platforms having a combined weight of approximately 12,000 tons. The materials were transported by barge from the Santa Barbara Channel a distance of 100 miles to San Pedro, California. Chevron reported that the steel was sold as scrap for $330,000 and that it cost $1.3 million to process the steel, resulting in a net loss of $1.0 million or $333.00 per ton of steel. In addition, Chevron had to dispose of 3,000 tons of marine growth ($800,000), 1,000 tons of cement ($275,000), and 300 tons of drilling muds and cuttings ($275,000) which aggregates to approximately $1.4 million for disposal materials other than steel. The costs for disposal of these other materials therefore approximated about $350,000 per platform.

Materials disposal and transportation costs in the POCSR are higher than in the Gulf of Mexico and other areas due to the lack of onshore disposal infrastructure. The local (San Pedro) scrap yard that was used by Chevron is no longer in service and existing scrap yards in southern California do not have the capability to process the large quantity of steel present in platforms. Due to consolidated ownership of scrap yards on the west coast and environmental constraints in southern California, scrap yards having the capability to process the quantity of steel present in offshore platforms are not likely to re-open in the foreseeable future. The nearest scrap yard facilities having such capability are located in the San Francisco Bay area (400 miles away) and Portland, Oregon (1,000 miles away).

Cost Assumptions

This report assumes that platform structures will be transported by barge from southern California to offloading facilities/scrap yards located along the west coast of the U.S., Mexico, or possibly Asia. It is assumed that other materials (nonferrous metals, cement, plastics, wood, etc.) will be transported to landfills in southern California for disposal. For steel, the disposal cost is estimated to be $400 per ton. This cost does not include any credit for scrap steel. This cost was estimated by MMS based on information presented in technical decommissioning studies of POCSR platforms conducted by engineering consultants for MMS and industry. The cost covers transportation, site preparation, and platform topsides and jacket offloading, demolition, and scrapping. For the purposes of this study we have assumed that the cost to dispose of other materials (nonferrous metals, cement, plastics, wood, etc.) will total $350,000 per platform for platforms in less than

400 feet of water, and $700,000 per platform for larger platforms located in greater than 400 feet of water. This cost is based on cost estimates provided by Chevron for the Chevron 4-H Project and information presented in technical decommissioning studies funded by MMS. Table 12-1 shows the platform transportation and disposal costs for each platform.

Table 12-1 Platform Transportation and Disposal Costs

Platform	Total Weight tons)*	Steel Disposal Cost	Misc. Disposal	Total Cost
A	4,090	$1,636,000	$350,000	$1,986,000
B	4,095	$1,638,000	$350,000	$1,988,000
C	4,010	$1,604,000	$350,000	$1,954,000
Edith	8,298	$3,319,200	$350,000	$3,670,000
Ellen	11,300	$4,520,000	$350,000	$4,870,000
Elly	9,400	$3,760,000	$350,000	$4,110,000
Eureka	34,000	$13,600,000	$700,000	$14,300,000
Gail	31,320	$12,528,000	$700,000	$13,228,000
Gilda	9,342	$3,736,800	$350,000	$4,087,000
Gina	1,102	$440,800	$350,000	$791,000
Grace	9,390	$3,756,000	$350,000	$4,106,000
Habitat	8,853	$3,541,200	$350,000	$3,892,000
Harmony	69,920	$27,968,000	$700,000	$28,668,000
Harvest	30,190	$12,076,000	$700,000	$12,776,000
Henry	3,118	$1,247,200	$350,000	$1,598,000
Heritage	60,556	$24,222,400	$700,000	$24,923,000
Hermosa	28,131	$11,252,400	$700,000	$11,953,000
Hidalgo	21,421	$8,568,400	$700,000	$9,269,000
Hillhouse	3,738	$1,495,200	$350,000	$1,846,000
Hogan	4,110	$1,644,000	$350,000	$1,994,000
Hondo	27,250	$10,900,000	$700,000	$11,600,000
Houchin	4,637	$1,854,800	$350,000	$2,205,000
Irene	7,652	$3,060,800	$350,000	$3,411,000
Total		$158,369,200	$10,850,000	$169,225,000

* Total Weight is the estimated total platform removal weight and includes the weights of the jacket, deck, piles, and conductors being removed to a depth of 15 feet below the mudline.

Section 13: Site Clearance

Site clearance operations are performed to ensure that the post-decommissioning lease and operational area surrounding platforms is free of obstructions that would interfere with other uses of the OCS, such as commercial trawling operations. OCS oil and gas decommissioning requirements including clearing a lease site are at 30 CFR 250.1700-1754.

Site clearance procedures for decommissioning a platform and associated pipelines and powercables in the POCSR will typically involve the following four step process (1) pre-decommissioning survey, (2) post-decommissioning survey, (3) Remotely Operated Vehicle (ROV)/diver target identification and recovery, and (4) test trawling. A survey vessel equipped with high-resolution sidescan sonar is used to conduct the pre- and post-decommissioning surveys. The pre-decommissioning survey documents the location and quantity of suspected debris targets. The survey is also used to map the location of pipelines, powercables, and sensitive environmental habitats (hard bottom areas and kelp beds) to ensure that the deployment and retrieval of anchors is done in a safe and environmentally sound manner. The post-decommissioning survey identifies debris lost during the project and documents any impacts from the operations such as anchor scars. An ROV and divers are deployed to further identify and remove any debris that could interfere with other uses of the area. Test trawling is conducted to verify that the area is free of any potential obstructions.

Cost Assumptions

Site clearance costs can vary significantly from project to project due to factors such as: water depth; the size of the area to be cleared and verified; the quantity, size, and type of debris; and weather conditions. The site clearance cost estimates presented below include costs for pre- and post-decommissioning sidescan-sonar surveys (SSS), ROV deployment, diving spreads, test trawl operations, and shell mound geotechnical and biological sampling. The costs do not include any expenses that would be incurred to remove shell mounds or mitigate impacts to commercial trawlers who may be precluded from trawling areas where shell mounds are located. The subject of shell mounds is still under study, in order to generate information on all aspects of the issue that will assist in the preparation of a thorough environmental assessment and appropriate decision on their final disposition based on a case-by-case review. The costs are based on information obtained from oil and gas companies and contractors that have conducted site clearance programs in the POCSR.

For platforms located in water depths up to 300 feet, we assumed that an air/gas diving spread would be used. For platforms located in water depths exceeding 300 feet, we assumed a saturation diving spread will be required. We also assumed that the time required to conduct ROV and test trawl operations will increase from 7 days for platforms located in less than 300 feet of water to 14 days for platforms located in greater than 300 feet of water.

Site Clearance Costs

The estimated costs for site clearance and verification are $722,000 for platforms in less than 300 feet of water depth and $1,139,000 for platforms in greater than 300 feet of water. The cost calculations are shown in Table 13-1 below.

