NATIONAL MARINE FISHERIES SERVICE REPORT

National Marine Fisheries Service (NMFS) Northwest Region will briefly report on recent regulatory developments relevant to groundfish fisheries and issues of interest to the Pacific Fishery Management Council (Council).

NMFS Northwest Fisheries Science Center (NWFSC) will also briefly report on groundfish-related science and research activities.

Council Task:

Discussion.

Mr. Barry Thom
Acting Regional Administrator
National Marine Fisheries Service
1201 NE Lloyd Boulevard, Suite 1100
Portland, OR 97232-1274

Dear Barry:

It has come to our attention that the Quileute Tribe has yet to commence harvesting the 8,000 mt of Pacific whiting that was made available to them by NMFS under their tribal treaty rights this year. We have also heard reports that the Tribe has no boats available to harvest the whiting and no fishing plan in effect. If this is indeed the case, we request that NMFS promptly pursue with the Tribe a reallocation of the unused whiting to other interested commercial fishing sectors. This would be in accordance with past practice regarding unharvested whiting from both the commercial and the tribal sectors. Any such reallocation would of course be without prejudice to any tribal treaty fishing rights.

For the non-tribal harvesting sectors, the Pacific groundfish regulations at 50 CFR 660.323 provide a reallocation mechanism that includes a survey of interest and a reallocation to be completed by September 15th or as soon as practicable thereafter and provides for reallocation based on percentages specified in federal regulations. We believe this is the best process to use in this case. An informal survey of shore-based whiting processors has indicated an interest in harvesting an appropriate share of the tribal fish and the fish remaining unharvested from the regular season opening. Whiting are still available to shore-based boats into the fall (weather permitting) and bycatch rates are traditionally low. A September 15th decision would also provide time for consultation with the Pacific Fishery Management Council during the NMFS report agenda item scheduled for September 14th. If the Quileute Tribe demonstrates that they intend to exercise their tribal treaty right to take whiting, then that can be clearly indicated so that there is no confusion or anticipation among non-tribal harvesting sectors. If not, then we hope that NMFS will honor the requirements of 16 U.S.C. 1851(a)(1).

Thank you for your consideration of this request.

Sincerely,

Rod Moore
Executive Director

PART II OF STOCK ASSESSMENTS FOR 2011-2012 GROUNDFISH FISHERIES

The Council process for setting groundfish harvest levels and other specifications depends on periodic assessments of the status of groundfish stocks and a report from a Stock Assessment Review (STAR) Panel. The Scientific and Statistical Committee (SSC) reviews this information and makes a recommendation relative to the standards of 1) the best available science, and 2) soundness for use in groundfish fishery management decision-making by the Council. The Council then approves the new assessments and relevant analyses used to set groundfish harvest levels and other specifications for the following biennial management period.

A new full assessment for petrale sole was considered for adoption at the June Council meeting. At that time the SSC recommended further review of the assessment and the biological basis for considering a target biomass (B_{MSY}) estimated in the assessment. Recommendations from the SSC Groundfish Subcommittee meeting on August 31 will be presented to the full SSC at this meeting. Their recommendations should be considered before adopting this new assessment.

The Council may want to set a B_{MSY} target and overfished level for this stock depending on SSC advice. The B_{MSY} target may be either a proxy value or deterministic as estimated in a quantitative assessment. The Groundfish Fishery Management Plan (FMP) specifies how B_{MSY} target levels are set in section 4.2 as follows:

> "Harvest policies are to be specified according to standard reference points such as MSY (MSY, interpreted as a maximum average achievable catch under prevailing ecological and environmental conditions over a prolonged period). The long-term average biomass associated with fishing at F_{MSY} is B_{MSY}. In this FMP, MSY generally refers to a constant F control rule that is assumed to produce the maximum average yield over time while protecting the spawning potential of the stock. … Absent a more accurate determination of F_{MSY}, the Council will apply default MSY proxies. … A biomass level of 40% (i.e., $0.4*B_{unfished}$) is a reasonable proxy for B_{MSY}. … If available information is sufficient, values of F_{MSY}, B_{MSY}, and more appropriate harvest control rules may be developed for any species or species group."

Section 4.4.3 of the FMP specifies how overfished levels are set as follows:

> "The default overfished/rebuilding threshold for category 1 groundfish (i.e., stocks with quantitative assessments) is $0.25*B_{unfished}$. The Council may establish different thresholds for any species based on information provided in stock assessments, the SAFE document, or other scientific or groundfish management-related report. For example, if B_{MSY} is known, the overfished threshold may be set equal to 50% of that amount."

The executive summary of the petrale sole assessment and the STAR panel report that were provided in June are provided again in Agenda Item E.2.a, Attachments 1 and 2, respectively. Agenda Item E.2.a, Attachment 3 is an addendum to the petrale sole assessment with the stock assessment team's responses to the SSC's June requests.

New full assessments for bocaccio, widow rockfish, lingcod, cabezon, yelloweye rockfish, and greenstriped rockfish were also prepared and reviewed by STAR Panels. The executive summaries of these assessments and the associated STAR Panel reports are provided as Agenda Item E.2.a, Attachments 4 through 15. An information session is scheduled for Saturday, September 12 to provide an opportunity to review assessment results and ask stock assessment teams (STATs) questions regarding their respective assessments. There will also be an opportunity to ask STATs and the SSC further questions under this agenda item. **All the assessments in their entirety and STAR Panel reports under Council consideration at this meeting are included in the CD copy of meeting materials.**

The Council should consider the new full assessments and STAR Panel reports, as well as the advice of the SSC, other advisory bodies, and the public before adopting the new stock assessments for use in 2011-2012 groundfish management.

Council Actions:

1. **Consider approving stock assessments.**
2. **Consider specifying a biomass target (B_{MSY}) and an overfished level for petrale sole pending SSC advice.**

Executive Summary

Stock

This assessment reports the status of the petrale sole (*Eopsetta jordani*) resource off the coast of California, Oregon, and Washington using data through 2008. While petrale sole are modeled as a single stock, the spatial aspects of the coast-wide population are addressed through geographic separation of data sources/fleets where possible and consideration of residual patterns that may be a result of inherent stock structure. There is currently no genetic evidence suggesting distinct biological stocks of petrale sole off the U.S. coast. The limited tagging data available to describe adult movement suggests that petrale sole may have some homing ability for deepwater spawning sites but also have the ability to move long distances between spawning sites and seasonally.

Catches

The earliest catches of petrale sole are reported in 1876 in California and 1884 in Oregon. Recent annual catches during 1981–2008 range between 1,244–2,854 mt (Table a, Figure a). Petrale sole are almost exclusively caught by trawl fleets. Non-trawl gears contribute less than 2% of the catches. Based on the previous 2005 assessment, subsequent OYs were reduced due to 2499 mt. From the inception of the fishery through the war years, the vast majority of catches occurred between March and October (the summer fishery), when the stock is dispersed over the continental shelf. The post-World War II period witnessed a steady decline in the amount and proportion of annual catches occurring during the summer months (March-October). Conversely, petrale catch during the winter season (November–February), when the fishery targets spawning aggregations, has exhibited a steadily increasing trend since the 1940's. Since the mid-1980s, catches during the winter months have been roughly equivalent to or exceeded catches throughout the remainder of the year (Figure a).

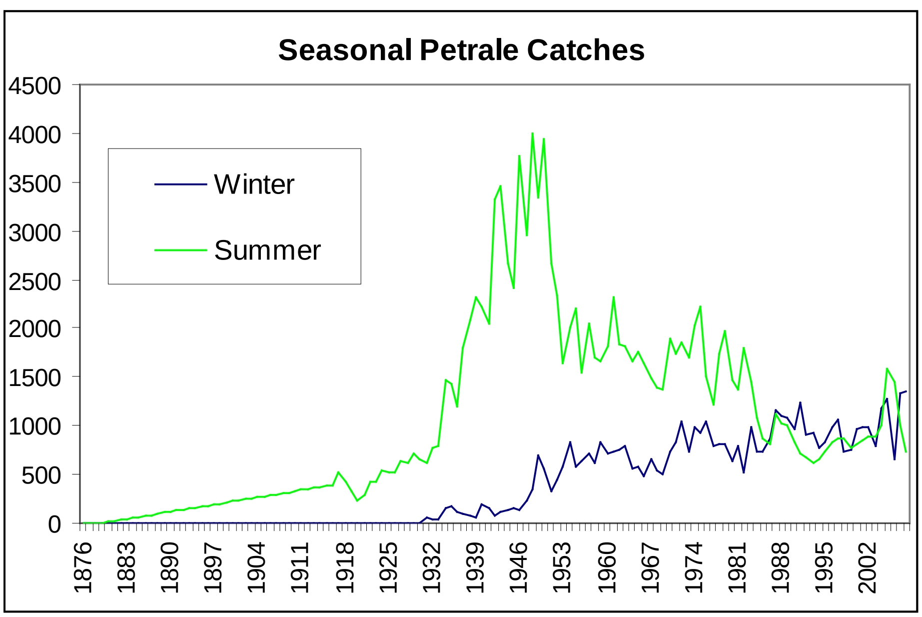

Figure a. Petrale sole catch history by season, 1876-2008.

Table a. Recent commercial fishery catches (mt) by combined summer and winter fleets.

Fishing year	Washington trawl	Oregon trawl	California trawl	Total
1999	443	517	560	1,520
2000	668	460	650	1,778
2001	675	584	579	1,838
2002	861	481	536	1,877
2003	837	408	441	1,686
2004	1,234	511	445	2,191
2005	1,319	661	874	2,854
2006	871	641	590	2,102
2007	635	732	963	2,329
2008	466	585	1,028	2,079

Data and Assessment

The previous stock assessment for petrale sole was developed during 2005 using Stock Synthesis 2. This assessment uses the Stock Synthesis 3 (SS-V3.03a-SAFE, 04/30/09) integrated length-age structured model. Due to higher wintertime catches in recent decades the assessment is based on winter (November to February) and summer (March to October) fishing seasons with the fishing year starting on November 1 and ending on October 31. The fisheries are divided into WA-Winter, WA-Summer, OR-Winter, OR-Summer, CA-Winter, and CA-Summer fisheries. The model includes catch, length- and age-frequency data from the trawl fleets described above as well as standardized CPUE indices developed by Sampson and Lee (1999) for the Oregon fleets from 1987–1997. The impact of rapidly changing regulations in the trawl fishery after these dates makes the fishery-based CPUE indices unreliable. Biological data are derived from both port and on-board observer sampling programs. The National Marine Fisheries Service (NMFS) triennial bottom trawl survey (1980, 1983, 1986, 1989, 1992, 1995, 1998, 2001, and 2004) and Northwest Fisheries Science Center (NWFSC) trawl survey (2003–2008) relative biomass indices and biological sampling provide fishery independent information on relative trend and demographics of the petrale sole stock.

The base case assessment model includes parameter uncertainty from a variety of sources, but likely underestimates the uncertainty in recent trend and current stock status. For this reason, in addition to asymptotic confidence intervals (based upon the model's analytical estimate of the variance near the converged solution), results from models that reflect alternate states of nature regarding the estimate of 2009 spawning biomass are presented as a decision table.

Stock biomass

Petrale sole were lightly exploited during the early 1900s but by the 1950s the fishery was well developed and showing clear signs of depletion and declines in catches and biomass (Figures a, b). The rate of decline in spawning biomass accelerated through the 1930s–1970s reaching minimums generally around or below 10% of the unexploited levels during the 1980s and 1990s (Figure b). The petrale sole spawning stock biomass is estimated to have increased slightly from the late 1990s, peaking in 2005, in response to above average recruitment (Table b, Figure b). However, this increasing trend has reversed since the 2005 assessment and the stock has been declining, most likely due to strong year classes having passed through the fishery (Table b). The estimated relative depletion level in 2009 is 11.6% (~95% asymptotic interval: ±4.8%, ~ 75% interval based on the range of states of nature: 9.4-13.8%), corresponding to 2937.6 mt (~95% asymptotic interval: ±832.7 mt, states of nature interval: 2407.8-3468.1 mt) of female spawning biomass in the base model (Table b). The base model indicates that the spawning biomass has been below 25% of the unfished level continuously since 1953.

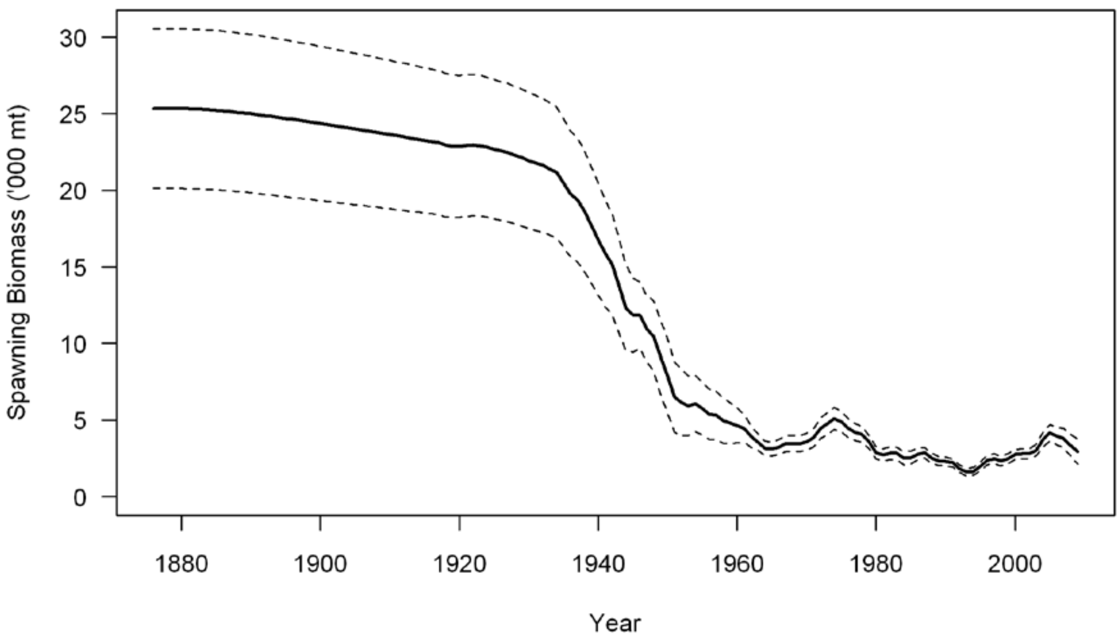

Figure b. Estimated spawning biomass time-series (1876-2009) for the base case model (solid line) with approximate asymptotic 95% confidence interval (dashed lines).

Table b. Recent trend in estimated petrale sole female spawning biomass and relative depletion.