Table 13-1 Site Clearance Cost Calculations

Platform Water Depth (<300 feet)		**Platform Water Depth (>300 feet)**	
Pre-Decommissioning SSS		Pre-Decommissioning SSS	
3 days x $11,000	$33,000	3 days x $11,000	$33,000
Mob/Demob	$12,000	Mob/Demob	$12,000
Data Analysis	$10,000	Data Analysis	$10,000
	$55,000		$55,000
Post-Decommissioning SSS		Post-Decommissioning SSS	
3 days x $11,000	$33,000	3 days x $11,000	$33,000
Mob/Demob	$12,000	Mob/Demob	$12,000
Data Analysis	$10,000	Data Analysis	$10,000
	$55,000		$55,000
ROV Deployment		ROV Deployment	
7 days x $11,000	$77,000	14 days x $11,000	$154,000
Diving Spread (air/gas diving)		Diving Spread (saturation diving)	
10 days x $30,000	$300,000	10 days x $60,000	$600,000
Test Trawl Program		Test Trawl Program	
7 days x $5,000	$35,000	14 days x $5,000	$70,000
Shell Mound Surveys		Shell Mound Surveys	
Geotechnical & Biological	$200,000	Geotechnical & Biological	$200,000
Total Cost	$722,000	Total Cost	$1,134,000

The Department of the Interior Mission

As the Nation's principal conservation agency, the Department of the Interior has responsibility for most of our nationally owned public lands and natural resources. This includes fostering sound use of our land and water resources; protecting our fish, wildlife, and biological diversity; preserving the environmental and cultural values of our national parks and historical places; and providing for the enjoyment of life through outdoor recreation. The Department assesses our energy and mineral resources and works to ensure that their development is in the best interests of all our people by encouraging stewardship and citizen participation in their care. The Department also has a major responsibility for American Indian reservation communities and for people who live in island territories under U.S. administration.

The Minerals Management Service Mission

As a bureau of the Department of the Interior, the Minerals Management Service's (MMS) primary responsibilities are to manage the mineral resources located on the Nation's Outer Continental Shelf (OCS), collect revenue from the Federal OCS and onshore Federal and Indian lands, and distribute those revenues.

Moreover, in working to meet its responsibilities, the **Offshore Minerals Management Program** administers the OCS competitive leasing program and oversees the safe and environmentally sound exploration and production of our Nation's offshore natural gas, oil and other mineral resources. The MMS **Minerals Revenue Management** meets its responsibilities by ensuring the efficient, timely and accurate collection and disbursement of revenue from mineral leasing and production due to Indian tribes and allottees, States and the U.S. Treasury.

The MMS strives to fulfill its responsibilities through the general guiding principles of: (1) being responsive to the public's concerns and interests by maintaining a dialogue with all potentially affected parties and (2) carrying out its programs with an emphasis on working to enhance the quality of life for all Americans by lending MMS assistance and expertise to economic development and environmental protection.

MMS Securing Ocean Energy & Economic Value for America

FISH ASSEMBLAGES ON MUSSEL MOUNDS SURROUNDING SEVEN OIL PLATFORMS IN THE SANTA BARBARA CHANNEL AND SANTA MARIA BASIN

Milton S. Love, Jennifer Caselle and Linda Snook

ABSTRACT

Mussel shell mounds surround all offshore oil and gas platforms in California. These biotic reefs are formed when large clumps of mussels are dislodged from the superstructure. In 1997, we surveyed the fish assemblages on the mussel mounds surrounding seven platforms in the Santa Barbara Channel and in the Santa Maria Basin, California. The objectives of this study were (1) to document the fish assemblages on the mussel reefs, (2) to investigate the spatial patterns of use of parts of mussel reefs by various fish species and (3) to compare species assemblages, population densities and fish sizes on the mussel reefs with those on adjacent platform bottoms. We observed at least 35 species on the mussel mounds, 18 of which were rockfishes (genus *Sebastes*). Most of the species that were found both in large numbers and were encountered at a number of mussel mounds were solitary, benthic forms. Most species appeared to be non-randomly distributed among parts of the mussel mounds with different percent shell cover. All species combined and all rockfish species tended to be slightly but significantly over-represented on areas of 80–100% cover (all species: $\chi^2 = 227$, n = 5, P < 0.001, all rockfishes: $\chi^2 = 211$, n = 5, P < 0.001). Species richness, density (fish 100 m^{-2}) and mean lengths of fishes were all less on the mussel mounds than on the platform bottoms. However, cluster analysis revealed that the species composition on each mussel mound is more similar to its adjacent platform bottom than to other mounds. There did not appear to be a distinct "mussel mound community", instead the mussel mounds should be considered as an integral part of the oil platform system.

Since 1958, offshore oil platforms have been a part of the southern California marine ecosystem. Currently, there are 19 platforms in operation in the Santa Barbara Channel and off central California (Fig. 1). While some of these platforms are as small as 23 m on the side at the surface, the newer structures are over 100 m long (MBC, 1987).

These platforms have a finite economic lifespan and, as they become uneconomical, questions have arisen as to their final disposition. Through 1997, all uneconomical structures have been removed. However, today there is considerable debate regarding the fate of oil platforms. In particular, questions have arisen as to the potential ecological and economic importance of the platforms as artificial reef systems (Seaman and Sprague, 1991). Therefore, understanding the biological communities on and around the platforms is one crucial element to deciding whether to remove or convert obsolete structures into permanent fish habitat.

A major feature of these platforms is the large number of sessile invertebrates (primarily mussels, barnacles and anemones) that encrust the pilings, crossbeams and well pipes. Among animals encrusting these surfaces, mussels (*Mytilus californianus* and *M. galloprovincialis*) are the dominant animals in about the first 15 m of the water column and are occasionally found down to at least 24 m (Carlisle et al., 1964). In shallow waters, thick layers of mussels tend to cover all available surfaces. These bivalves are held to the platform and to each other by byssal threads. Eventually, the weight of these mussel masses is sufficiently large that the holding strength of the byssal threads is approached or surpassed. When this occurs, wave action or storm surge loosens and then dislodges mussel clumps and they fall to the bottom. The amount of mussels dislodged can be substantial; on one platform an estimated 70 kg wet weight of mussels fell to the seafloor each day (Wolfson et al., 1979).

As these invertebrates cover the bottom, they form an extensive, low-relief reef, called a "mussel mound", that may cover a fairly extensive area. Current estimates are that these mounds rise above the sea floor an average of 6–8 m and are on average 60 m in diameter (C. Fusaro, pers. comm.). While mussels form the bulk of the mussel mounds, a large variety of invertebrates, including various species of crabs, seastars, sea cucumbers, anemones and other organisms are also common (Simpson, 1977).

However, while there have been some surveys of the invertebrates on these mounds, there has been no directed research on the fishes inhabiting these communities. In 1997, as part of a survey of the fishes living on offshore platforms of southern and central California, we conducted a survey of the fishes living on these mussel reefs. The objectives of this study were (1) to document the fish assemblages on the mussel reefs adjacent to seven oil platforms, (2) to investigate the spatial patterns of use of parts of mussel reefs by various fish species and (3) to compare species assemblages, population densities and fish sizes on the mussel reefs with those on adjacent platform bottoms.

Methods

Using the submersible Delta, we surveyed fish assemblages on mussel mounds surrounding seven oil platforms situated in the Santa Barbara Channel and Santa Maria Basin (Fig. 1). These surveys were part of a larger study investigating fish communities on the oil platforms (Love et al., in press). Surveys were conducted between 10–14 October 1997. Late fall is the optimal time to conduct surveys of this type because of generally good weather and water clarity. In addition, many species have completed their seasonal juvenile recruitment by this time. We conducted belt transects on the mussel mounds. The submarine maintained a speed of approximately 0.5 kt and stayed approximately 1m above the bottom. Dives were conducted during daylight hours, between 1 hr after sunrise and 2 hr before sunset. For a discussion of the oceanography around the survey areas see Love et al., (in press).

During the transects, researchers made their observations from the central starboard side viewing port. An externally mounted Hi-8 mm video camera with associated lights filmed the same viewing field as seen by the observers. Observers identified, counted and estimated the lengths of all fishes and verbally recorded those data on the video. All fishes within 2 m of the submarine were counted. Fish lengths were estimated during the survey using a pair of dual-beam lasers mounted on either side of the external video camera. The projected reference spots were 20 cm apart and were visible both to the observer and the video camera. An environmental monitoring system aboard the submarine continuously recorded date and time, depth and altitude of the vessel above the sea floor.

After the dive, the environmental data was overlaid on the original videotape. Either aboard the research vessel or in the laboratory, we then reviewed the transect videos. For each fish, we recorded: (1) species to lowest identifiable taxa; (2) estimated total length to the nearest cm; and (3) percent shell coverage of the substrata under each individual.

We estimated transect length by first determining the submersible speed. This was done by evaluating a 10 s segment for every one minute of transect. The video was manually forwarded frame by frame and the number of 20 cm segments passing the lasers in a 10 s section was counted. To obtain speed in cm s^{-1}, the number of 20 cm segments per 10 s was divided by 2. All subsamples were then

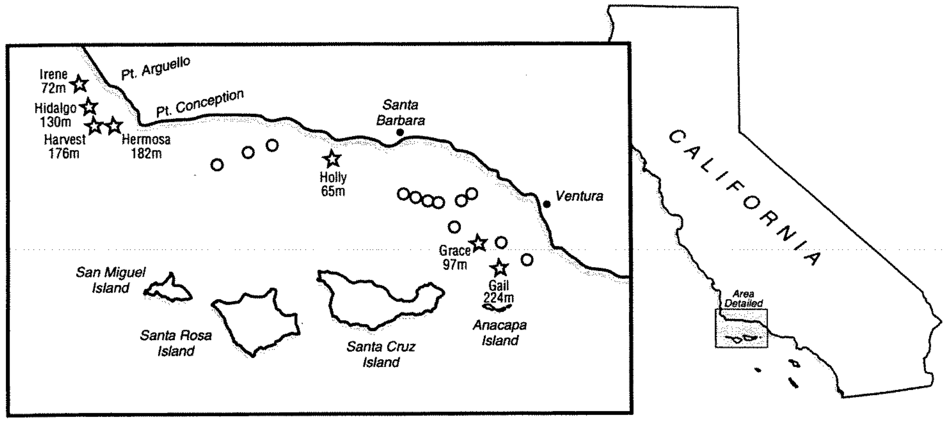

Figure 1. Locations of oil platforms and mussel mounds in the Santa Barbara Channel and Santa Maria Basin.

averaged to obtain mean transect speed (cm^{-s}). The mean speed was then multiplied by the number of seconds in the transect and divided by 100 to obtain transect length in meters. The length was then multiplied by 2 m (the transect width) to obtain transect area, allowing us to estimate fish densities. All densities are presented in fish 100 m^{-2}.

Compared to carbonate reefs, mussel mounds are fairly homogeneous in terms of relief and complexity. Even at the edges of the mounds, we saw no abrupt changes in vertical relief, but rather a slow diminishment of shell cover. In general, the mounds contain few crevices larger than the largest mussel shell. At this time, the spatial extent of the mounds around these platforms is unknown.

Mussel mounds vary in the percentage of mussel cover, ranging from sandy patches with no shells to 100% coverage. Percent cover was categorized as 0–20, 21–40, 41–60, 61–80 and 81–100%. We assessed the patterns of use of the mounds by comparing the number of fishes observed over each area of differing percentage cover with the number of fishes expected according to the proportional availability of that percentage cover. We did this for all mounds combined. For example, if 50% of the area of all the mussel mounds is 100% cover, than assuming no preference for mussel cover, 50% of all fishes observed should be over the 100% cover. We plotted frequency histograms of the observed and expected numbers of fishes for all of the common species in the survey. To test for non-random mound use we used chi-square goodness-of-fit tests. Since calculated values of chi-square are biased when expected frequencies are small, and we observed low numbers of individuals of most species, we only performed the test on species that had zero or one expected frequency less than 5 (Siegel and Castellan, 1988).

Mean lengths of fishes on the mussel mounds and adjacent platforms were compared using Students t-tests in all cases where the variances were equal. When variances were found to be unequal, we used Welch approximate t-test.

To compare the assemblage structure on the mussel mounds with that on the platform bottoms, species abundance data were converted to a triangular matrix of similarity between every pair of samples using the Bray-Curtis similarity coefficient (Bray and Curtis, 1957). Densities (fish 100 m^{-2}) were log (x+1) transformed to decrease the importance of the abundant species. Species present on only one mussel mound or one platform were dropped from the analysis. Samples were clustered using group-average sorting on the Bray-Curtis similarities. The resulting dendrogram ordered samples into groups of increasingly greater similarity based on relative species abundance.

Results

Mussel Mound Assemblages.—Thirty-four identifiable fish species (or groups) were found associated with the mussel mounds of the seven platforms (Table 1). Rockfishes were the most speciose group; a minimum of 18 species was seen. While no species was found on every mound, several species or species groups (Pacific sanddab, lingcod, halfbanded rockfish and *Sebastomus* group) were found on six. Other commonly seen species included greenspotted and rosy rockfishes (five mussel mounds), and painted greenling, shortspine combfish, greenstriped and flag rockfishes, and young-of-the-year (YOY) rockfish (four mounds).

Most of the species that were both abundant (found in large numbers) and common (encountered at a number of mussel mounds) were solitary, benthic forms. Typical of this group were greenspotted, greenstriped and rosy rockfishes, lingcod and Pacific sanddab. The first four species were usually found resting on the bottom and were often sheltered among the mussel shells. We often saw Pacific sanddab swimming slightly above the bottom, although they were also commonly encountered resting either on soft substrata or occasionally on the shells. The only commonly encountered schooling forms were the halfbanded rockfish and YOY rockfishes. Halfbanded rockfish were very abundant on a number of the mounds. They were almost always seen in large, active schools that often numbered in the hundreds of individuals. These schools were usually positioned from less than 1 m to approximately 3 m above the substrata. The small numbers of YOY rockfishes observed on the mounds relative to the platforms were in small groups and usually very close to the shell-covered substratum.

Several other species of schooling fishes were found in large numbers at only single platforms. At Platform Grace, thousands of shiner surfperch were encountered over the mussel mound and adjacent to the platform (Table 1). Pacific sardines were seen over the mussels at Holly and northern anchovies were observed over the mussels at Gail. It is likely that the sardines and anchovies, and perhaps the shiner surfperches, are highly motile and not representative mussel mound fauna.

We recorded 11 identifiable fish species around Platform Irene (Table 1). Halfbanded rockfish were by far the most common species. Pacific sanddab, lingcod (primarily juveniles), copper rockfish (juveniles) and painted greenling were also frequently encountered. The high density of juvenile lingcod on the Irene mussel mounds is particularly noteworthy, as we have never observed this species in such high density on any other artificial or natural structure in southern or central California (Love, unpubl. data). Halfbanded rockfish were also the most abundant species on the Hidalgo mussel mound, where we found 13 species. Young greenspotted rockfish, lingcod, YOY rockfish, rosy rockfish and painted greenling were also quite abundant. Relatively few species (10) were seen at Harvest and it also had the lowest fish densities overall. Sharpchin rockfish, greenstriped rockfish, greenspotted rockfish and poachers were most common. As with a number of other sites, halfbanded rockfish were the most abundant species on the Hermosa mound, where 13 species were noted. Greenspotted rockfish, shortspine combfish and greenstriped rockfish were also fairly common. A school of Pacific sardines dominated the mound at Holly, where 10 species were seen. As noted above, it is likely that this was a transient event, as sardines are highly mobile. Among the more typical species, young copper rockfish were the most abundant, followed by calico rockfish, pink surfperch, rosy rockfish and halfbanded rockfish. While a very large school of shiner surfperch

Table 1. Densities (number fish 100 m^{-2}) of all species observed on each platform (P) and its corresponding mussel mound (MM). Dots indicate zero density values. Platforms and mounds are ordered by depth from shallow to deep with bottom depths given. The minimum number of species was calculated by not including any unidentified species that could be confused with an identifiable species.