Fishing year	Spawning biomass (mt)	~95% confidence interval	Range of states of nature	Estimated depletion	~95% confidence interval	Range of states of nature
2000	2,765.2	±329.7	2743.9-2776.9	10.9	±3.4	10.7-11.1
2001	2,810.3	±328.3	2781.5-2829.5	11.1	±3.4	10.8-11.3
2002	2,798.4	±333.6	2759.3-2827.8	11.0	±3.4	10.7-11.3
2003	3,030.0	±381.0	2969.1-3080.3	12.0	±3.8	11.5-12.3
2004	3,706.4	±463.0	3605.0-3796.5	14.6	±4.7	14.0-15.1
2005	4,160.7	±529.5	4002.0-4308.6	16.4	±5.2	15.5-17.2
2006	3,949.8	±576.0	3720.7-4169.9	15.6	±5.1	14.5-16.6
2007	3,818.0	±624.1	3507.4-4122.5	15.1	±5.1	13.6-16.4
2008	3,349.6	±704.6	2940.8-3755.2	13.2	±4.8	11.4-14.9
2009	2,937.6	±832.7	2407.8-3468.1	11.6	±4.8	9.4-13.8

Recruitment

Annual recruitment was treated as stochastic, and estimated as annual deviations from log-mean recruitment where mean recruitment is the fitted Beverton-Holt stock recruitment curve. The time-series of estimated recruitments shows a weak relationship with the decline in spawning biomass, punctuated by larger recruitments (Figure c). The four weakest recruitments since 1939 are estimated to be in 1972, 1985-1986, 1991 and 2003. The four strongest recruitments since 1939 are estimated to be in 1939-1940, 1960, 1965, and 1997-1998 (Figure c). The most recent above average recruitment event, is estimated to be in 2005, and is about 20% smaller than of the 1997–1998 recruitment event (Table c).

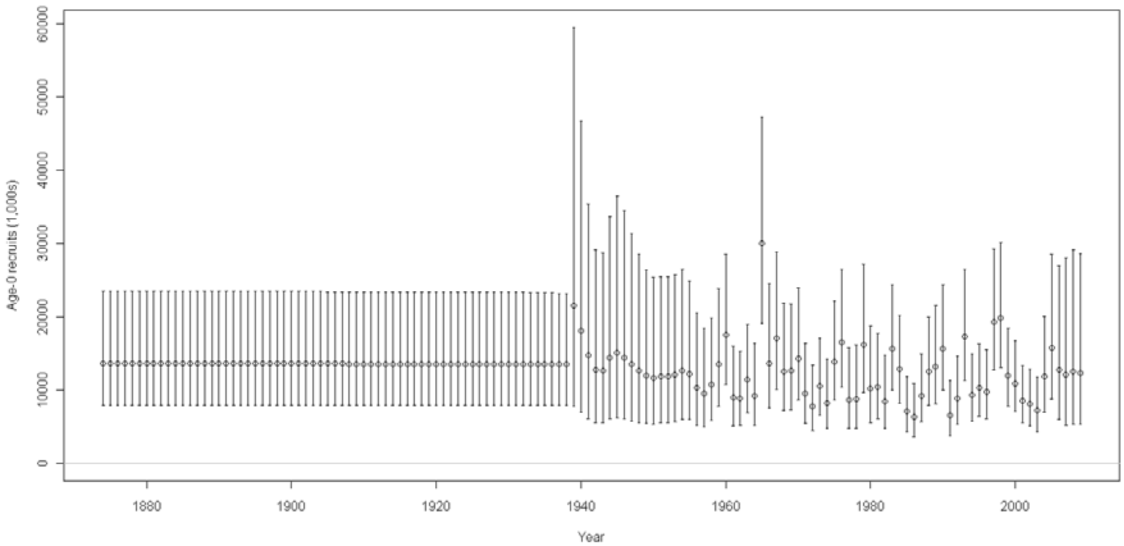

Figure c. Time series of estimated petrale sole recruitments for the base case model (round points) with approximate asymptotic 95% confidence interval (vertical bars).

Table c. Recent estimated trend in petrale sole recruitment.

Fishing year	Estimated recruitment (1000s)	~95% confidence interval	Range of states of nature
2000	10,903.2	±4,721.5	10,022.7-11,679.2
2001	8,562.7	±3,816.7	7,674-9,382.8
2002	8,161.0	±3,805.4	7,040.9-9,241.4
2003	7,164.5	±3,606.0	5,965.2-8,354.8
2004	11,897.1	±6,338.7	9,554.3-14,285.1
2005	15,770.9	±9,522.5	12,415.7-19,223.9
2006	12,740.4	±9,912.5	10,911.6-14,269.5
2007	12,048.8	±10,655.9	11,335.2-12,513
2008	12,508.7	±11,097.5	11,826.7-12,947.8
2009	10,903.2	±4,721.5	10,022.7-11,679.2

Reference Points

Unfished spawning stock biomass was estimated to be 25,334 mt in the base case model (Figure b). The target stock size ($SB_{40\%}$) is therefore 10,134 mt which gives a catch of 2060 mt (Table i, Figure b). The estimates of unfished spawning biomass, and therefore the $SB_{40\%}$ reference points were very sensitive to the assumption of stock-recruitment relationship (see section 2.9.1). Model estimates of spawning biomass at MSY and MSY yield were more robust to the assumption of stock-recruitment relationship (see section 2.9.1). Maximum sustained yield (MSY) applying recent fishery selectivity and allocations was estimated in the assessment model at 2376 mt, occuring at a spawning stock biomass of 4796 mt (SPR = 0.20) (Table i, Figures d,h,i) , which is 18.9% of the unfished level.

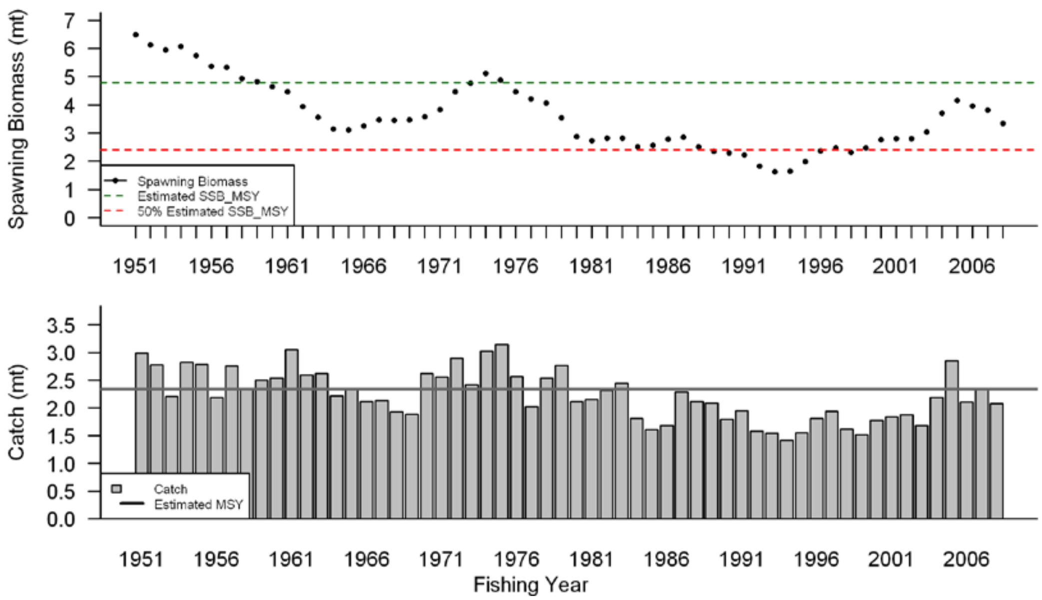

Figure d. Time series of catches startin in 1950 in comparison to the model estimated time series of spawning biomass and summary (age 3+) biomass. The solid horizontal line is the estimated MSY catch and the dashed line is the estimated spawning biomass at MSY.

Exploitation status

The abundance of petrale sole was estimated to have dropped below the $SB_{40\%}$ management target in 1949 and the overfished threshold in 1953. Beginning in 1980 the stock size was around 10–12% of unfished spawning biomass and in 1988 the stock dropped below 10% of the unfished spawning biomass (Figure e). Since 2000 the stock has increased, reaching a peak of 16.4% of unfished biomass in 2005, followed by a decreasing trend through 2009. Fishing mortality rates in excess of the current F-target for flatfish of $SPR_{40\%}$ are estimated to have begun in the late 1930s and persisted through 2008 (Table d, Figures f,g). Current F (catch/biomass of age-3 and older fish) is estimated to have been 0.29 in 2008 (Table d, Figure f).

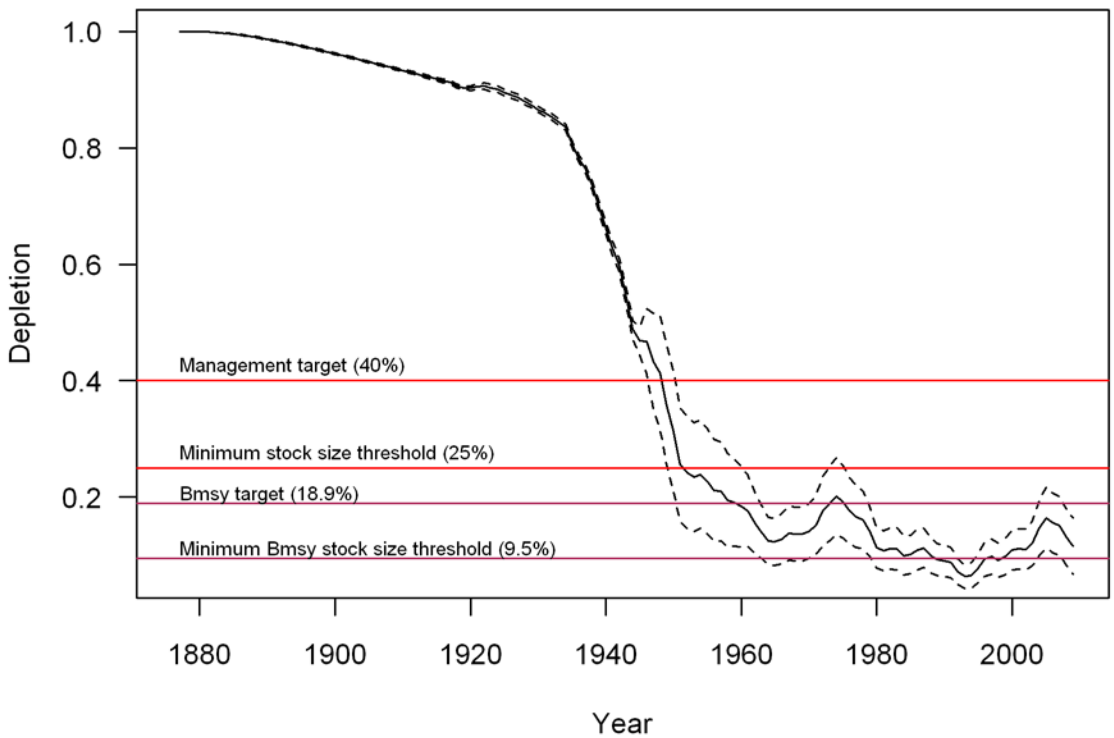

Figure e. Time series of depletion level as estimated in the base case model (round points) with approximate asymptotic 95% confidence interval (dashed lines) and alternate states of nature (light lines).

Table d. Recent trend in spawning potential ratio (1-SPR) and relative exploitation rate (catch/biomass of age-3 and older fish).

Fishing year	Estimated 1-SPR (%)	Range of states of nature	F	Range of states of nature
2000	0.86	0.86-0.86	0.28	0.28-0.27
2001	0.87	0.87-0.86	0.27	0.27-0.27
2002	0.86	0.87-0.86	0.26	0.27-0.26
2003	0.82	0.83-0.81	0.21	0.22-0.21
2004	0.83	0.84-0.83	0.25	0.26-0.24
2005	0.87	0.87-0.86	0.32	0.34-0.31
2006	0.83	0.85-0.82	0.27	0.29-0.25
2007	0.85	0.87-0.83	0.31	0.34-0.28
2008	0.85	0.87-0.83	0.29	0.34-0.26
2009	0.90	0.93-0.87	0.36	0.45-0.31

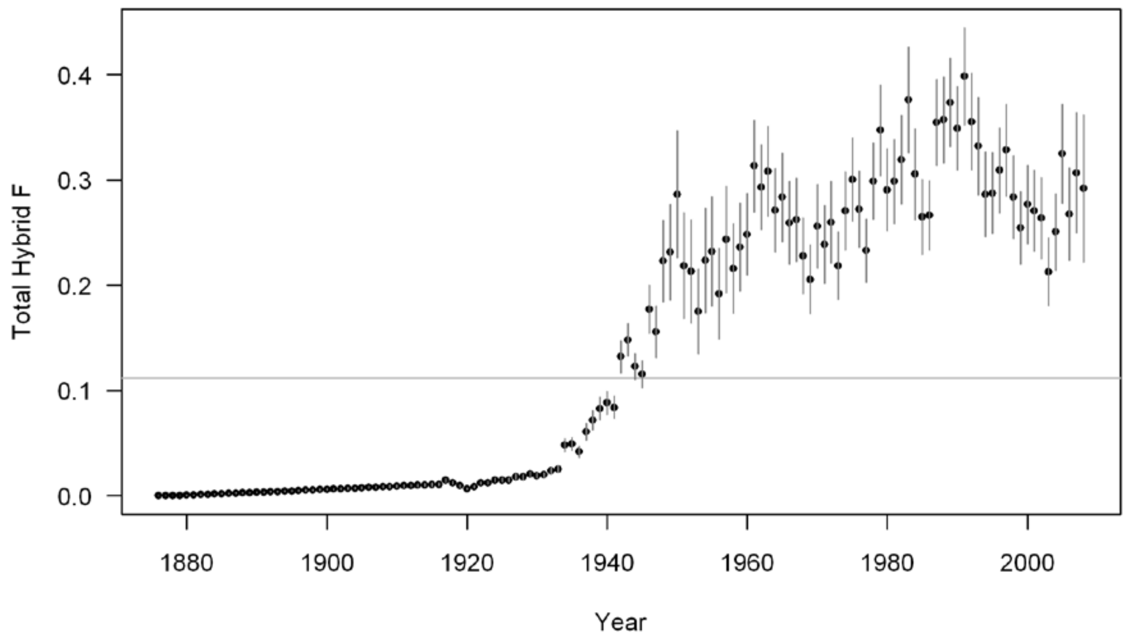

Figure f. Time series of estimated relative exploitation rate (catch/age 3 and older biomass) for the base case model (round points). Values of relative exploitation rate in excess of horizontal line are above the rate corresponding to the overfishing proxy from the base case.

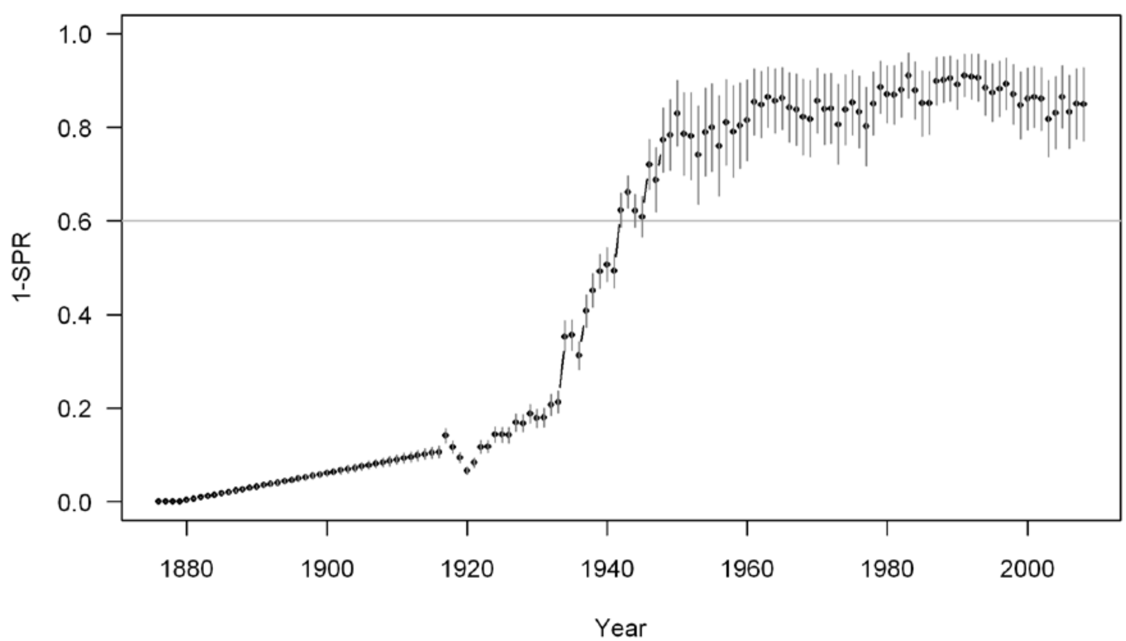

Figure g. Estimated spawning potential ratio from the base case model. One minus SPR is plotted so that higher exploitation rates occur on the upper portion of the y-axis.

Management performance

The most recent 2005 assessment of petrale sole stock assessment split the stock into two areas, the northern area that included U.S. Vancouver and Columbia INPFC areas and the southern area that included the Eureka, Monterey and Conception INPFC areas (Lai et al. 2006). In 2005 petrale sole were estimated to be at 34 and 29 percent of unfished spawning stock biomass in the northern and southern areas, respectively. Based on the 2005 stock assessment coast-wide ABCs were set at 3025 mt and 2919 mt for 2007 and 2008, respectively, with an OY of 2499 mt for both years (Table e). Recent coast-wide annual landings have not exceeded the ABC except for 2005 when the ABC was exceeded by 92 mt, 3.3%. The 2005 stock assessment estimated that petrale sole have been below the Pacific Council's minimum stock size threshold of 25 percent of unfished biomass from the mid-1970s until recently with estimated harvest rates in excess of the target fishing mortality rate of F40%. The 2005 assessment estimated the spawning stock biomass in 1998 at 12 percent of unfished stock biomass. The current assessment estimates that petrale sole have been below the $SB_{40\%}$ management target since 1949 and below the overfished threshold since 1953 (Table b, Figures e) with fishing mortality rates in excess of the current F-target for flatfish of $SPR_{40\%}$ since the late 1930s (Table d, Figure h). Using reference points based on the model estimates of Bmsy from the base case model suggests that the petrale sole fishery has been fishing at or near the management targets for a large portion of the time (Figure i). A summary of recent trends in the fishery and petrale sole population can be found in Table h.

Table e. Recent trend in estimated total petrale sole catch and commercial landings (mt) relative to management guidelines.

Fishing year	ABC (mt)	OY (mt)	Commercial Landings (mt)	Estimated[1] Total Catch (mt) for the Annual Year	Estimated Total Catch (mt) for the Fishing Year
1999	2,700	2,700	1,520	1,617	1,591
2000	2,950	2,950	1,778	1,888	1,856
2001	2,762	2,762	1,838	1,975	1,934
2002	2,762	2,762	1,877	2,066	2,024
2003	2,762	2,762	1,686	1,786	1,809
2004	2,762	2,762	2,191	2,273	2,284
2005	2,762	2,762	2,854	2,948	2,960
2006	2,762	2,762	2,102	2,173	2,183
2007	3,025	2,499	2,329	2,372	2,376
2008	2,919	2,499	2,079	2,114	2,117

[1] Total annual catches reflect the commercial landings plus the model estimated annual discard biomass (commercial landings * retained catch/total catch). The total amounts of discard may differ from those reported in the NWFSC reports on total catch for some of these years.

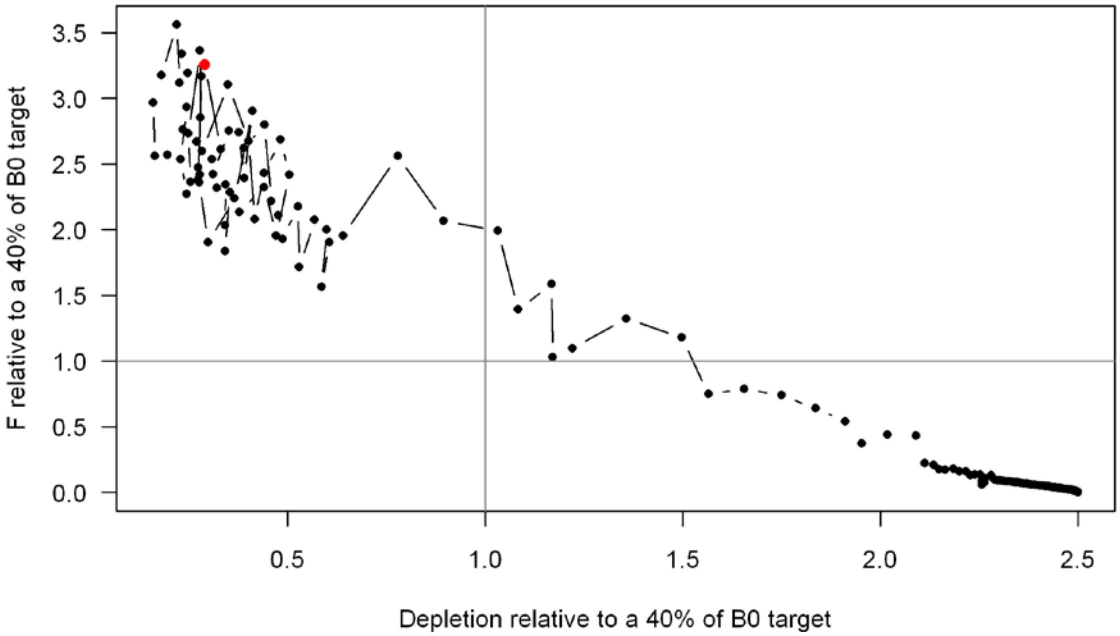

Figure h. Phase plot of estimated fishing intensity vs. relative spawning biomass for the base case model. Fishing intensity is the relative exploitation rate divided by the level corresponding to the overfishing proxy. Relative spawning biomass is annual spawning biomass relative to virgin spawning biomass divided by the 40% rebuilding target. The red point is 2009.

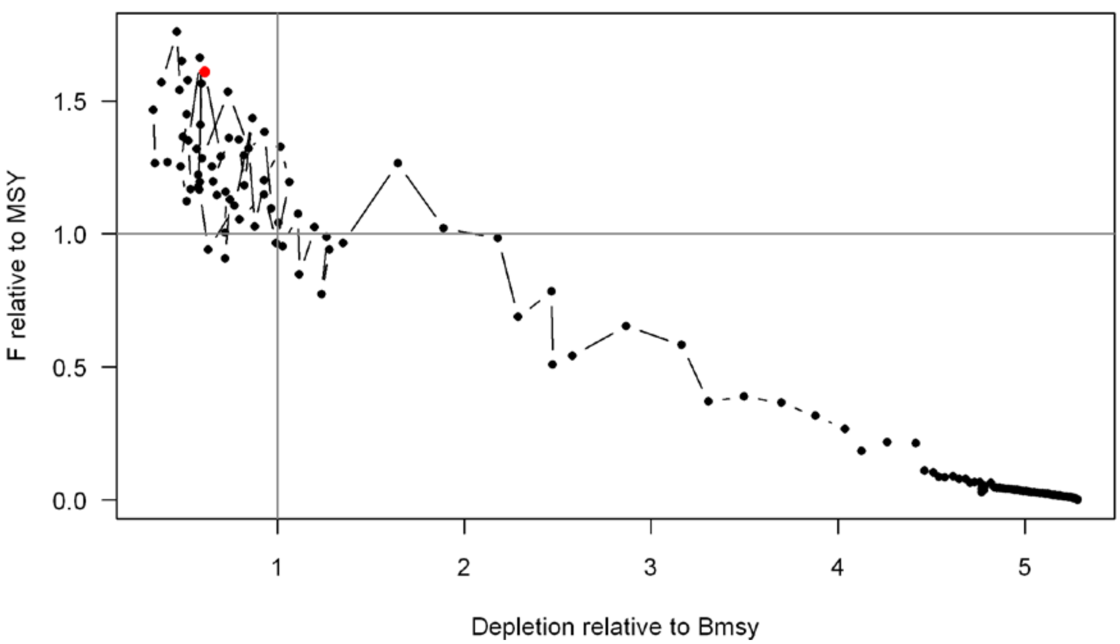

Figure i. Phase plot of estimated fishing intensity vs. relative spawning biomass for the base case model. Fishing intensity is the relative exploitation rate divided by the level corresponding to Fmsy. Relative spawning biomass is annual spawning biomass relative to the model estimate of Bmsy. The red point is 2009.

Unresolved problems and major uncertainties

Parameter uncertainty is explicitly captured in the asymptotic confidence intervals reported throughout this assessment for key parameters and management quantities. These intervals reflect the uncertainty in the model fit to the data sources included in the assessment, but do not include uncertainty associated with alternative model configurations, weighting of data sources (a combination of input sample sizes and relative weighting of likelihood components), or fixed parameters.

There are a number of major uncertainties regarding model parameters that have been explored via sensitivity analysis using both the model submitted to the STAR panel and variations which were evaluated during the STAR meeting. The most notable explorations involved the sensitivity of model estimates to the specification of the stock-recruitment relationship.

The comparability of age data within and between age-reading laboratories over time due to changes in ageing methods, a variety of ageing methods being applied to the same sample, inadequate otolith sampling, and between-laboratory variation is a major source of uncertainty. The application of the 'combo' age reading method for petrale, where petrale up to approximately age 10 are surface read and those otoliths thought to be greater than age 10 are broken and burned leads to a high level of variability in the age data, especially at older ages, when the 'combo' method is applied. Recent bomb radiocarbon analysis shows that the best ages for petrale are obtained using the break and burn method. The break and burn method should be used for ageing petrale sole.

There are problems with the Oregon commercial age data from 1981–1999. Ages from this period were aged using a combination of methods and non-randomly (i.e. one individual aged all males and another individual aged all females). While age reader information exists it is not currently in the PacFIN database, making it impossible to closely examine the impact of varying ageing methods and non-random reader design. This leads to large levels of ageing error for ages from this period of the Oregon fishery. If possible, these otoliths should be re-aged and age reader information needs to routinely be included in PacFIN.

Forecasts

The forecast of stock abundance and yield was developed using the base model. The total catch in 2009 and 2010 are set at 2433 and 2393 mt. The exploitation rate for 2011 and beyond is based upon an SPR of 40%. The 40:10 control rule reduces forecasted yields below those corresponding to $F_{40\%}$ because the stocks are estimated to be lower than the management target of $SB_{40\%}$ (Table f). The 2008 exploitation rate was used to distribute catches among the fisheries. Uncertainty in the forecasts is based upon the three states of nature agreed upon at the STAR panel. The high and low states are differentiated from the base case by the size of the 2009 spawning biomass, assuming values that were 1.25 standard deviations higher and lower, respectively, than the base case.. Manipulation of the amount of NWFSC survey biomass in 2008 was used to achieve these alternative sizes for the 2009 spawning biomass. Each forecast scenario includes random variability in future recruitment deviations (Table g). Current medium-term forecasts predict a declining trend in abundance and catch through 2011, with OY values for 2011 set at zero catch under the 40-10 harvest policy. This decline is followed by increasing abundance and catches, with the stock moving above the minimum stock size threshold of $SB_{25\%}$ in 2015. The following table shows the projection of expected petrale sole catch, spawning biomass and depletion from the base model using the 40-10 control rule (Table f).

Table f. Projection of potential petrale sole ABC, OY , spawning biomass and depletion for the base case model based on the SPR= 40% fishing mortality target used for the last plan (OY) and $F_{40\%}$ overfishing limit/target (ABC). Assuming the OYs of 2433 and 2393 mt are attained in 2009 and 2010.

Year	ABC (mt)	OY (mt)	Age 3+ biomass (mt)	Spawning biomass (mt)	Depletion
2009	2,499	2,433	7,151	2,938	11.6%
2010	2,499	2,393	6,776	2,400	9.5%
2011	535	0	6,468	2,171	8.6%
2012	802	311	8,646	3,427	13.5%
2013	1,068	680	10,680	4,712	18.6%
2014	1,301	997	12,358	5,843	23.1%
2015	1,489	1,311	13,675	6,778	26.8%
2016	1,631	1,489	14,678	7,503	29.6%
2017	1,735	1,621	15,437	8,037	31.7%
2018	1,812	1,718	16,022	8,431	33.3%
2019	1,870	1,794	16,482	8,740	34.5%
2020	1,917	1,838	16,850	8,991	35.5%

Decision table

Relative probabilities of each state of nature are based on the 2009 estimate of spawning biomass. Landings in 2009–2010 are 2,433 and 2,393 mt for all cases. Selectivity and fleet allocations are projected based on 2008 values.

Table g. Decision table of 12-year projections for alternate states of nature (columns) and management options (rows) beginning in 2011. There are two values for depletion, the first calculates depetion using the SB40% Bmsy proxy and the second calculates depletion relative to the model estimate of Bmsy. Relative probabilities of each state of nature are based on identifying low and high values from the model-estimated distribution of 2009 spawning biomass, those high and low values for 2009 were achieved through changing the size of the 2008 NWFSC survey biomass. Landings in 2009–2010 are 2433 mt

Research and data needs

Progress on a number of research topics and data issues would substantially improve the ability of this assessment to reliably and precisely model petrale sole population dynamics in the future:

1. The estimate of the NWFSC survey catchability in the base case model is higher than expected. This may be due to the use of the total area within each strata during the expansion of the survey data rather than the trawlable areas only. At this time there are no area estimates for trawlable and untrawlable areas. However the petrale sole population is most likely well surveyed by the trawl survey and expanding using areas that include untrawlable areas may not be appropriate.
2. In the past many assessments have derived historical catches independently. Since 2005 each of the states has undertaken comprehensive historical catch reconstructions. At the time of this assessment only a partial reconstruction was available for Washington, and no catch reconstruction was available from Oregon Department of Fish and Wildlife. Completion of the Washington and Oregon catch reconstructions would provide the best possible estimated catch series that accounts for all the catch and makes sense for flatfish as a group.
3. Due to limited data, new studies on both the maturity and fecundity relationships for petrale sole would be beneficial.
4. Increased collection of commercial fishery age data from California would help reduce uncertainty. No recent age data are available from the California fleet. However, the greatest landings by state have come from California in the most recent two years. Without age data, the ability to estimate year-class strength and the extent of variation in recruitment is compromised.
5. The comparability of ages between agencies is unknown. A common set of otoliths should be aged by each agency to be able to compile between agency age error information.
6. Where possible historicalotoliths should be re-aged using the break-and-burn method.
7. Effect of fishery regulations. The impacts of trip-limits and other management approaches, such as closed areas, on discards and fishery selectivity requires further study.
8. Studies on stock structure and movement of petrale sole, particularly with regard to the winter-summer spawning migration of petrale sole.
9. Continue and if possible increase the recent collection of length compositions for discarded petrale sole for both the winter (Nov–Feb) and summer (Mar–Oct) fisheries.

Table h. Summary of recent trends in estimated petrale sole exploitation and stock levels from the base case model; all values reported at the beginning of the fishing year.