* YOY means young-of-the-year

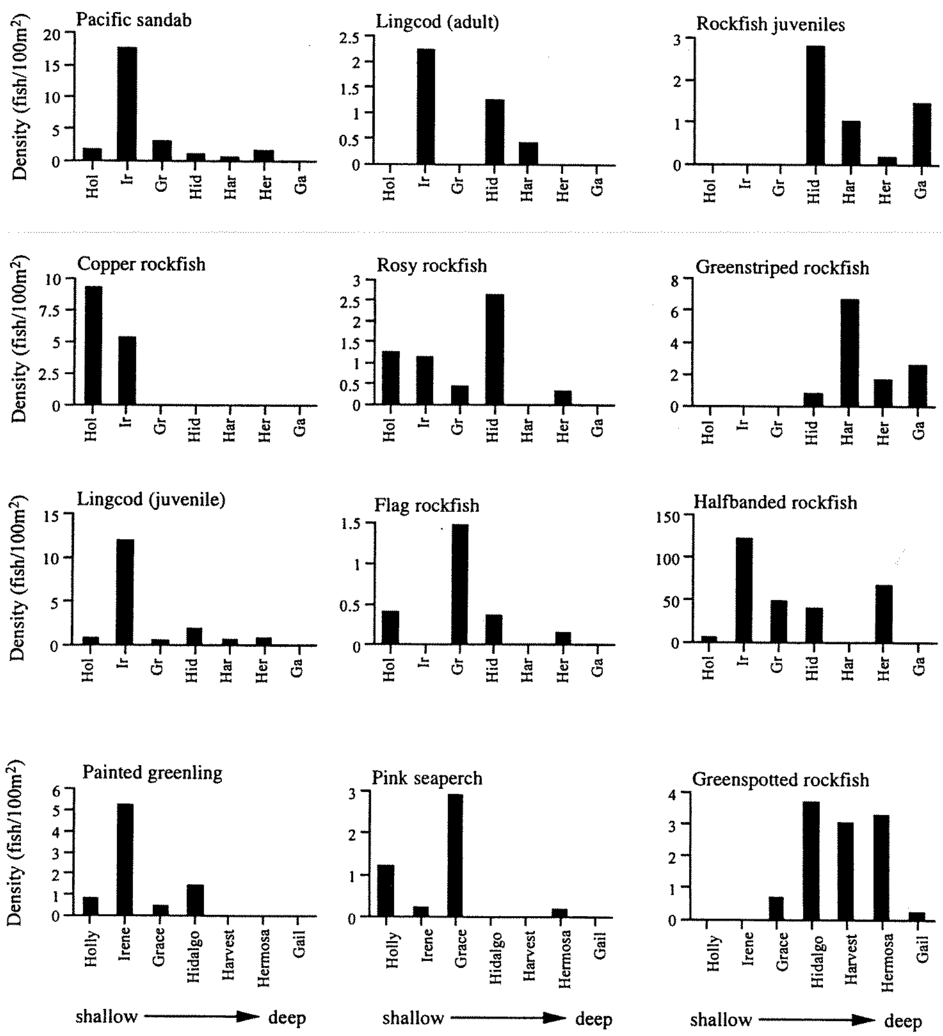

Figure 2. Densities of common mussel mound species on each mound. Mounds arranged by depth from shallow (Holly) to deep (Gail).

dominated the mussel mound around Grace (14 species observed), halfbanded rockfish, pink seaperch, combfish and young flag rockfish were also often seen. Sixteen species were noted around Gail, the greatest species richness among the mounds. Around Gail, a single, large school of northern anchovy was present, which caused it to be the most dense species here. Other common species at Gail included stripetail, greenblotched, swordspine, sharpchin and greenstriped rockfishes.

Some of these differences among mussel mound species assemblages appear to be related to bottom depth (Table 1, Fig. 2). Among the rockfishes, coppers tended to found on the shallowest mounds while rosies, halfbandeds, flags and greenspotteds were most common in midrange (Fig. 2). Sharpchins, darkblotched, greenblotched, greenstriped and rockfish YOY tended to be found on the deepest mussel mounds (Table 1, Fig. 2). Painted

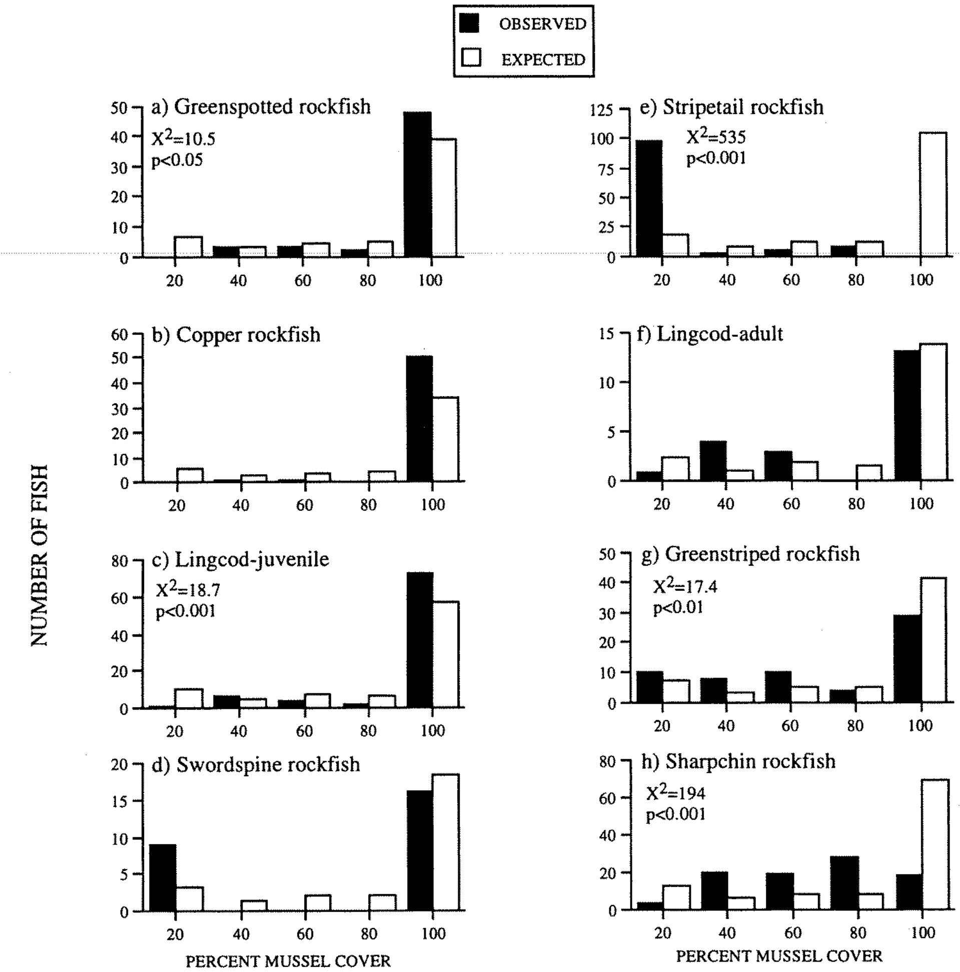

Figure 3. Observed and expected numbers of individuals of various species on mussel mounds. Expected numbers were calculated based on the availability of the different percentage classes of mussel cover. Chi-square goodness-of-fit tests were performed on species with zero or one expected frequency less than 5 (Siegel and Castellan, 1988).

greenling, juvenile lingcod, pink seaperch and Pacific sanddab also were found in shallow waters (Fig. 2).

Differential Use of Parts of Mussel Mounds.—Most species appeared to be nonrandomly distributed among parts of the mussel mounds. We compared the distributions of individuals across areas with different percent mussel cover with the expected distributions based on the availability of areas of different percent cover (Fig. 3A–H). We did this graphically or with chi-square goodness-of-fit tests (see Methods).

Among the more abundant species, greenspotted and copper rockfishes, as well as juvenile lingcod, were all disproportionately present over areas with 80–100% mussel cover (Fig. 3A–C). Greenspotted rockfish and lingcod juveniles showed a significant deviation from the expected based on the availability of different percent covers (Fig. 3A,C). At the other extreme, swordspine, stripetail and greenstriped rockfishes and adult

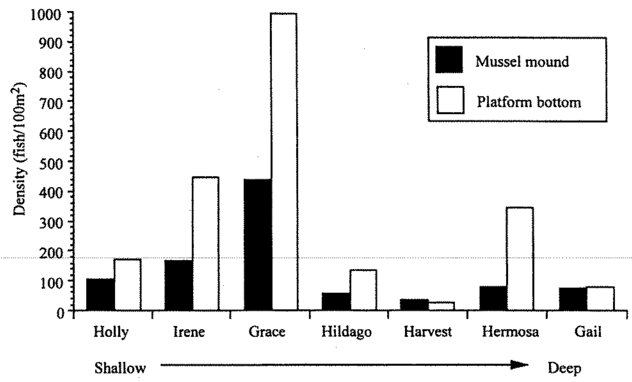

Figure 4. Density (fish 100 m^{-2}) of all species of fishes per platform and mound. Platforms ordered by depth.

lingcod were over-represented on bottoms with relatively little shell cover, with stripetail and greenstriped significantly so (Fig. 3D–G). Sharpchin rockfish were significantly non-randomly distributed and were most abundant over a mixed shell-mud bottom (Fig. 3H).

COMPARISONS WITH PLATFORM BOTTOMS.—*Species Richness and Diversity.*—Species richness was slightly greater on the platform bottoms (40 species) than on the mussel mounds (34 species). Mean number of species on a platform bottom was 14.7 (range 7–24) compared to an average of 12.6 species per mussel mound (range 10–16) (Table 1). This difference was not significant ($t = -0.88$, $df = 6$, $P = 0.4$).

Density.—The mean density of all species combined was 136.2 fish 100 m^{-2} on the mussel mounds compared to 314.6 fish 100 m^{-2} on the platform bottoms and the difference was significant ($t = -2.3$, $df = 6$, $P = 0.03$). At five of the seven sites, the total density of all species on the mussel mounds was approximately half that on the adjacent platform bottom (Fig. 4). The exceptions were around Platforms Harvest and Gail, where densities were very similar. In no case was total fish density substantially greater on the mound compared to the adjacent platform bottom. However, the large-scale spatial pattern of densities among platform bottoms and adjacent mussel mounds was similar. That is, there was a significant correlation between the density of fishes on a platform and on the adjacent mound (Spearmans rank correlation, $Rs = 0.93$, $n = 7$, $P < 0.005$). However, there was no relationship between total fish density on the mussel mounds and either bottom depth ($Rs = 0.057$, $n = 7$, $P > 0.05$) or geography (measured as the ranking of the platforms from north to south) ($Rs = 0.18$, $n = 7$, $P > 0.05$). We have also previously shown that the densities of fishes around platform bottoms also show no relationship with either bottom depth or geography (Love et al., in press).

Fish Lengths.—In general, the mean lengths (TL) of fishes inhabiting the mussel mounds were significantly smaller than fishes on the platforms (Table 2). For the 14 species that were present in relatively large numbers on both types of habitat, 10 were significantly smaller on the mussel mounds, one was significantly larger and three showed no significant length differences. The size differences were particularly large for copper, greenblotched, flag and halfbanded rockfishes and lingcod, all of which were larger on the platforms. Only stripetail rockfish were, in general, larger on the mounds than on the platforms.

Table 2. Mean total length (cm) and 1 SE and sample size for species of fish inhabiting both mussel mounds and platform bottoms. P-values are for student t-tests except in cases where variances are unequal. Welch approximate t-test's were substituted in these cases and are noted with *.

Community Composition.—We asked whether species compositions were more similar among the various mussel mounds or between each mussel mound and adjacent platform bottom. That is, is there a mussel mound fish community that differs from a platform bottom community? Numerical classification revealed that, in general, each mussel mound is more similar to its adjacent platform bottom than to other mounds (Fig. 5). The only exception to this pattern is the Hidalgo mussel mound, which is more similar to the Hermosa platform/mound pair than to the Hidalgo platform. Overall, the mean similarity (average Bray-Curtis coefficient on log (x+1) transformed densities) was lower among all platforms (0.27, n = 21 platform-platform pairs) and among all mussel mounds (0.28, n = 21 mound-mound pairs) than among each adjacent mussel mound-platform pair (0.61, n = 7).

The strongest differences distinguish fish assemblages from platform/mound pairs at different depths. Three major clusters arose (Fig. 5). Cluster 1 contains the shallowest sites (Holly mound/platform and Irene mound/platform). Cluster 2 generally contains the mid-depth sites, while cluster 3 contains the deepest sites. The exception to this pattern is that Hermosa (platform and mound at 182 m) clustered with Hidalgo (130 m) and Grace (97 m), while Harvest (176 m) clustered with Gail (the deepest at 224 m).

Despite the similarities in assemblage structure between a mussel mound and its adjacent platform bottom, there were also some notable differences in term of species presence and absence. This was particularly true among the rockfishes. Widow and canary rockfishes and bocaccio were found either entirely or primarily on the platforms whereas swordspine rockfish were observed solely on the mussel mounds (Table 1). Greenstriped rockfish and shortspine combfish were both more abundant on the mussel mounds than on the platform bottoms.

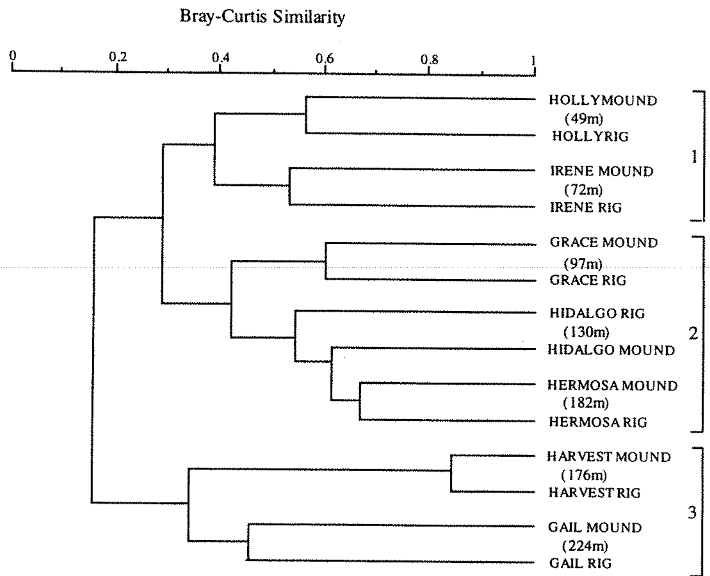

Figure 5. The dendrogram resulting from clustering (Group-Average sorting) of Bray-Curtis similarities on fish species composition between samples at all platform bottoms and mussel mounds. Three major clusters were found and numbered 1 through 3. The depth of each platform and mussel mound is shown in parentheses between each pair.