1. Introduction

1.1 Distribution and Stock Structure

Petrale sole (*Eopsetta jordani*) is a right-eyed flounder in the family Pleuronectidae ranging from the western Gulf of Alaska to the Coronado Islands, northern Baja California, (Hart 1973; Kramer et al. 1995; Love et al. 2005) with a preference for sand and mud bottoms at depths ranging from 0-550m (Love et al. 2005). Common names include brill, California sole, Jordan's flounder, cape sole, round nose sole, English sole, soglia, petorau, nameta, and tsubame garei (Smith 1937; Hart 1973; Gates and Frey 1974; Love 1996; Eschmeyer and Herald 1983). In northern and central California petrale sole are dominant on the middle and outer continental shelf (Allen et al. 2006). PacFIN fishery logbook data show that adults are caught in depths from 18 to 1,280 m off the U.S. west coast with a majority of the catches of petrale sole being taken between 70–220 m during March through October, and between 290–440 m during November through February.

There is little information regarding the stock structure of petrale sole off the U.S. Pacific coast. No genetic research has been undertaken for petrale sole and there is no other published research indicating separate stocks of petrale sole within U.S. waters. Tagging studies show adult petrale sole can move up 350 - 390 miles, having the ability to be highly migratory with the possibility for homing ability (Alverson 1957; MBC Appl. Environ. Sci. 1987). Juveniles show little coast-wide or bathymetric movement while some studies suggest that adults generally move inshore and northward onto the continental shelf during the spring and summer to feeding grounds and offshore and southward during the fall and winter to deep water spawning grounds (Hart 1973; MBC Appl. Environ. Sci. 1987; Horton 1989; Love 1996). Adult petrale sole can tolerate a wide range of bottom temperatures (Perry et al., 1994).

Tagging studies indicate limited mixing of adults between different spawning groups. DiDonato and Pasquale (1970) reported that five fish tagged on the Willapa Deep grounds during the spawning season were recaptured during subsequent spawning seasons at other deepwater spawning grounds, as far south as Eureka (northern California) and the Umpqua River (southern Oregon). However, Pederson (1975) reported that most of the fish (97%) recaptured from spawning grounds in winter were originally caught and tagged on those same grounds.

Mixing of fish from multiple deep water spawning grounds likely occurs during the spring and summer when petrale sole are feeding on the continental shelf. Fish that were captured, tagged, and released off the northwest coast of Washington during May and September were subsequently recaptured during winter from spawning grounds off Vancouver Island (British Columbia, 1 fish), Heceta Bank (central Oregon, 2 fish), Eureka (northern California, 2 fish), and Halfmoon Bay (central California, 2 fish) (Pederson, 1975). Fish tagged south of Fort Bragg (central California) during July 1964 were later recaptured off Oregon (11 fish), Washington (6 fish), and Swiftsure Bank (southwestern tip of Vancouver Island, 1 fish) (D. Thomas, California Department of Fish and Game, Menlo Park, CA, cited by Sampson and Lee, 1999).

Off British Columbia, the highest densities of spawning adults, as well as of eggs, larvae and juveniles, are found in the waters around Vancouver Island. Adults may utilize nearshore areas as summer feeding grounds and non-migrating adults may stay there during winter (Starr and Fargo, 2004).

Past assessments completed by Demory (1984), Turnock et al. (1993), and Sampson and Lee (1999) considered petrale sole in the Columbia and U.S. Vancouver INPFC areas a single stock. Sampson and Lee (1999) assumed that petrale sole in the Eureka and Monterey INPFC areas represented two additional distinct socks. The most recent 2005 petrale sole assessment assumed two stocks, northern (U.S. Vancouver and Columbia INPFC areas) and southern (Eureka, Monterey and Conception INPFC areas), to maintain continuity with previous assessments. Three stocks (west coast Vancouver Island, Queen Charlotte Sound, and Heceta Strait) are considered for petrale sole in the waters off British Columbia, Canada (Starr and Fargo, 2004). This assessment integrates the previously separate north-south assessments, providing a status evaluation through 2008. The decision to conduct a single-area assessment is based on strong evidence of a mixed stock from tagging studies, a lack of genetic studies on stock structure, and due to the fact that the limited evidence for differences in growth between the 2005 northern and southern assessment area are confounded with differences in data collection between Washington, Oregon, and California.

Fishing fleets are separated both geographically and seasonally to account for spatial and seasonal patterns in catch given the coast-wide assessment area. The petrale sole fisheries possess a distinct seasonality, with catches peaking during the winter months, so the fisheries are divided into winter (November-February) and summer (March-October) fisheries (Figure 1). Note that the "fishing year" for this assessment (November 1 to October 31) differs from the standard calendar year. The U.S.-Canadian border is the northern boundary for the assessed stock, although the basis for this choice appears to be largely due to current management needs. Given the lack of clear information regarding the status of distinct biological populations, this assessment treats the U.S. petrale sole resource from the Mexican border to the Canadian border as a single coast-wide stock.

1.2 Life history and ecosystem interactions

Petrale sole spawn during the winter at several discrete deepwater sites (270-460 m) off the U.S. west coast, from November to April, with peak spawning taking place from December to February (Harry 1959; Best 1960; Gregory and Jow 1976; Castillo et al. 1993; Carison and Miller 1982; Reilly et al. 1994; Castillo 1995; Love 1996; Moser 1996a; Casillas et al. 1998). Females spawn once each year and fecundity varies with fish size, with one large female laying as many as 1.5 million eggs (Porter, 1964). Petrale sole eggs are planktonic, ranging in size from 1.2 to 1.3 mm, and are found in deep water habitats at water temperatures of 4–10^{o}C and salinities of 25–30 ppt (Best 1960; Ketchen and Forrester, 1966; Alderdice and Forrester 1971; Gregory and Jow 1976). The duration of the egg stage can range from approximately 6 to 14 days (Alderdice and Forrester 1971; Hart 1973; Love 1996, Casillas et al. 1998). The most favorable conditions for egg incubation and larval growth are 6–7^{o}C and 27.5–29.5 ppt (Ketchen and Forrester, 1966; Alderice and Forrester, 1971; Castillo et al., 1995). Predators of petrale sole eggs include planktonic invertebrates and pelagic fishes (Casillas et al. 1998).

Petrale sole larvae are planktonic, ranging in size from approximately 3 to 20 mm, and are found up to 150 km offshore foraging upon copepod eggs and nauplii (Hart 1973; Moser 1996a; MBS Appl. Env. Sci 198; Casillas et al. 1998). The larval duration, including the egg stage, spans approximately 6 months with larvae settling at about 2.2cm in length on the inner continental shelf (Pearcy 1977). Juveniles are benthic and found on sandy or sand-mud bottoms (Eschmeyer and Herald 1983; MBS Appl. Environ. Sci. 1987) and range in size from approximately 2.2 cm to the size at maturity, 50% of the population is mature at approximately 38 cm and 41 cm for males and females, respectively (Casillas et al. 1998). No specific areas have been identified as nursery grounds for juvenile petrale sole. In the waters off British Columbia, Canada larvae are usually found in the upper 50 m far offshore, juveniles at 19–82 m and large juveniles at 25–125 m (Starr and Fargo 2004). Juveniles are carnivorous, foraging on annelid worms, clams, brittle star, mysids, scuplin, amphipods, and other juvenile flatfish (Ford 1965; Casillas et al. 1998; Pearsall and Fargo In prep. (see Starr and Fargo 2004). Predators on juvenile petrale sole include adult petrale sole as well as other larger fish (Ford 1965; Casillas et al. 1998) while adults are preyed upon by marine mammals, sharks, and larger fishes (Trumble 1995; Love 1996; Casillas et al. 1998).

One of the ambushing flatfishes, adult petrale sole have diverse diets which become more piscivourous at larger sizes (Allen et al. 2006). Adult petrale sole are found on sandy and sand-mud bottoms (Eschmeyer and Herald 1983) foraging for a variety of invertebrates including, crab, octopi, squid, euphausiids, and shrimp, as well as anchovies. hake, herring, sand lance, and other smaller rockfish and flatfish (Ford 1965; Hart 1973; Kravitz et al. 1977; Birtwell et al. 1984; Reilly et al. 1994; Love 1996; Pearsall and Fargo In prep.). In Canadian waters evidence suggests that petrale sole tend to prefer herring (Pearsall and Fargo In prep.). On the continental shelf petrale sole generally co-occur with English sole, rex sole, Pacific sand dab, and rock sole (Kravitz et al. 1977). Adult petrale sole achieve a maximum size of around 50 cm and 63 cm for males and females, respectively (Best 1963; Pedersen 1975). The maximum length reported for petrale sole is 70 cm (Hart 1973; Eschmeyer and Herald 1983; Love et al. 2005) while the maximum observed break and burn age is 31 years (Haltuch et al. In prep.).

Ecosystem factors have not been explicitly modeled in this assessment, but there are several important aspects of the California current ecosystem that may impact petrale sole population dynamics. Castillo (1992) and Castillo et al. (1995) suggest that density-independent survival of early life stages is low and show that offshore Ekman transportation of eggs and larvae may be an important source of variation in year-class strength in the Columbia INPFC area. The effects of the Pacific Decadal Oscillation (PDO) on California current temperature and productivity (Mantua et al. 1997) may also contribute to non-stationary dynamics for petrale sole. The prevalence of a strong 1999 year-class for many west coast groundfish species suggest that environmentally driven recruitment variation may be correlated among species with relatively diverse life-history strategies. Although current research efforts along these lines are limited, a more explicit exploration of ecosystem processes may be possible in future petrale sole stock assessments.

1.3 Historical and Current Fishery

Petrale sole have been caught in the flatfish fishery off the U.S. Pacific coast since the late 19th century. The fishery first developed off California where, prior to 1876, fishing in San Francisco Bay was by hand or using set lines and beach seining (Scofield 1948). By 1880 two San Francisco based trawler companies were running a total of six boats, extending the fishing grounds beyond the Golden Gate Bridge northward to Point Reyes (Scofield 1948). Steam trawlers entered the fishery in 1888 and in 1889 four steam tugs based out of San Francisco were sufficient to flood market with flatfish (Scofield 1948). By 1915 San Francisco and Santa Cruz trawlers were operating at depths of about 45–100 m with daily catches averaging 10,000 lbs per tow or 3,000 lbs per hour (Scofield 1948). Flatfish comprised approximately 90% of the catch with 20–25% being discarded as unmarketable (Scofield 1948). In 1915 laws prohibited dragging in California waters and declared it illegal to possess a trawl net from Santa Barbara County southward (Scofield 1948). By 1934 twenty 56–72 foot diesel engine trawlers operated out of San Francisco fishing between about 55 and 185 m (Scofield 1948). From 1944-1947 the number of California trawlers fluctuated between 16 to 46 boats (Scofield 1948). Although the flatfish fishery in California was well developed by the 1950s and 1960s catch statistics were not reported until 1970 (Heimann and Carlisle 1970). In this early California report petrale sole landings during 1916 to 1930 were not separated from the total flatfish landings. During 1931–68, the landings of petrale sole averaged about 700 mt annually.

The earliest trawl fishing off Oregon began in 1884-1885, but the fishery did not become established until 1937, with the fishery increasing rapidly during WWII (Harry and Morgan, 1961). Initially trawlers stayed close to the fishing grounds adjacent to Newport and Astoria, operating at about 35–90 m between Stonewall Bank and Depoe Bay. Fishing operations gradually extended into deep water. For example, Newport-based trawlers were commonly fishing at about 185 m in 1949, at about 185–365 m by 1952, and at about 550 fm by 1953.

Alverson and Chatwin (1957) describe the history of the petrale sole fishery off of Washington and British Columbia with fishing grounds ranging from Cape Flattery to Destruction Island. Petrale catches off of Washington were small until the late 1930s with the fishery extending to about 365 m following the development of deepwater rockfish fisheries in 1950s.

By the 1950s the petrale sole fishery was showing signs of depletion with reports suggesting that petrale sole abundance had declined by at least 50% during 1942 to 1947 (Harry 1956). Sampson and Lee (1999) reported that three fishery regulations were implemented during 1957–67: 1) a winter closure off Oregon, Washington and British Columbia, 2) a 3,000 lb per trip limit, and 3) no more than two trips per month during 1957. With the 1977 enactment of the Magnuson Fishery Conservation and Management Act (MFCMA) the large foreign-dominated fishery that had developed since the late 1960s was replaced by the domestic fishery that continues today. Petrale sole are harvested almost exclusively by bottom trawls in the U.S. west coast groundfish fishery. Recent petrale sole catches exhibit marked seasonal variation, with substantial portions of the annual harvest taken from the spawning grounds during December and January. Evidence suggests that the winter fishery on the deepwater spawning grounds developed sporadically during the 1950s and 1960s as fishers discovered new locations (e.g., Alverson and Chatwin, 1957; Ketchen and Forrester, 1966). Both historical and current petrale sole fisheries have primarily relied upon trawl fleets.

Lai et al. (2005) reconstructed the historical U.S. petrale sole landings from 1876 to 2004 from a variety of sources. Subsequently California has completed a comprehensive catch reconstruction that shows peak catches occurred during the late 1940s and 1950s. Off of Washington and Oregon peak catches occurred during the 1940s and 1950s followed by declines and remained at historical lows until the mid-2000s. (Table 1, Figure 1). Total reconstructed historical catches from 1876 to 2008 peaked at a high of 4515 mt in 1950 followed by a decline to a low of 1417 mt in 1994 (Table 1, Figure 1).

1.4 Management History and performance

Beginning in 1983 the Pacific Fishery Management Council (PFMC) established coast-wide Acceptable Biological Catch (ABC) limits for the annual harvests of petrale sole in the waters off the US west coast (see, for example, PFMC, 2002). Previous assessments of petrale sole in the U.S. Vancouver and Columbia INPFC areas have been conducted by Demory (1984), Turnock et al. (1993), Sampson and Lee (1999), and Lai at al. (2005) (Figure 2). Based on the 1999 assessment a coastwide ABC of 2762 mt was specified and remained unchanged between 2001 and 2006 (Table 2).

The most recent 2005 assessment of petrale sole stock assessment split the stock into two areas, the northern area that included U.S. Vancouver and Columbia INPFC areas and the southern area that included the Eureka, Monterey and Conception INPFC areas (Lai et al. 2006) (Figure 2). While petrale sole stock structure is not well understood data on growth, CPUE, and geographical differences between states were used to support the use of two separate assessment areas. In 2005 petrale sole were estimated to be at 34 and 29 percent of unfished spawning stock biomass in the northern and southern areas, respectively. In spite of different models and data biomass trends were qualitatively similar in both areas, providing evidence for a coast wide stock. Based on the 2005 stock assessment ABCs were set at 3025 mt and 2919 mt for 2007 and 2008, respectively, with an OY of 2499 mt for both years (Table 2). Recent coast-wide annual landings have not exceeded the ABC except for 2005 when the ABC was exceeded by 4 mt (PFMC 2006) (Table 2).

The 2005 stock assessment estimated that petrale sole had been below the Pacific Council's minimum stock size threshold of 25 percent of unfished biomass from the mid-1970s until recently with estimated harvest rates in excess of the target fishing mortality rate of F40%. In comparison to the 1999 assessment of petrale sole, the 2005 assessment represented a significant change in the perception of petrale sole stock status. The stock assessment conducted in 1999 (Washington-Oregon only) estimated the spawning stock biomass in 1998 at 39 percent of unfished stock biomass. The 2005 assessment estimated the spawning stock biomass in 1998 at a similar size as the 1999 assessment but the estimate of unfished biomass increased resulting in the estimate of current stock size at 12 percent of unfished stock biomass. The change in status between the 1999 and 2005 analysis was due to the use of the complete reconstructed catch history in the 2005 stock assessment. The 1999 stock assessment used a catch history that started in 1977, after the bulk of the removals from the fishery had already taken place. Thus the 1999 stock assessment produced a more optimistic view of the petrale stock.