Discussion

A major objective of this study was to document the fish assemblages on mussel mounds and to compare the mussel mounds to nearby oil platforms. One significant finding is that there does not appear to be a unique "mussel mound assemblage" that differs from assemblages found on nearby platforms. Instead, each mussel mound is more similar in terms of relative species abundance to its adjacent rig than it is to other mounds. A pilot study comparing the fish assemblage on one oil platform to several natural reefs in the vicinity showed that there were distinct differences in species composition and abundance between the platform and the natural reefs (Love et al., 1994). Several of the natural reefs in that study were located within 3 km of the platform. Thus it appears that the mussel reefs which are directly below and adjacent to the platforms could be considered more as a part of one "platform system" than even relatively close-by natural reefs. Natural reefs, mussel reefs and oil platforms all differ in habitat. That the species composition between a mussel reef and adjacent platform is more similar than among all mussel reefs is likely due simply to close proximity. Movement from a mussel reef to the adjacent platform must be more easily accomplished than movements among platforms surrounded by large expanses of sand or mud bottom. Thus, there is likely to be a greater flux of individuals between a platform and the adjacent mussel mound than between various platforms.

This study cannot address the issue of movement between platforms and mussel mounds. It should be noted that the surveys discussed here are a "snapshot" in time. Whether the assemblages at the various platforms/mussel reefs are stable over time remains to be seen. Longer-term surveys of the fish fauna on two platforms in the Gulf of Mexico as well as one in the Santa Barbara Channel showed considerable diel and seasonal variation in the number of species present (Carlisle et al., 1964; Hastings et al., 1975). In addition, monthly SCUBA observations on one shallow-water platform indicate that there may be large temporal changes in assemblage structure (D. Schroeder, unpub data). Despite this, no obvious differences were detected between the mussel mound and platform assemblages.

Although there are similar species assemblages on a platform and adjacent mussel mound, there are depth-related differences among the platform/mussel mound pairs (hereafter referred to as "sites"). Cluster analysis showed differences in the fish assemblages between sites in shallow, moderate and deep waters. It is widely accepted that fish have depth preferences and there was a large range of depths surveyed in this study (49 to 224 m). We have previously shown that fish assemblages differ between the midwater portions and the bottoms of the platforms (Love et al., in press). We related those differences to both depth preferences and to habitat structure. The strongest differences in this study were between the two shallowest sites (Holly and Irene at 49 and 72 m, respectively) and the others. Both Holly and Irene are located in relatively nearshore, shallow waters compared to all the other platforms that are situated farther from shore and in deeper water. Several rockfish and surfperch species were only present at these two shallow sites. These included brown, gopher, yellowtail, calico, and squarespot rockfishes and sharpnose, rubberlip and pile surfperches. Surfperches are livebearers and tend to live in shallow water. As livebearers, this family has no pelagic phase; thus juvenile dispersal across deep water is probably extremely limited. Surfperches, by swimming along the bottom, may only be able to reach the shallower of the sites. The moderate and deepest sites were less distinctive. There may be a threshold depth and/or distance from shore that once exceeded, determines which species can colonize or survive at a site. Only one species, the stripetail rockfish, was present only at the deepest site (Gail, 224 m). Thus, bottom depth may be more important in determining differences in species composition among widely separated sites than specific features of microhabitat. That is, species will only occupy or disperse between platforms within a certain depth range. Within the preferred depth ranges, fish may distribute themselves randomly or based on other characteristics such as habitat structure (e.g., mussel mound or platform members), presence or absence of competitors or predators, or food availability.

Similarity in species composition might indicate random and frequent movements between mounds and platforms. Although we could not distinguish a "mussel mound community" from a "platform community", there were several important differences between the mounds and platforms that suggest that movements may not be frequent or random. First, mussel reefs are inhabited almost entirely by small individuals. Fishes greater than about 20 cm in TL were relatively rare at all of the mounds. In the case of rockfishes, the smaller fishes on the mussel mounds were either juveniles or dwarf species that do not grow large (e.g., swordspine and halfbanded). A number of the other common mussel mound species, such as Pacific sanddab, painted greenling and shortspine combfish, are also small taxa.

On the other hand, the fishes observed at the bottom of the platforms are, in general, larger than those found on the mounds. What might account for this size difference? Both the type and amount of habitat structure have been shown to influence the species composition and abundance of fishes (Choat and Ayling, 1987; Anderson et al., 1989; Caselle and Warner, 1996; Light and Jones, 1997; Friedlander and Parrish, 1998). Although we did not measure characteristics of the habitats in this study, there were easily observable differences. First, the platform superstructure, particularly the crossbeam usually found near the bottom, provide large crevices that tend to harbor large rockfishes and lingcod. These crossbeams appear to provide shelter to these larger fishes (Love et. al., in prep). Smaller individuals may be avoiding this predator-filled habitat. By the same token, many larger fishes may avoid the relatively low relief mussel mounds, because of a lack of sheltering caves and crevices. This allows small fishes the opportunity to inhabit a mound habitat relatively free of predators. The only large individuals commonly seen on the mounds were lingcod. Lingcod are known to inhabit a wide range of habitats, from relatively smooth bottom to high, rocky relief (Miller and Geibel, 1973). Lingcod are also predatory on small fishes and may make periodic forays to the mussel mound to forage.

There were also differences in the density of fishes between the mounds and the platforms. The total density of all species on the platform bottoms was almost twice as high as on the mounds. Given that the fishes are larger on the platform bottoms, estimates of biomass density are even higher on the platforms compared to the mussel mounds. The density differences observed in this study support the notion that there may be competition for the higher structural complexity space offered by the platforms. Younger individuals and smaller individuals tend to be found on the mounds, but in most cases can also be found on the platforms. The similarities in assemblage structure but differences in individual sizes and densities suggest that younger and smaller fish may be using the mussel mounds instead of the platforms due to competition with larger or older individuals for space or predator avoidance. These alternatives could be tested in the future with field manipulations and measurement of survival and growth rates in the two habitats. The patterns observed do suggest that if there are movements between the two habitats, they are probably uni-directional, with younger fish settling or colonizing the mound and later moving to the platforms. Clearly, the differences in habitat structure between the mussel mounds and the platform bottoms influence the distribution of various size classes and the abundance of fishes. Whether these distributions are formed in response to predation, competition for space or other factors such as food availability or food preference remains to be seen.