The most recent 2005 petrale sole stock assessment determined that the stock was in the precautionary zone and was not overfished (i.e. the spawning stock biomass (SB) was not below 25% of the unfished spawning stock biomass (SB_0)). The fishery for petrale sole (and groundfish in general) has been altered substantially by changes in fishery regulations implemented since 1998. Specifically, the PFMC implemented 2-month cumulative vessel limits to reduce discards in 1996. Beginning in 2000, restrictions were placed on the use of large footropes (more than 8”). Large footrope gear has been prohibited from the waters inside of 275 m (150 fm) following the advent of rockfish conservation areas delineated by depth-based management lines. Although the January and February months of the winter petrale sole fishery have not been subject to vessel landing limits until recently, the 2-month limits have restricted petrale sole landings from March through October, and more recently during November and December. The areas in which the winter petrale sole fishery has been allowed to operate have also been restricted by actions designed to reduce bycatch of slope rockfish.

Area closures have been used by the PFMC for groundfish management since 2001. Current area closures are: i) the Cowcod Conservation Area (CCA): agreed upon in 2000 and implemented in 2001; ii) the Yelloweye Rockfish Conservation Area (YRCA): agreed upon in 2002 and implemented in 2003; and iii) the Rockfish Conservation Areas (RCAs) for several rockfish species: agreed upon in 2002, implemented as an emergency regulation during fall of 2002 and through regulatory amendment in 2003. Since then, RCAs have been specified continuously for regions north and south of 40^{o}10’N latitude for trawl and fixed-gear groups (Figure 2). The boundaries of the RCAs are delineated by depth-based management lines, and may be changed throughout the year in an effort to achieve fishery management objectives. The area between 180 m and 275 m has been continuously closed to most all bottom groundfish trawling since the implementation of the RCAs.

Vessels with exempt fishing permits (EFPs) issued under 50 CFR part 600 are allowed to operate in some conservation areas. Oregon EFP (Experimental Fishing Plan) vessels were allowed to fish in the RCA using more selective trawl gear from February–October during 2003 and 2004. Beginning in 2005, the modified “selective flatfish” trawl gear has been required shoreward of the RCA, north of 40^{o}10’N latitude. This gear was found to reduce the catch-per-unit-effort of overfished rockfish relative to standard commercial gear in pilot experiments (King et al. 2004). The ABC/OYs for several species under Rebuilding Plans have resulted in limited harvests of other groundfishes in recent years.

Port sampling conducted by each state routinely sample market categories to determine the species composition of these mixed-species categories. Since 1967, various port sampling programs have been utilized by state and federal marine fishery agencies to determine the species compositions of the commercial groundfish landings off the U.S. Pacific coast (Sampson and Crone 1997). Current port sampling programs use stratified multistage sampling designs to evaluate the species compositions of the total landings in each market category, as well as for obtaining biological data on individual species (Crone 1995, Sampson and Crone 1997).

1.5 Fisheries in Canada and Alaska

Landings of petrale sole in the Canadian fishery had decreased substantially by the mid-1960s after the largest removals during the late 1940s to late 1950s (Starr and Fargo 2004). By the 1970s, analysis conducted by Pederson (1975) suggested that petrale abundance was low, primarily due to environmental factors, and abundance remained low into the 1990s. As of 2005 petrale sole off of British Columbia were treated as three "stocks" and were considered to be at low levels. Winter quarter landings of petrale sole were limited to 44,000 lb per trip during 1985–91; to 10,000 lb per trip during 1991–95; and to 2,000 lb per trip in 1996. Since 1996, the British Columbia trawl fishers have been limited to incidental harvests only (Fargo, 1997). The recent assessments for the Canadian stocks have been based on catch histories and limited biological data.

The most recent assessment of petrale sole in British Columbia uses a single area combined sex delay-difference stock assessment model with knife edge recruitment (at 6 or 7 years old) and tuned to fishery CPUE, mean fish weight of the commercial landings, and a number of fishery independent surveys beginning in the early 1980s (pers. comm., P. Starr). Stock predictions are based on average recruitment (pers. comm., P. Starr). This assessment suggests that the stock is currently above the target reference point and that there is some evidence for above average recruitment (about 10% above average) since about 1996 (pers. comm., P. Starr). Petrale sole in Canadian waters appear to have similar life-history characteristics (Starr and Fargo 2004).

In Alaska petrale sole are not targeted in the Bering Sea/Aleutian Island fisheries and are treated as a minor species in the "other flatfish" management complex.

2. Assessment

The following sources of data were used in building this assessment:

1) Fishery independent data including bottom trawl survey-based indices of abundance and biological data (age and length) from 2003-2008 (NWFSC survey) and 1980-2004 (Triennial survey)
2) Estimates of fecundity, maturity, length-weight relationships and ageing error from various sources
3) Commercial landings from 1876-2008
4) Estimates of the length frequencies, mean weight, and total biomass discarded in the fishery obtained from the West Coast Groundfish Observer Program (WCGOP) and the study by Pikitch et al (1988).
5) Fishery CPUE (Oregon, 1987-1998).

Data availability by source and year is presented in Table a-3b. A description of each of the specific data sources is presented below.

2.1 Fishery Independent Data

2.1.1 NWFSC trawl survey

Data from the NWFSC fishery-independent shelf and slope trawl survey has become available since the 2005 petrale sole stock assessment. Three sources of information are produced by this survey: an index of relative abundance, length-frequency distributions, and age-frequency distributions. Only years in which the NWFSC survey included the continental shelf are considered (2003-2006) since petrale sole are found on the continental shelf.

The NWFSC survey is based on a random-grid design; covering the coastal waters from a depth of 55 m to 1,280 m (Keller et al. 2007). This design uses four industry chartered vessels per year, assigned to a roughly equal number of randomly selected grid cells and is divided into two 'passes' of the coast which are executed from north to south. Two vessels fish during each pass, which have been conducted from late-May to early-October each year. This design therefore incorporates both vessel-to-vessel differences in catchability as well as variance associated with selecting a relatively small number (~700) of possible cells from a very large population of possible cells spread from the Mexican to the Canadian border. Much effort has been expended on appropriate analysis methods for this type of data, culminating in the west coast trawl survey workshop held in Seattle in November 2006 (see background materials).

The NWFSC survey commonly encounters petrale sole along the U.S. west coast, except south of Point Conception (Table 4, Figures 3-4). Figure 4 shows the density of petrale catch in the NWFSC survey. The survey did not fish shallower than 54 meters and no petrale sole were caught deeper than 537.5 meters in any year. Figure 5 shows that the percentage of positive tows and the catch rate over depth peak around 100 meters and decline as depth increases. Figure 5 also shows that the prevalence and density of petrale are generally higher in the northern latitudes.

Petrale sole are known to form winter spawning aggregations in deep water. It could therefore be expected that large-sized petrale sole would also appear more frequently in deep water. Figure 6 displays the mean fish length per tow of petrale sole against tow depth and shows that the mean length of females increases initially with depth and then levels out (even though the survey was conducted during the summer rather than winter). This trend of increasing size at depth is also apparent for male petrale sole. Given the ontogenetic shift of increasing size at depth, the 2005 assessment (Lai et al. 2005) re-stratified the survey data into three depth strata. We followed a similar approach and used piece-wise linear regression (Neter et al., 1985) of year- and sex-specific mean length and depth data to aid in choosing a depth stratum boundary (Appendix A). Based on this analysis the survey tows were stratified into three depth zones (54.864–100 m, 100–182.88 m and 182.88–548.64 m) for each INPFC area (Figure 2).

Two indices of abundance are available from this time series: a design-based estimator relying on the mean catch-per-unit-effort in each of several strata, and an index based on a Generalized Linear Mixed Model (GLMM) approach which was endorsed by the trawl survey workshop for use in west coast stock assessments. These two methods are based on fundamentally different approaches to interpreting the data. In the GLMM approach, vessel-specific differences in catchability (due to engine power, trawling experience of the skipper, etc.) are explicitly captured via inclusion of random effects. In contrast, the design-based estimator relies on the balance of the design (which may be difficult to assess, given that this balance must occur through random allocation of cells in quality habitat for the species of interest). Further, due to the presence of a large number of tows capturing none of a given species and a few tows showing very high catch rates, the design-based estimator may be very sensitive to one or a small number of very large tows. The GLMM approach explicitly models both the zero catches as well as allows for skewness in the distribution of catch rates through the use of a Gamma or lognormal error structure. These factors result in the GLMM approach being much more robust to a few large tows and likely more reflective of actual trends in population abundance.

When implementing the GLMM approach, it is recommended that there are at least three positive tows in each stratum/year combination. Since the Eureka Deep and Vancouver Deep strata had fewer than three observations in some years, the original stratification of five INPFC areas and three depth zones was collapsed. Because depth shows strong trends in catch rates and fish lengths, and catch rates are smaller in the Conception area, the five INPFC strata were collapsed into three areas by combining Vancouver with Columbia and Eureka with Monterey (Figure 2).

The biomass index based on both methods shows an increase up to the year 2005, peaking around 24 000 metric tons, followed by a steady decline to around 13 000 metric tons in 2008 (Table 5, Figure 7). The biomass by stratum, estimated from the GLMM, shows a decreasing trend in recent years for the middle and shallow depths (Figure 8).

Length bins from 12 to 62 cm in increments of 2 cm were used to summarize the length frequency of the survey catches in each year. Table 4 shows the number of lengths taken by the survey. The first bin includes all observations less than 14 cm and the last bin includes all fish larger than 62 cm. The length frequency distributions for the NWFSC survey from 2003-2008 generally show a strong cohort growing through 2005 and smaller fish in 2007 and 2008 (Figure 9). Age-frequency data from the NWFSC survey (Figure 10) were included in the model as conditional age-at-length distributions by sex and year. Individual length- and age-observations can be thought of as entries in an age-length key (matrix), with age across the columns and length down the rows. The approach consists of tabulating the sums within rows as the standard length-frequency distribution and, instead of also tabulating the sums to the age margin, instead the distribution of ages in each row of the age-length key is treated as a separate observation, conditioned on the row (length) from which it came. This approach has several benefits for analysis above the standard use of marginal age compositions. First, age structures are generally collected as a subset of the fish that have been measured. If the ages are to be used to create an external age-length key to transform the lengths to ages, then the uncertainty due to sampling and missing data in the key are not included in the resulting age-compositions used in the stock assessment. If the marginal age compositions are used with the length compositions in the assessment, the information content on sex-ratio and year class strength is largely double-counted as the same fish are contributing to likelihood components that are assumed to be independent. Using conditional age-distributions for each length bin allows only the additional information provided by the limited age data (relative to the generally far more numerous length observations) to be captured, without creating a ‘double-counting’ of the data in the total likelihood. The second major benefit of using conditional age-composition observations is that in addition to being able to estimate the basic growth parameters (L_{minAge}, L_{maxAge}, K) inside the assessment model, the distribution of lengths at a given age, governed by two parameters for the standard deviation of length at a young age and the standard deviation at an older age, are also quite reliably estimated. This information could only be derived from marginal age-composition observations where very strong and well-separated cohorts existed and where they were quite accurately aged and measured; rare conditions at best. By fully estimating the growth specifications within the stock assessment model, this major source of uncertainty is included in the assessment results, and bias due to size-based selectivity is avoided. Therefore, to retain objective weighting of the length and age data, and to fully include the uncertainty in growth parameters (and avoid potential bias due to external estimation where size-based selectivity is operating) conditional age-at-length compositions were developed using the NWFSC trawl survey age data.

Age distributions included bins from age 1 to age 17, with the last bin including all fish of greater age (Figure 9). Approximately 4,738 fish were sampled for age from more than 74% of the tows containing petrale sole, compared to 21,348 fish sampled for length (Table 4). These data show the growth trajectory of females reaching a maximum size near 56 cm and males reaching a maximum size of about 41 cm (Figure 11).

It is often useful to compute the marginal age-compositions to allow for easier visual tracking of strong cohorts (although this information is still imparted to the model using conditional age-at-length observations, it is harder to visualize) and offer a more familiar summary view of the data. The NWFSC age distributions show what is probably the strong 97-98 cohort ageing from years 2003 to 2007, with younger fish appearing in 2008 (Figure 10). The exception to this is the female composition in 2005, where only one female fish aged from the tow with the largest catch rate. The expansion of numbers to tow can greatly affect the marginal age distribution, but does not have as much affect on the conditional age-at-length data. This time series is short, and does not encompass the period when substantial reductions in the petrale sole population occurred, and so may be relatively uninformative in the assessment model, except for estimation of growth parameters.

2.1.2 Triennial trawl survey

The triennial shelf trawl survey conducted by NMFS starting in 1977 is the second source of fishery-independent data regarding the abundance of petrale sole (Dark and Wilkins 1994). The sampling methods used in the survey over the 21-year period are most recently described in Weinberg et al. (2002); the basic design was a series of equally spaced transects from which searches for tows in a specific depth range were initiated (Figure 12). In general, all of the surveys were conducted in the mid-summer through early fall: the survey in 1977 was conducted from early July through late September; the surveys from 1980 through 1989 ran from mid-July to late September; the survey in 1992 spanned from mid-July through early October; the survey in 1995 was conducted from early June to late August; the 1998 survey ran from early June through early August; and the 2001, 2004 surveys were conducted in May-July (Figure 13). Haul depths ranged from 91–457 m during the 1977 survey with no hauls shallower than 91 m. In all subsequent years the survey sampled depths from 55–366 m. Given the different depths surveyed during 1977 the results from the 1977 survey are not included in this assessment. Water hauls (Zimmermann et al., 2003) and tows located in Canadian and Mexican waters were also excluded for the analyses of this assessment. Also, the Conception area was removed from the analysis since it was not surveyed in the early years.

Similarly to the NWFSC trawl survey, petrale sole were encountered throughout the West Coast (Table 6, Figure 14). Larger catch rates were observed around depths of 100 m but no trend in catch rate was apparent over latitude, other than low catch rates in the Conception INPFC area which was only partially sampled (Figure 15). An analysis of the mean length by depth also showed evidence of an ontogenetic movement of petrale to deeper water (Figure 16) and the same depth stratification was used for the triennial survey (54.864–100 m, 100–182.88 m and 182.88–548.64 m).

Two indices of abundance are available from the Triennial trawl survey, one each from a design-based and a general linear mixed model (GLMM) based estimator. For the design-based approach, the catch-per-unit-effort (CPUE) index was created from the swept-area estimates of biomass (Gunderson and Sample 1980) using INPFC and depth as strata. To provide an adequate number of positive tows in the GLMM analysis, the two deeper strata were combined as well as the Monterey and Eureka INPFC areas and the Columbia and Vancouver INPFC areas. The estimated total biomass by stratum for each survey index is given in Table 5 and Figure 17. Both methods show a general increase in biomass from 1992 onwards and a very large increase in 2004.

Size distributions (fork length in cm) were calculated following the same procedures as the NWFSC survey. The numbers of fish and number of hauls represented in each year of the survey are presented in Table 6. The length frequency distributions generally show little trend, although there is evidence of small fish in 1992 and large fish in 2004 (Figure 18).

There are no petrale sole age data for the Triennial survey.

2.1.3 Other fishery independent data

A series of trawl surveys was conducted by the ODFW during 1971–74, the data from which are stored in the survey database at the Alaska Fishery Science Center (RACEBASE). However, the data from these surveys are not included in the assessment owing to their very limited temporal and spatial coverage.

2.2 Biological Data

The following section outlines a number of biological parameters estimated outside the assessment model from a variety of data sources.

2.2.1 Weight-Length

The weight-length relationship is based on the standard power function: $W = a\ (L^b)$ where W is weight in grams and L is length in centimeters. The parameters used are those used in both the 1999 and 2005 assessments (Sampson and Lee 1999; Lai et al. 2005). These assessments used length and weight data from ODFW (1971–86), WDFW market samples, and the ODFW flatfish surveys (1971–72; Demory et al., 1976) to estimate the following length-weight relationships for males, $W = 0.007168L^{3.1337}$, and females, $W = 0.003416L^{3.3462}$ (Figure 19). No new length and weight data have been collected since the mid-1980s so these length-weight relationships represent the most current information for west coast petrale sole. The previous analysis of the length-weight data did not show any temporal trends however it would be preferable to have more recent data.

More recent length weight parameters estimated for the British Columbia petrale sole suggest that petrale sole in British Columbia generally weigh less at a given size than petrale sole of the U.S. west coast (Starr and Fargo 2004).

2.2.2 Maturity and fecundity

Petrale sole maturity-at-length information is generally sparse in space and time, has not been collected in a systematic fashion across time, is of varying quality, and does not always agree between studies. It is possible that maturity may have changed over time. However, it is not possible to assess this quantitatively owing to differences in when historical samples on which maturity ogives could be based were taken, and how maturity stage (visual vs. histological) was determined. The 2005 petrale sole assessment used the most recent study for the west coast of the U.S. that was based on observations collected during 2002 from Oregon and Washington (Hannah et al. 2002). The maturity observations were fitted to a logistic model: $p_l - \frac{e^{B_0+B_l^1}}{1+e^{B_0+B_l^1}}$ where p_l is the proportion of natural fish at length *l*, and B_0 and B_1 are the regression coefficients. Parameter estimates from the Hannah et al. (2002) are: β_0= -24.593, β_1=0.743. The length at 50% maturity for females is 33.1 cm (Figure 19).

2.2.3 Natural Mortality

The instantaneous rate of natural mortality for a wild fish population is notoriously difficult to estimate. One accepted method is to examine the age distribution of an unexploited or lightly exploited stock. This method cannot readily be applied to petrale sole given the long history of exploitation off the US West Coast. Ketchen and Forrester (1966) estimated that the natural mortality coefficients were 0.18–0.26 yr^{-1} for males and 0.19–0.21 yr^{-1} for females based on a catch curve analysis of relatively early (1943–45) Washington trawl data from Swiftsure Bank, off the southwest corner of Vancouver Island. Starr and Fargo (2004) estimated the instantaneous rate of natural mortality (*M*) using Hoenig's method (Hoenig 1983): $\ln(M) = 1.44 - 0.984\ln(t_{\max})$ where *M* is natural mortality and t_{max} is the maximum age of petrale sole. *M* Values of 0.22 and 0.15 were estimated given maximum ages of 20 and 30 years, respectively. An archived set of commercial samples collected between the late 1950s and early 1980s from Northern California recently found that multiple samples were aged between 20-31 years old suggesting a similar range of M values for U.S. west coast petrale sole encompass a similar range. Past and current British Columbia and U.S. stock assessments assumed a value of *M* = 0.2 for both sexes.

2.2.4 Length at age

Sager and Summler (1982) summarize the growth of petrale sole in length using several growth functions. Female petrale sole can grow to 70 cm total length, with males being smaller. Petrale sole can live to at least 30 yrs, although more recent data show that few are aged to be older than 17 yrs. This information on growth is subject to error for two reasons: 1) growth determination is difficult because two ageing techniques (otolith surface and break-and-burn) were used in the past, and 2) the observed lengths of young fish may be positively biased due to gear selectivity. Pederson (1975) estimated growth parameters for several locations (see Table 6 of Turnock et al. (1993)). Sampson and Lee (1999) estimated the values of the parameters of the von Bertalanffy growth curve using data based on BB readings for petrale sole older than age 3, and ODFW survey observations (1970–74) for younger ages. In the 2005 stock assessment the mean-length-at-age data used to estimate parameters for the growth equation were obtained from the 2004 NMFS triennial survey. The empirical estimate of the CV of length at age in the 2004 survey, used in Lai et al. (2005), is 0.08, the same value that was used by Sampson and Lee (1999).

In the current, 2009 assessment, length at age was estimated inside the stock assessment model. Starting parameter values for the estimation were determined by fitting the von-Bertalanffy model ($L_i = L_\infty e^{(-k[t-t_0])}$) where L_i is length in cm at age *i*, *t* is age in years, *k* is the rate of increase in growth, t_0 is the intercept, and L_∞ is the maximum length to data from the 2003 - 2008 NWFSC survey (Figure 6).

2.2.5 Sex Ratios

Both the Triennial and NWFSC sex ratios for petrale sole are generally about 50% each males and females (Figure20). Canadian data from the most recent published stock assessment also suggests sex ratios of petrale sole in British Columbia are generally 50% males, 50% females (Starr and Fargo 2004).

2.2.6 Ageing Precision and Bias

Historically petrale sole have been aged using the otolith surface ageing technique by all three state agencies that provide age data (WA, OR, and CA). At some point during the 1980s the Oregon and Washington protocols for ageing petrale sole were: i) surface readings for all males, ii) surface readings for females up to age 10, and iii) BB readings for any females that appeared to be older than 10 years (Lai et al. 2005). However, age readers often failed to track gender, resulting the break and burn ages for males and females (Bob Hannah, ODFW, pers. comm.). Otoliths that were difficult to read and appeared older were also broken and burned, resulting in break and burn ages for fish younger than age 7 (Bob Hannah, ODFW, pers. comm.). The Cooperative Aging Project (between the Oregon and NMFS) formed in 1996 and started aging petrale sole for the 1999 stock assessment. During 1999, otolith samples collected by ODFW between 1981 and 1999 were aged by three different age readers in the Cooperative Ageing Lab (CAP) in Newport, Oregon using a combination of surface and break-and-burn (BB) techniques. The samples were not randomly distributed between age readers, that is, one reader aged all females, one reader aged primarily males (and some females), and one reader read both. Furthermore, while two of the age readers produced surface ages one age reader was using a 'combination' ageing method where otoliths that appeared to be younger than about 10 years were surface aged and those that appeared older were broken and burned. The multitude of problems with the age data for Oregon resulted in most of these data being removed from the 2005 northern area stock assessment during the STAR panel review (Lai et al. 2005). Oregon otoliths aged for the 2005 stock assessment were solely surface aged. The Washington Department of Fish and Wildlife (WDFW) continue to use the 'combination' ageing method for all commercial otolith samples.

An unpublished study in 1981–82 by W. Barss (ODFW, Newport) indicated that ages based on otolith surface readings are biased relative to ages based on break-and-burn readings for male petrale sole, with significant under-aging for males older than about 10 years. However, the same study suggested that ages based on surface and break-and-burn (BB) readings were similar for females. Turnock et al. (1993) reported differences between ages based on surface and break-and-burn readings for males and also argued that there was no apparent bias for females. This unpublished information informed the ageing error used in the 1993 and 1999 assessments (Turnock et al., 1993; Sampson and Lee, 1999). However, given the variety of ageing protocols for petrale sole the results from early ageing bias and precision studies need to be revisited.

More recent comparisons of surface and BB readings were conducted by the CAP laboratory as well as comparisons of the 'combination' and break and burn methods by the WDFW for the 2005 petrale sole stock assessment. Lai et al. (2005) concluded that CAP ages based on surface readings are younger than those based on BB readings, but the differences were not statistically significant. However, the results of the CAP study are not consistent with those from the WDFW data analyzed by Lai et al. (2005). Nevertheless, both data sets suggested that the differences in age estimates between the surface and break and burn techniques are smaller than implied by the ageing error matrix reported by Turnock et al. (1993). The September 2005 STAR Panel discussed the ageing error matrices used in the 2005 stock assessment and the implied ageing error coefficients of variation. It was concluded that the current ageing error matrices are not informative and should be used with caution because the ageing method is not standardized between agencies.

Oregon commercial samples from 2000 to 2004 and a limited number of the 2004 NWFSC survey otoliths were exclusively surface aged for the 2005 stock assessment. For the current assessment Oregon commercial samples from 2007-2008 and the 2003 and 2005-2008 NWFSC survey otoliths were aged using the break and burn method for most fish except those young fish for which they feel only need to be surface aged (generally age 0-3 year olds that are very clear) (pers comm. P. MacDonald). It is common procedure for the CAP lab to surface read young fish with clear otoliths, no matter the species. Otolith samples from the 2004 survey that were not aged for the 2005 assessment were aged using the surface read method to complete the age composition previously partially completed for the 2005 assessment.

In order to conduct a comprehensive estimation of ageing bias and imprecision this assessment has compiled and analyzed all of the available double-read data from the state of Oregon, the CAP, and the WDFW, as well as unpublished information from a bomb radiocarbon age validation study for petrale sole off the U.S. west coast (Table 7) (Haltuch et al. in prep). For the current analysis, all sources of ageing information were revisited both through inspection of the various cross- and double-read efforts as well as through simultaneous estimation of bias and imprecision for all studies in a rigorous statistical framework programmed in AD Model Builder (Otter Research Ltd. 2005) by A. Punt, University of Washington (Punt et al. 2008). This program estimates the underlying age distribution of a sample from up to four double- or cross-reads for each age structure, and can do this for multiple samples simultaneously. The most important assumption of the estimation technique is that at least one ageing method must be unbiased, so it is therefore not an age-validation. Functional forms can be explored for each method for both the bias (none, linear, type 2) and the imprecision (constant CV, or type 2 increase in CV with age). Because the technique requires that the underlying age structure of each sample be estimated, a reasonably large quantity of data spread over the entire range of ages present in the sample is needed (Punt et al. 2008). A few very old ages do not contribute appreciable information but require many more parameters in the underlying model and create instability during estimation. For this reason, each analysis must be truncated at a maximum age that is reasonably well represented in all samples.

Results from the bomb radiocarbon study shows that age reader #1 break and burn ages are unbiased (Figure 22). Therefore these ages are used as the unbiased 'radiocarbon' ages in the analysis. Sex information is available for some, but not all, of the double read samples. In order to increase the power of the analysis and reduce the total number of data sets in the analysis double-read samples are pooled over age reader and sex. It is important to compress the data down into the fewest number of data sets in each analysis because this reduces the number of age compositions that need to be estimated (these are essentially nuisance parameters). Table 7 shows the double-read data collected by agency and ageing method. Tables 8a-c shows the structure of the analysis as well as which estimates of ageing bias and imprecision are used in the stock assessment. Data sets with triple and quadruple reads were treated as double reads since the ageing error program handles multiple data sets with double read information better than data sets with triple reads. The model cannot deal with quadruple reads. Tables 9a-c show the different models fit to each data set as well as the likelihoods, the model with the best fit model is highlighted. A variety of models were explored for each dataset (Tables 9a-c). The analysis of the CAP data found that both the bias and standard deviation are linear for both the break and burn and surface read age methods (Table 9a). Linear bias and standard deviation were also chosen for the CAP combo method as the modeling found a strong trade off between fitting bias as a type 2 function and fitting the standard deviation as increasing with age (Table 9b). When the bias was modeled as nonlinear, the estimate of bias at older ages was unreasonably large and when the standard deviation was modeled as an increase in CV with age, the CV was unreasonable large (Table 9b). None of these models converged. The only model that fit the WDFW dataset found that the bias follows a type 2 function and that the standard deviation is linear (Table 9c).

Generally, all of the ageing methods applied to petrale sole are negatively biased (under ageing), particularly for older ages (Table 10, Figure 23). The CAP break-and-burn ages show the least bias, about 0.5 years. The CAP combo method is only slightly more biased (generally less that one year for ages less than 30) than the break-and-burn method, followed by the Oregon surface ages (1-2 years) (Table 10, Figure 23). The WDFW combination method was the most biased, over-ageing fish less than five years and under ageing fish older than 7 years by 1-2 years (Table 10, Figure 23). The estimated standard deviations for combo-age methods were largest, followed by the break-and-burn method, with the surface method being the least variable (Table 10, Figure 23).

2.2.7 Research removals

Catches of petrale sole for research purposes are very small in comparison to the trawl fishery catches and are therefore included in the total catches.

2.3 Fishery Dependent Data

2.3.1 Historical Catch Reconstruction

The 2005 stock assessment reconstructed the historical removals to more realistically reflect both the cumulative removals that have occurred from the coast-wide petrale sole population as well as to capture the variability during the time series (Lai et al. 2005). Recently new catch data have been provided by the NWFSC, CDFW and WDFW for some years previously reconstructed by Lai et al. (2005). These new catch data represent the best catch reconstructions available and are noted in the description of data sources (Table 1, Figure 1). See Appendix B for a comparison between the 2005 and 2009 catch histories. The catches used in this assessment begin in 1916 with the commercial landings data obtained from the following sources:

i) The PacFIN database (1981–2004);

ii) The Pacific Marine Fisheries Commission (PMFC) Data Series for 1956-1980 (PMFC, 1979) for Washington and Oregon. A comprehensive set of these data were not available for the 2005 stock assessment. The paper document was key punched after the 2007 round of assessments and is generally accepted as the best data currently available for catches during this period. The only exception to this is for the state of California, which has completed a comprehensive catch reconstruction for this period (pers comm. D. Pearson).

iii) State of California catch reconstruction extending from 1931-1980 (pers comm. D. Pearson). CDFG Fish Bulletins for 1916–1930 catches (Heimann and Carlisle, 1970) as reconstructed by Lai et al. (2005). The California fishery began in 1876 but no catch data are available from 1876-1915. Therefore a linear interpolation between catches of 1 ton in 1876 and the catches recorded for 1916 are used to filling this period. Lai et al. (2005) found that this early assumed increase in the petrale sole fishery did not impact the model;

iv) Oregon Fish Commission publications for 1943–1949 catches (Cleaver, 1951) and for 1950–1953 catches (Smith, 1956) as reconstructed by Lai et al. (2005);

v) WDFW catch reconstruction for 1935 (ref), 1939 and 1949– 1969 (pers. comm. T. Tsou and G. Lippert). These catches from WDFW are much larger than the catches used for Washington in the 2005 (Lai et al. 2005) stock assessment. Therefore catches for the early years that have not yet been reconstructed by WDFW are filled in by interpolating between the years with catch data;

Changes to the historical reconstruction from 1916 through 1980 are due to the digitizing of the Pacific Marine Fisheries Commission (PMFC) Data Series (PMFC, 1979) as well as the states individual efforts to provide better catch data. Catch data from 1981 – 2008 have been extracted from PacFIN as updates and corrections to the PacFIN database can cause small changes to this portion of the catch history. Monthly data are mostly unavailable for the early petrale fisheries. If monthly landings data were not available all landings are assumed to be from the summer fishery because it is likely that most of the fleets operating early in the development of the fishery did not fish in deep water during winter. All catches are compiled by the fishing year and use the PFMC regions. The Washington fleet includes catches from PSMFC areas 3A, 3B and 3S. The Oregon fleet includes catches from PSMFC areas 2A, 2B, and 2C. The California fleet includes catches from PSMFC areas 1A, 1B, and 1C.