While it might be expected that dwarf or small rockfishes would preferentially inhabit those parts of the mussel mounds with the highest mussel concentrations, thus affording themselves maximum protection from predation, this was not the case. To some extent, the affinity exhibited by some species for certain degrees of mussel cover, reflects their preferences in natural habitats. Both greenstripe and stripetail rockfishes are most often found over a substrata composed of both mud and rock (Yoklavich et al., submitted for publication) and over the mussel mounds both species were more prevalent over a substrata with relatively low mussel density. Similarly, copper rockfish were always found over the heaviest mussel cover, which would be expected from this high-relief outcrop dweller. However, some of the mussel mound data does not neatly fit expected patterns. Greenspotted rockfish are, relative to many rockfish, habitat generalists, and thus are frequently found over virtually all habitat types (Yoklavich et al., submitted for publication). Yet over the mussel mounds, they were most likely to live over the highest mussel cover. Just as we do not know for certain the extent of fish movements from the mussel mound to platform bottom at a site, we also do not know the extent to which there is temporal variation in use of parts of the mussel mounds. However, the analyses investigating differential use of the mounds were all performed on data from all mounds combined. The fact that there were significant patterns in mussel mound use, indicates that the preferences shown by some species for different parts of the mounds, may be consistent.

The entire mussel mound-platform system is characterized by high levels of spatial variability in fish assemblage structure. Although each mussel mound is more similar to its platform than to other mounds, the overall levels of similarity were quite low (Fig. 5). The differences in assemblage structure appear to reflect different habitat requirements for at least several species. Species that appear to need large shelter areas, such as bocaccio and vermilion, canary and flag rockfishes are common around some platforms and are rare or absent on the adjacent mounds. However, a number of species seem equally abundant (though with differences in size compositions) both near and away from the platforms. Only a few taxa appear to prefer the low relief afforded by the mussel mounds; these include the greenstripe rockfish and the shortspine combfish. On our surveys of natural reefs, these two species are usually found on reef edges and other low relief habitats.

In summary, mussel mounds harbor lower densities, fewer species, smaller species and smaller individuals than platform bottoms. Larger spatial scale patterns of species composition appear to be determined by depth with the two, nearshore shallow mounds having different species composition than the offshore deeper sites. Based on our first-year survey, it appears that these mussel mounds may provide a nursery function for some species, particularly for some of the rockfishes. We found a few YOY rockfishes and large numbers of somewhat older juveniles, particularly of copper and greenspotted rockfishes, on some of the mussel mounds. However, based on only 1 yr of work, we cannot determine the stability of the patterns we observed. For instance, it is quite possible that 1997, an El Niño year, was a poor one for recruitment of many rockfish species. Our surveys of the adjacent platforms showed 1997 rockfish recruitment to be very low compared to past years. It is quite possible that recruitment on these mounds might be considerably greater during more favorable years. At this point, it appears that there is not a unique mussel mound community. We suggest that the mussel mounds adjacent to the oil platforms in the Santa Barbara Channel be considered an integral part of the "platform system".

Acknowledgments

We would like to express our appreciation to the crew of the R/V Cavalier, D. Morse, J. Blackman, D. Chesnut, D. Tondro, N. Stewart and E. Kohnhorst and the pilots of the submersible Delta, C. Ijames and D. Slater, for their very professional handling of the technical aspects of this survey. L. Thorsteinson was, as always, extremely supportive and we thank him. The manuscript benefited from comments of D. Schroeder, M. Sheehy, J. Stevens and two anonymous reviewers. This research was based on an information need identified by the Minerals Management Service's Pacific OCS Region and funded through the U.S. Geological Survey Biological Resources Division's National Offshore Environmental Studies Program (1445-CA-0995-0386).

Gulf of Mexico Offshore Operations Monitoring Experiment (GOOMEX), Phase I: Sublethal responses to contaminant exposure — introduction and overview

Mahlon C. Kennicutt II, Roger H. Green, Paul Montagna, and Pasquale F. Roscigno

Abstract: The Gulf of Mexico Offshore Operations Monitoring Experiment (GOOMEX) is a three-phase study to test and evaluate a range of biological, biochemical, and chemical methodologies to detect and assess chronic sublethal biological impacts in the vicinity of long-duration activities associated with oil and gas exploration and production. A chronic impact is defined as an effect on the biota caused by exposure to the long-term accumulation of chemicals in the environment. The basic program, comprising four field activities over a 2-yr period, was designed to detect nearfield impacts and contaminant gradients extending out from each site. Five test sites were evaluated and three selected as most appropriate for long-term study: MU-A85, MAI-686, and HI-A389. The sampling design included a radial pattern with stations at 30–50, 100, 200, 500, and 3000 m distance and employed a dose–response model to test the hypotheses that biological, chemical, and biochemical variations are due to platform-derived contaminants. Study components included contaminant (trace metals and hydrocarbons) analysis in sediments, pore waters, and biological tissues; assemblage analysis of benthic meiofauna, infauna, and epifauna, assessment of community health based on life history and reproduction studies; and the induction of detoxification responses.

Résumé : L'Expérience de surveillance des opérations extracôtières dans le golfe du Mexique, dite « GOOMEX », est une étude en trois étapes visant à vérifier et à évaluer une gamme de méthodes biologiques, biochimiques et chimiques de détection et d'évaluation des effets biologiques sublétaux chroniques au voisinage d'activités de longue durée, associées à la prospection et à la production de pétrole et de gaz. Un effet chronique s'entend d'un effet sur le biote d'une exposition à l'accumulation prolongée de produits chimiques dans l'environnement. Le programme de base, comportant quatre activités sur le terrain en 2 ans, vise à détecter les effets des contaminants à proximité de chaque site et leurs gradients en s'en éloignant. Cinq sites d'essai ontété évalués, et trois ont été choisis comme les plus appropriés pour une étude à long terme : MU-A85, MAI-686 et HI-A389. Dans le plan d'échantillonnage de géométrie radiale, où les stations étaient réparties à des distances de 30–50, 100, 200, 500 et 3 000 m, le modèle dose–réponse retenu visait à vérifier les hypothèses selon lesquelles les variations biologiques, chimiques et biochimiques tiennent aux contaminants de plate-forme. Les volets de l'étude comprenaient l'analyse des contaminants (hydrocarbures et métaux à l'état de traces) dans les sédiments, les eaux interstitielles et les tissus biologiques, l'analyse d'assemblages de la méiofaune, de l'endofaune et de l'épifaune benthiques, l'évaluation de la santé du milieu d'après des études du cycle biologique et de la reproduction et l'induction de réponses de détoxification.
[Traduit par la Rédaction]

Introduction

The most significant unanswered questions related to the environmental impacts of offshore oil and gas development and production are those involving chronic, low-level stresses on ecosystems. These stresses result from discharges, spills, and leaks associated with the long-term development of energy resources on the continental shelf (Boesch et al. 1987; Aurand 1988; Ahlfeld 1990; Kendall 1990). A three-phase program, called the Gulf of Mexico Offshore Operations Monitoring Experiment (GOOMEX), is being conducted to test and evaluate a range of biological, biochemical, and chemical methodologies that may indicate whether the local environment around platforms is responding to chronic, sublethal exposure to discharged contaminants. A multidisciplinary team of scientists was assembled to implement Phase I of the program (Table 1). Work elements included ancillary physical, chemical, and sedimentological variables, analysis of contaminants (trace metals and hydrocarbons) in sediments, pore waters, and biological tissues; assemblage analysis of benthic meiofauna, macroinfauna, and megafauna, meiofaunal and megafaunal invertebrate life history and reproduction studies, and the presence and intensity of inducible detoxification responses in megafaunal biota (Table 2).

The program involved an intensive sampling of the study sites and utilization of a variety of analytical techniques to produce a comprehensive data set to test the programmatic hypotheses. Field and laboratory methods are summarized in Tables 3 and 4. All study components were linked by common study and sampling designs to ensure an integrated synthesis. A comprehensive summary of the samples collected is provided in Table 5.