Although they are not used in this assessment, the Canadian landings of petrale sole can be found in Starr and Fargo (2004).

2.3.2 Recent Landings (1981 to present)

Commercial landings estimates of petrale sole from 1981 to 2008 were generated from the PacFIN database (Extraction: March, 2009). Annual catches as used in the model are summarized by state in Table 1 and Figure 1. The landings of petrale sole by gear types other than groundfish-trawl have been inconsequential, averaging < 2% of the coastwide landings during 1981–89. The non-trawl landings are included in the trawl landings but the catches do not include discarded petrale sole (Table 11).

The post-World War II period witnessed a steady decline in the amount and proportion of annual catches occurring during the summer months (March-October). Conversely, petrale catch during the winter season (November–February), when the fishery targets spawning aggregations, has exhibited a steadily increasing trend since the 1940's. In the past few decades there has been a distinct seasonality in petrale sole landings that corresponds to the targeting of spawning aggregations during winter. Due to the seasonal harvesting pattern this assessment, similarly to previous assessments, separates the landings into two time periods: winter (November-February) and summer (March–October). The landings are divided into six fisheries (Table 3) based on the fleets from the states of Washington, Oregon, and California. The six fleets are Washington-Winter, Washington-Summer, Oregon-Winter, Oregon-Summer, California-Winter and California-Summer.

2.3.3 Discards

The catch statistics in Table 1 do not include discards. Prior to the 2001 implementation of the Northwest Fishery Science Center West Coast Groundfish Observer Program (NWFSC WCGOP) data on fishery discard for petrale sole was sparse and of mostly questionable quality. While several historical studies report discard estimates, in most cases the original data and estimation methods, which likely vary between studies, are not reported.

A limited 1950 study of Astoria, Oregon based trawlers estimated that 32.5% of the "number" of the petrale sole caught were discarded (Harry 1956). However, the details of the data collection as well as the original data are missing so this value is not used in the assessment. A 1977–81 study reported annual discard factors for the U.S Vancouver and Columbia INPFC areas (total catch weight / retained catch) that ranged from 1.1 to 1.4 with an average value of 1.21, or 17% by total catch weight was discarded (Demory 1984). However, Demory (1984) did not provide the data used to derive the discard factor, $f = 1 + Discard/Retained$, from which the discard rate is derived. Therefore the Demory measures of discard are not used. Scofield (1948) reported that 20–25% of the catches of sole in California were discarded during the 1940s and 1950s, but no specific date, data sources, or analyses were reported, so this value is not used in the assessment. Data collected by Pikitch et al. (1988) off the Oregon coast during 1986-1987 inform discard rates for the Oregon fisheries and were analyzed by Sampson and Lee (1999), producing a discard rate of 8.8%. These more recent Pikitch (1988) discard estimates are used as discard fraction in the Oregon fishery.

Discard observations for the trawl fleet from the WCGOP provide yearly discard rates and average weight of the discard based on at-sea observer data for 2002-2008 (2008 includes winter only, as summer data are not yet avaliable) (pers. comm. E. Heery) (Table 11, Figure 24). Recently the collection of length data for petrale sole has begun, providing length compositions of the discard for 2006-2007 and summer 2008 (Figures 25-27). These length compositions are used to estimate the retention curves for each of the fleets.

Several studies have reported retention curves for petrale sole. TenEyck and Demory (1975) reported that the age-at-50%-retention is 5.6 years for male petrale sole and 5.1 years for females, equivalent to a 30 cm length-at-50%-retention. Turnock et al. (1993) estimated a logistic length-retention curve using the unpublished data collected during a mesh-size study (Wallace et al., 1996), and reported that the length-at-50%-retention was 21.3 cm. Sampson and Lee (1999) estimated the length-at-50%-retention to be 28.6 cm for males and 29.5 cm for females, based on unpublished data from the discard study by Pikitch et al. (1988).

2.3.4 Foreign Catches

The impact of catches of petrale sole by foreign fishing fleets prior to the institution of the exclusive economic zone (EEZ) of the U.S. west coast are currently not quantified and remains an area for research.

2.3.5 Fishery Logbooks

Sampson and Lee (1999) used commercial logbook data from PacFIN to construct a delta GLM based standardized CPUE indices of abundance for the Oregon fleets from 1987-1997. This index was also used in the 2005 northern area stock assessment (Lai et al. 2005). The logbook data for the years prior to 1987 were not included because information on location is not available for these data. Beginning in 1998 the west coast groundfish fishery was impacted by a series of regulatory changes that make the generation of a standardized CPUE index in the stock assessment unreliable.

Lai et al. (2005) produced delta GLM-based indices of abundance for the 2005 southern area assessment using data filtered in a similar manner to Sampson and Lee (1999). However the southern area CPUE indices used more vessels that had been in the fishery a relatively short amount of time and extended the index to 2004, well beyond the time where regulatory changes began to restrict the groundfish fishery. These problems were noted during the 2005 STAR panel review.

This assessment uses only the CPUE indices of abundance from Sampson and Lee (1999) (Figure 28) for the reasons noted above. Additional indices for the winter fleets were not analyzed due to concerns regarding the potential for hyper-stability in winter catch rates due to the targeting of spawning aggregations. However plots of raw CPUE (lbs/hour) for all fleets were calculated for comparison with the fishery independent NWFSC survey index (Figure 29). The downturn in the NWFSC survey index (from the summer season) during the last three years is also apparent in the raw CPUE from the summer fisheries (Figure 29).

2.3.6 Fishery Biological Sampling

Commercial landings and the biological characteristics of these landings were not consistently sampled for scientific purposes until the mid-1950s. Statewide sampling of landed catches began in 1955 in Washington, 1966 in Oregon, and sporadically in 1948 in California. The first rigorous monitoring programs that included routine collection of biological data (e.g., sex, age, size, maturity, etc.) began in 1980. Currently, port biologists employed by each state fishery agency (California Department Fish and Game, Oregon Department of Fish and Wildlife - ODFW, and Washington Department of Fish and Wildlife - WDFW) collect species-composition information and biological data from the landed catches of commercial trawling vessels. The sampling sites are commonly processing facilities located at ports in California, Oregon and Washington. The monitoring programs currently in place vary between the states but are generally based on stratified, multistage sampling designs.

The PacFIN BDS database contains data from ODFW (1966–2008) and WDFW (1955–2008), but only 2001–2008 data from CDFG. The CDFG dataset for the years prior to 2000 was extracted and provided from CALCOM by Brenda Erwin (CDFG). Demory and Bailey (1967) provide length compositions for the Columbia INPFC area for 1949–51, 1960, and 1963–65. However no information is provided on the total size of the landings or sampling protocol, making it impossible to expand the raw length data. Therefore, the Demory and Bailey (1967) data are not used in the current assessment.

Commercial length-frequency distributions based on the fishing year were developed for each fleet for which observations were available, following the same bin structure as was used for research observations (Table 12). For each fleet, the raw observations (compiled from the PacFIN and CalCOM databases) were expanded to the sample level, to allow for any fish that were not measured, then to the trip level to account for the relative size of the landing from which the sample was obtained. The commercial composition data were summarized by PSMFC strata (Figure 2) since this is the finest resolution for which the data are available. The expanded length observations were then expanded by the catches in each PSMFC strata and combined within years for each fleet. Age frequencies were computed in the same manner. Length and age data collected from commercial landings for each fleet are summarized by the number of samples and the number of fish measured (Tables 12-13). Figures 30-35 show plots of the length and age composition data.

2.4 History of Modeling Approaches

2.4.1 Previous assessments

United States

Early stock assessments only assessed petrale sole in the combined U.S. Vancouver and Columbia INPFC areas, i.e. petrale in these areas were treated as a unit stock, using time series of data that began during the 1970s (Demory 1984, Turnock et al. 1993). The first assessment used stock reduction analysis and the second assessment used the length-based Stock Synthesis model (Methot 1989). The third petrale sole assessment utilized the hybrid length-and-age-based Stock Synthesis 1 model using data from 1977–1998 (Sampson and Lee 1999). During the 1999 stock assessment an attempt was made to include separate area assessments for the Eureka and

Monterey INPFC areas but acceptable models could not be configured due to a lack of data (Sampson and Lee 1999).

The previous, 2005, petrale sole assessment was conducted as two separate stocks, the northern stock encompassing the U.S. Vancouver and Columbia INPFC areas and the southern stock including the Eureka, Monterey and Conception INPFC areas, using Stock Synthesis 2, a length-age structured model (Methot 2000). Both the northern and southern area models defined the fishing year as beginning on November 1 and ending on October 31 with a winter fishery including November–February and a summer fishery from March–October. Catches prior to 1957 were assumed to be taken during the summer season when monthly data were not available to split the historical catches seasonally. The complete catch history was reconstructed for petrale sole for the 2005 stock assessment, leading the northern area model to start in 1910 and the southern area model in 1876.

Canada

Ketchen and Forrester (1966) conducted the first assessment of petrale sole off British Columbia. A recent series of petrale sole assessments in Canadian waters were conducted by Tyler and Fargo (1990), Fargo (1997, 1999), Fargo et al. (2000), Starr and Fargo (2004), and Starr (pers. comm.). The 2004 stock assessment of petrale sole was based on three areas: the west coast of Vancouver Island, Queen Charlotte Sound, and Hecate Strait (Starr and Fargo, 2004). In the most recent 2006 assessment in British Columbia petrale sole are assessed using a single area, combined sex, delay-difference stock assessment model with knife edge recruitment (at 6 or 7 years old). The model is tuned to fishery CPUE, mean fish weight of the commercial landings, and a number of fishery independent surveys beginning in the early 1980s (pers. comm., P. Starr). Stock predictions are based on average recruitment (pers. comm., P. Starr).

2.4.2 GAP and GMT input

The GMT representative on the petrale sole STAR panel has compiled a history of regulatory actions that impacted the petrale sole fishery, and more generally the groundfish fishery (Appendix D). The GAP representative provided ancillary information on the comparative catches of petrale sole by the fishery, indicating that during the 1980s catch rates were very poor but that recently catch rates have much improved (pers comm. B. Pettinger). The GAP representative as well as members of the fleet present at the STAR panel provided invaluable information regarding the history of the fishery and the impact of management regulations on fleet behavior.

2.4.3 Response to the review panel recommendations in 2005

Both the 1999 and 2005 STAR panel reports called for increased collection of biological data for petrale sole. Although the biological data collection has generally improved one notable, gap is the lack of recent age data from the California fleets, the most data poor fleet in the assessment. This is of particular concern because total landings of petrale sole from California waters during the past two years have surpassed those of Washington and Oregon.

The STAR and “Follow-up” panel reports from 2005 outlined a number of research and modeling recommendations. The current assessment has addressed as many of these recommendations as possible and substantial progress, as outlined below, has been made on most of them.

1. The Panel noted that the petrale sole stock trends were similar in both northern and southern areas, in spite of the different modeling choices made for each area, and that a single coast-wide assessment should be considered. This assessment treats petrale sole as a single coast-wide stock.

2. In the 2005 southern area assessment there was not enough discard data to estimate retention curves. There was also an indication that the discard data were interacting in a pathological way with the age- and length-composition data. The group discussed at length approaches to correct this problem and noted that it would be preferable in this case to assume the discard rates based on limited observations and inflate the landings to reflect this level to eliminate the spurious interactions between the retention curve estimates and fits to length and age compositions. A simple assumption of a constant percent discard was agreed to by the Panel and STAT team, primarily because of concerns about the reliability of historical discard estimates. This relatively crude approach assumes that discard and landed catch have the same length distribution, but it is likely that discard is primarily market (i.e., size) based. Therefore a retention curve was not estimated in the final southern area model. This is no longer an issue in the current assessment as the model is able to fit both discard fractions, mean weight of the discards, and the discard length compositions available for each fleet as well as estimate retention curves for each fleet.

3. The panel requested plots investigating changes in sex ratio over time. The current assessment has produced these plots. There is no indication of changes in sex ratio over time in the recent survey data. The fishery data show a somewhat higher proportion of females to males, as might be expected given dimorphic growth and winter fisheries that target spawning aggregations.

4. A large proportion of the discussion focused on aging bias and imprecision for the various ageing methods applied to petrale sole otoliths. The panel found no data for specifying whether the CV should be equal to 0.06 or 0.12 (the options that were considered) and recommended instead using as an approximation the vector of standard deviations used from the surface-ageing method (where data were available). The ageing-errors for the break-and-burn age data were also based on surface age data. There were also apparent shifts in ageing criteria that were causing poor model fits in the northern area assessment which caused the STAR panel to recommend removing all age composition data from the stock assessment. A bomb radiocarbon age validation study was designed and carried out for petrale sole and all available double read information for each ageing method applied to petrale sole otoliths was compiled. All of these data were used to estimate the ageing bias and precision for each of the ageing methods used in the current petrale sole stock assessment. There are no longer strong conflicts between the age data and other data sources.

5. The STAR panel discussed the possibility for differential natural mortality for males and females. Based on Beverton (1992) a flatfish species with similar longevity as petrale sole had values for female M ranging from 0.17 to 0.25 per year and values for male M ranging from 0.2 to 0.3. The Panel therefore suggested doing a sensitivity run with female M specified at 0.2 (the default value, which will provide some consistency in female spawning biomass in the base-case configuration) and setting the natural mortality for males at a value of 0.25. The rationale for this sensitivity analysis is to improve the interpretation of the highly domed-shaped selectivity curves currently estimated for males in virtually all model runs. The current assessment is able to estimate the values of M for both females and males.

6. A number of age-structures were collected during the NWFSC survey but were not aged. These structures have been aged for the current assessment.

7. The 2005 STAR panel expressed general concern regarding possible changes in growth over time and suggested that spatial and/or temporal factors impacting growth should be investigated. Time-invariant growth is well estimated in the current assessment. Investigations into including time varying growth in the assessment model suggest that the data available do not strongly support time-varying growth.

8. The STAR panel was concerned that discard practices may have changed in recent years and that data are limited on where and when this may have occurred. The panel suggested that information on the size composition of discards should be collected and analyzed from the groundfish observer program. The current assessment has two years of length composition data from the WCGOP for each of the fleets in the model. There is a general lack of reliable historical discard data.

9. There was concern that the CPUE data used in the southern area GLM analysis may have been affected by changes in regulations during the recent period. It was also suggested that future GLM analysis of CPUE be based on a finer spatial scale and that a greater level of vessel standardization should be done. The southern area model CPUE has been removed from this analysis. Only the CPUE data from Sampson and Lee (1999) were used in the current assessment.

10. In comparison to previous assessments of petrale sole, this assessment represents a significant change in our perception of petrale sole stock status. For example, in the 1999 assessment, spawning biomass stock biomass in 1998 was estimated to be at 39% of unfished stock biomass. The current assessment now estimates biomass in 1998 to have been at 12% of unfished stock biomass (northern area). An extended period of low stock abundance followed by a rapid increase was a consistent feature of model results regardless of geographic area, model configuration, or selection of input data. Nevertheless, this pattern of extreme stock dynamics is difficult to reconcile with the long-term stability of the petrale sole fishery, and the Panel recommends exploration of this issue in future assessments. The catch history for petrale shows peak catches in 1950 followed by a general decline in total catches through the

1980s, low catches through the 1990s, and a small increase in subsequent years. This is generally consistent with the trend in biomass estimated by the stock assessment model and suggests that historically the fishery is not as stable as it first appears, particularly considering the offshore movement of the fishery to focusing on winter spawning aggregations during the 1980s. The difference between the 1999 and more recent 2005 and 2009 stock assessments is also a classic case of shifting baselines since the catch history used in the 1999 assessment started in 1977 and the catch history used in the 2005 stock assessment started in 1876. Figure 36 shows comparisons of each of the stock assessment models estimates of spawning biomass and stock depletion.