The objective of GOOMEX Phase I was to test a variety of variables representing all levels of biological organization for suitability as indicators to detect chronic, sublethal biological responses to long-term production activities. The central question is whether the variables measured are significantly different near a platform as compared with away from the platform and can these differences be attributed to the release of contaminants from the platform. While contaminants were identified as the primary agent of concern, it was recognized that the physical presence of the structure will lead to other alterations in the local environment. For example, disposal of coarse materials to the surrounding sediments also sets the stage for a shift in community structure. The outcome of these events is commonly referred to as rig ecology. Differences in various parameters or variables related to distance from the platform can only be fully understood in the context of cause, effect, and biological significance. Any two places on the continental shelf can be demonstrated to be different, if the areas are analyzed to a sufficient level of detail. Tacit in the design of the GOOMEX program is an effort to provide correlative support for cause and effect at several levels of biological organization and provide a focus for the scope of future studies. Concordance amongst independent biological responses was evaluated to determine if it supported the interpretations. Another guiding principle was biological significance. The goals of monitoring are to detect resource degradation or damage and to provide guidance on how to prevent or reverse the undesired response.

Detection of impacts or biological effects responding to contaminant exposure requires confirmation that the exposure has taken place and that the observed "biological patterns" are beyond those attributable to natural variations (Carney 1987). Biological response to exposure can be highly variable in both mechanism and intensity. Biological changes can have a short time span (i.e., induced detoxification or reduced reproductive effort in an individual) or a long time span (i.e., compositional shifts in communities). Impact can be expected to manifest itself differently from species to species and from population to population due to differences in the history of exposure and the response to exposure.

Based on the objectives, the GOOMEX Phase I study was designed to collect a data set to provide statistical tests of two interrelated hypotheses. The null hypotheses tested were as follows:

H_0: There are no differences in any sedimentological, chemical, community, population, reproductive, toxic, or detoxification measures between seasons, among platforms (or platform groups), or with distance or direction away from platforms (or platform groups).

H_0: There are no functional relationships between chemical

Table 2. Summary of GOOMEX Phase I work elements.

Work element	Variables
	Independent variables: sediments/water column
Physiochemical	Salinity, oxygen, nutrients, light transmittance, and temperature
Sedimentology	Grain size, carbon content (organic and inorganics), minerology, redox condition
Contaminants	Hydrocarbons and metals
	Independent variables: biota
Contaminants	Hydrocarbons and metals in fish livers, fish stomach contents, and invertebrate soft tissues
Physiological	Percent moisture and lipid content
	Independent variables: pore waters
Contaminants	Hydrocarbons and trace metals
	Dependent variables
Meiofauna[a]	Abundance, diversity, community structure, nematode trophic dynamics, life history and reproduction, and genetic diversity
Macroinfauna[b]	Abundance, diversity, community structure
Megafauna: invertebrates	Catch per unit effort, size and frequency, histopathology, reproductive effort, reproductive development, and detoxification response[c]
Megafauna: fish	Fish food analysis, histopathology, and detoxification response[d]

[a]Also pore water toxicity testing: bioassays with meiobenthic species.
[b]Also pore water toxicity testing: sea urchin fertilization and embryological development test.
[c]Detoxification response: AHH activity, in vitro rat hepatoma H-4IIE cell assays.
[d]Detoxification response: EROD and AHH activity, biliary PAH metabolites, P4501A and mRNA levels, laboratory dosing experiments.

contaminant gradients and community, population, reproductive, toxic, or detoxification measures.

To test the first hypothesis, univariate analysis of variance (ANOVA) for all variables being measured at all stations in the study design was the method of choice. The categorical variables in such a design, particularly distance from a platform, are surrogates of the contaminant gradients that might exist among and within platform stations. Therefore, the approach to test the second hypothesis was a multivariate approach.

Study design

Two study designs formed the basis of the GOOMEX Phase I program. Both rely on a dose–response model but differ in the details of the sampling design. The first design provided for an assessment of the benthos by using a quantitative boxcorer to sample sediments and resident organisms adjacent to platforms. The sampling plan was designed to detect near-field impacts and contaminant gradients extending out from a platform. The sampling design included a radial pattern to ≥3000 m distance to define the platform's contamination gradient. The sediment sampling design included five radii, five distances per radii, and two or three pseudoreplicates, i.e., replicates from within boxcores, at each station (Fig. 1). The number of stations was maximized to test for directional and distance patterns. With four sampling events, this led to a total of 600 or 900 samples for the three study sites (Table 5). Twenty-five stations comprised the sampling grid at each site (5 distances × 5 radii at 50, 100, 200, 500, and ≥3000 m distance; Fig. 1). Control sites were provided by extension of the radii beyond the distance of measurable contaminants, generally ≥3000 m distance. Controls were chosen to be as similar in setting to the near-field stations as possible to minimize differences due to non-platform-related variations.

The second study design employed a Near (or impacted) versus Far (or unimpacted) pairwise comparison of indicators of contaminant exposure. Due to the need for large amounts of biomass for the various work elements, boxcorers were insufficient as a collection technique. Therefore, biomass sample collection relied primarily on otter trawls. Samples were taken as close as possible to the platform (<100 m) and at a comparison station (≥3000 m). The studies utilizing this design employed laboratory techniques that were generally time intensive and/or relatively untested so that they were only evaluated at the presumed extremes of exposure.

The study design is based on a dose–response model. Contaminant concentrations are expected to decline exponentially with distance away from a platform. Biological variables should respond to the contaminant gradient; thus, the magnitude of the response is expected to decrease with increasing distance from a platform. These five distances away from the platform were chosen on a log scale. This model indicates that contaminant concentration and organism abundance variables should be transformed using the natural logarithm. Percentage data, e.g., percent sand, or toxicity test results

Table 3. Summary of field methods.

Work element	Description	Reference(s)
Boxcorer	Ocean Instruments BX-600 deep ocean corer	Hessler and Jumars 1974; Jumars 1975
Trawling	Otter trawl:mesh 4.04 cm, mouth opening 17.58 m, bridle 67.58 m, wood doors (1.83 × 0.92 m), time 10–15 min, speed 0.5 kt	—
Navigation	DGPS (±3 m)	
Continuous profiles	Seabird SEACAT Profiler, Sea-Tech transmissometer	—
Discrete water samples	5-L Niskin bottle; nutrients, frozen (−20°C), plastic bottles; salinity: glass bottles	
Sedimentology grain size, mineralogy	Refrigerated (4°C), plastic bags	
Redox potential	Combination platinum electrode	Whitfield 1969
TOC, TIC	Frozen (−20°C), glass jars	NOAA 1993
Contaminants: sediments		
Hydrocarbons	Frozen (−20°C), glass jars	NOAA 1993
Metals	Frozen (−20°C), plastic jars	
Contaminants: tissues		
Hydrocarbons	Disected, frozen, glass jars	NOAA 1993
Metals	Dissected, frozen, plastic jars	NOAA 1993
Meiofauna		
Abundance, diversity, life history, reproduction	1.9-cm i.d. core tube, depth 0–2 cm, anesthetized with 7% $MgCl_2$ (5 min), preserved 10% buffered formalin; two replicates	Montagna 1991; Hulings and Gray 1971
Genetic diversity	Depth 0–2 cm, preserved in EDTA–buffered alcohol, stored at 4°C	Dessauer et al. 1990