11. Concerns regarding limited data for California in comparison to Washington and Oregon remain an issue. Although collection of length data for petrale sole in Californiahas increased, no recent age data are available.

2.5 Model Description

2.5.1 Link from the 2005 to current assessment model

Based on the results of the 2005 stock assessment (Lai et al. 2005) and recommendations from the STAR panel reviews, the current stock assessment for petrale sole is implemented as a single area model. This is because the rather complicated modeling of multiple fisheries with dome-shaped selectivity patterns using sex-specific age data from different agencies caused model convergence to be slow and erratic. Thse problems suggest that the 2005 models may have been over parameterized given the quality and quantity of the available data. The current assessment has been upgraded to the newest version of SS. The data inputs have been rebuilt for a coastwide assessment and reflect the best information currently available. A thorough description of the 2009 assessment model is presented separately below; this section linking the two models is intended only to more clearly identify where substantive changes were made.

The 2005 northern area model removed all of the age data due to problems with shifts in ageing criteria for an uncertain period of time. This problem has been addressed in the best manner possible, and all of the age data from the northern area are now included in the assessment. A new analysis has provided ageing-error estimates of bias and standard deviations for each ageing method applied to petrale otoliths. The NWFSC survey was not included in the 2005 assessment since time series was not long enough to be informative. There are now six years of data from the NWFSC survey that provides a biomass index, length compositions, and conditional age-at-length data that are introduced in this 2009 assessment. Because of the use of conditional age data in place of marginal age-frequency distributions the parameters describing the distribution of length at a given age were freely estimable. The discard data from the WCGOP, that were not included in the 2005 assessment are used directly in this 2009 stock assessment. The catch history for petrale sole has also been updated, resulting in generally higher landings during the early part of the fishery.

2.5.2 Summary of data for fleets and areas

Fishery removals were divided among 6 fleets: 1) winter Washington trawl, 2) summer Washington trawl, 3) winter Oregon trawl, 4) summer Oregon trawl, 5) winter California trawl, and 6) summer California trawl. The landings for the Washington fleet are defined as those fish caught in PSMFC areas 3A (a small portion of northern Oregon is included in area 3A), 3B and 3S. The landings for the Oregon fleet are defined as those fish caught in PSMFC area 2A, 2B, and 2C. The landings for the California fleet are defined as those fish caught in PSFMC area 1A, 1B, and 1C. Removals associated with research projects (the trawl surveys, and other much smaller sources of permitted mortality due to scientific research) are very small and are included in the trawl fishery removal. The data available for each fleet are described in Table 2.

2.5.3 Modeling software

This assessment used the Stock Synthesis 3 modeling framework written by Dr. Richard Methot at the NWFSC. The most recent version (SS-V3.02E) was used, since it included many improvements and corrections to older versions (Methot 2007).

2.5.4 Sample Weighting

Indices of relative abundance all had variance estimates generated as part of the analysis of raw catch data. These variances are converted to standard deviations in log space (as is required by SSv3) for use in the model, no iterative re-weighting is done for the abundance indices. Initial input sample size for compositional data was based on a method developed by I. Stewart and S. Miller, as part of the data and modeling workshop in 2006 (see background materials). Briefly, this method was based on analysis of the input and model-derived effective sample sizes from stock assessments completed in 2005 for west coast groundfish. It makes the input sample size a function of both the number of fish sampled and the number of trips or hauls sampled. A piece-wise linear regression was used to estimate the increase in effective sample size per sample based on fish-per-sample and the maximum effective sample size for large numbers of individual fish. These values are likely to represent a reasonable starting point that generally reflects the degree of observation error commensurate with sampling a given number of fish from a given number of samples.

This assessment follows the iterative re-weighting approach to developing consistency between the input composition sample sizes (or standard errors) and the effective sample sizes based on model fit. This approach attempts to reduce the potential for particular data sources to have a disproportionate effect on total model fit, while creating estimates of uncertainty that are commensurate with the uncertainty inherent in the input data. Iterative re-weighting was applied to the length and age data from the survey and all fleets. This consisted of comparing the mean input sample size for compositional data with the mean effective sample size based on model fit. Where the input sample size was greater, this implied the model was unable to fit the data in a manner that was consistent with the level of variability expected in the data and so a multiplicative scalar was used to reduce the input sample size for all length- or age-composition samples for that fleet accordingly.

A second weighting issue arises when both length and age data are included from the same individual fish and samples. In this case, it is theoretically appealing to treat the age data as conditional to the length observations (as described above) and avoid duplication of the information content. This is the approach taken for survey data. However, due to the technical constraints described above (very long run times), this approach was not feasible for all of the commercial sampling in this assessment at this time. Instead the approach taken is to use the lambda values (emphasis; a direct multiplier on the likelihood component) reducing the lambdas to 0.5 for length and age data from a given fleet where both types of data are available. This is consistent with many other west coast groundfish assessments.

The value of σ_R was determined using an iterative procedure to ensure that the value of σ_R assumed by the assessment model and the empirical variance in recruitment were self-consistent. This involved setting σ_R to an initial value, fitting the model and calculating the variance of the recruitment deviations for the years for which recruitments are estimated in the model (1959–2005), replacing the assumed value of σ_R by the calculated value, and repeating the process until convergence occurred. Very little iterative reweighting was necessary for σ_R.

2.5.5 Priors

Priors were not applied to most estimated parameters in the base case model. Only natural mortality has a normally distributed prior with a mean of 0.2 and a standard deviation of 0.025 for females with males estimated as an offset from females. The parameter bounds are sufficiently wide to avoid truncating the searching procedure during maximum likelihood estimation.

2.5.6 General model specifications

Stock synthesis has a broad suite of structural options available for each application. Where possible, the 'default' or most commonly used approaches are applied to this stock assessment. The assessment is sex-specific, including separate growth curves and estimated for natural mortality for males and females, and therefore tracking the spawning biomass of only females for use in calculating management quantities.

For the internal population dynamics, ages 0-40 are individually tracked, with the accumulator age of 40 determining when the 'plus-group' calculations are applied. As there is little growth occurring at this age, and the data are accumulated at age 17, this should be a robust choice (there needs to be enough space between the data 'plus-group' and that of the dynamics to avoid ageing error moving very old fish into observations of younger ages where this is unwarranted).

There are no explicit areas structuring the modeled dynamics of this assessment. Seasons and fleets based on landings in each state are used to structure catches. Since the time-series of catches starts in 1876 the stock is assumed to be in equilibrium at the beginning of the modeled period. The sex-ratio at birth is fixed at 1:1, although by allowing increased natural mortality on males, size-based selectivity, and dimorphic growth the sex ratio can vary appreciably due to differential mortality by age and sex.

2.5.7 Estimated and fixed parameters

A full list of all estimated parameters and values of key parameters that are fixed is provided in Table 14. Time-invariant sex-specific growth is fully estimated in this assessment with the length at age 1 assumed to be equal for males and females. The log of the unexploited recruitment level for the Beverton-Holt stock-recruit function is treated as an estimated parameter. Recruitment deviations are estimated for each year of the period informed by the data (1939-2005) based on evaluation of the variance of the early deviations. This approach may underestimate uncertainty in recruitment variability (and therefore derived quantities like spawning biomass) in the early years of the model. However, it provides for an efficient maximum likelihood minimization and reduces unwarranted patterns in early deviations. Asymptotic selectivity is used for both the triennial and NWFSC surveys and for all fishing fleets in the base case model. Selectivity for the fishing fleets is modeled as time-varying using either four or five time blocks (Table 15). The catchability parameters are not directly estimated, but are set as scaling factors such that the estimate is median unbiased, which is comparable to the way q was treated in the 2005 stock assessment.

2.6 Model Selection and Evaluation

2.6.1 Key assumptions and structural choices

All structural choices for stock assessment models are likely to be important under some circumstances. In this assessment these choices are generally made to 1) be as objective as possible, 2) follow generally accepted methods of approaching similar models and data and 3) address the previous STAR and Follow-up panel concerns. The relative effect on assessment results of each of these choices is often unknown; however an effort is made to explore alternate choices through sensitivity analysis.

Major choices in the structuring of this stock assessment model include a coastwide model with seasonal fleet structure for each state, splitting the triennial survey into an early and late time period, and estimates selectivity and retention curves for each fleet.

2.6.2 Alternate models explored

Many variations on the base case model were explored during this analysis; only the most relevant and recent are reported in this document. Many of these are reported as sensitivity and retrospective analyses. Many of these types of runs are described below.

Both prior to and during the STAR panel, detailed exploration was made to evaluate:

1. time varying selectivity
2. time varying growth
3. estimation of natural mortality

4. estimation of the stock-recruitment steepness
5. tuning of composition sample sizes
6. the period over which recruitment deviations are estimated
7. asymptotic versus dome shaped selectivity curves for all fishing fleets and surveys
8. the tuning of recruitment variability
9. values for the NWFSC survey q
10. data sources that have been added since the 2005 assessment including, Oregon and Washington ages, discard data, and the NWFSC survey.
11. splitting of the trienneial survey into two time periods
12. commercial age data
13. the 2005 catch history

2.6.3 Convergence status

Convergence testing through use of over dispersed starting values often requires very extreme values to actually explore new areas of the multivariate likelihood surface. For this reason, a good target for convergence testing is to 'jitter' or randomly adjust starting values between reasonable upper and lower bounds by a factor that produces low (~20-40%) rates of successful model estimation. When too much over-dispersion is included the approach is very inefficient, when too little, other minima are unlikely to be identified. Jitter is an SSv3 option which allows the generation of a uniform random number equal to the product of the input value and the range between upper and lower parameter bounds for each parameter. These random numbers are then added to initial parameter values in the input files and the model minimization started at these new conditions.

Poor behavior may be primarily due to multivariate parameter correlation and 'ridges' in the likelihood surface making the search difficult. Further, conflicting signal from various data sources can cause shifts that yield very similar results, but with different combinations of parameters or values for specific likelihood components. This exercise was repeated for the final base-case model and none of these trials found a different global minimum. These results, in conjunction with other convergence checks, indicate that it is likely that the base case model result represents the global minimum.

2.7 Response to STAR panel recommendations

During the STAR panel review auxiliary analyses were performed to explore data sources, better understand model performance, and to identify a single base case model on which both the STAT and STAR panel were in agreement. Areas identified for future research include:

1. The completion of comprehensive catch reconstructions currently underway by Washington and Oregon.
2. Gaining a better understanding of the mixing of U.S. and Canadian catches, particularly for the historical catches for the Washington fleet.

3. Investigating simpler, less structured, models including statistical catch/length models for comparing and contrasting purposes.
4. Expand stock assessment area to include Canadian waters to cover the actual biological range.
5. Expansion of the survey area insore of the since the abundance vs. survey depth plot suggests that there are still a high abundance of petrale inshore of the survey area.
6. A management strategy for petrale sole because the estimates of B_0 and $B_{current}$ are highly sensitive to the assumed stock-recruitment relationship, making these reference points more uncertain, while B_{MSY} estimates are consistent among all the model run results.

2.8 Base case model results

The biological parameters estimated from the base case model are reasonable and consistent with the raw data (Tables 16-17, Figure 37). Female and male petrale sole have similar growth trajectories until about age 5, beyond age 5 females grow to a maximum size of 58.0 cm while males grow to 42.0 cm (Figure 37). Both sexes show a similar distribution of lengths-at-age and relative CVs at age (Figure 37). Natural mortality for females is estimated to be lower, 0.15, compared to males, 0.17 (Table 17). This difference in sex-specific natural mortality suggests that the sex ratios will be dominated by females at older ages.

Estimated selectivity curves for the NWFSC and triennial surveys were generally similar, although in the later years, the triennial survey selected a slightly higher fraction of small petrale sole (Figure 38). The catchability values for the NWFSC and the early and late triennial surveys are different, 3.07 and 0.52 and 0.72 (the direct model estimate of 0.295 needs to be multiplied by 2 to be in the same scale as the NWFSC catchability), respectively (Table 17). The catchability estimate for the triennial survey is in-between the values estimated by the 2005 northern area assessment, 0.35, and 0.706 for 2005 southern area assessment.

Selectivity curves for the fishing fleets largely showed, as expected, a tendency towards larger fish being caught in the winter fisheries and smaller fish being captured in the summer fisheries (Figures 39-44). Time blocks were implemented to account for residual patterns in the composition data that are likely due to the impact of changing management regulations. Ten year time blocks beginning in 1973, 1983, 1993, and 2003 are used to estimate different selectivity parameters in each fleet (Table 15).

The base case model was able to fit both fishery independent and dependent indices well, with the exception of the 2004 data point from the triennial survey (Figures 45-46). Fits to the length and age distributions are fairly good, with no strong trends in the Pearson residuals (Figures 48-51, Appendix B). The Pearson residuals reflect the noise in the data both within and between years. The model is unable to fit the last two years of NWFSC survey composition data very well (Figure 47-49). These compositions suggest that there are proportionally more small/young fish in the population than expected (Figure 47-49). The fishery length- and age-frequency data required some tuning of input sample sizes to make the average effective sample sizes equal to or greater than average input sample sizes (Appendix B). The model also fits the discard data well (Figures 55-60).

The estimated recruitment deviations show relatively low variability, input value of 0.4. output value of 0.33, which is slightly lower than the output values from the 2005 stock assessment, 0.5 and 0.46 for the northern and southern assessment models, respectively. The choice of start year for estimating recruitment deviations, 1939, is based on the estimated variance of the recruitment deviations from the model being close to the input value for recruitment variability. Extending the series to earlier years degraded the model fit and estimates of recruitment deviations since there is little or no composition data to inform the estimation of the recruitment deviations during the earlier years of the model. The time-series of estimated recruitments shows a weak relationship with the decline in spawning biomass, punctuate by larger recruitments (Table 18, Figures 61-62). The four weakest recruitments since 1939 are estimated to be in 1972, 1985-1986, 1991 and 2003(Table 18, Figures 61-62). The four strongest recruitments since 1939 are estimated to be in 1939-1940, 1960, 1965, and 1997-1998 (Table 18, Figures 61-62). The most recent above average recruitment event, is estimated to be in 2005, and is about 20% smaller than of the 1997–1998 recruitment event (Table 18, Figures 61-62). The estimate of stock-recruitment steepness is 0.95 (Table17, Figure 63), which is higher than in both the 2005 northern and southern area assessments.

The biomass time series shows a strong decline from the late-1930s through the mid 1960s, followed by a small recovery through the mid-1970s, and another decline to its lowest point during the early 1990s (7-8% of unexploited) (Tables 18-19, Figure 64). This general pattern of stock decline is coincident with increasing catches (Figure 1). From the mid-1990s through 2005 the stock increased slightly to an estimated depletion of 16.4%, but since 2005 the biomass has declined to an estimated depletion of 11.6% in 2009 (Table 18-19, 65).

2.9 Uncertainty and Sensitivity Analysis

The base case assessment model includes parameter uncertainty from a variety of sources, but underestimates the considerable uncertainty in recent trend and current stock status. For this reason, in addition to asymptotic confidence intervals (based upon the model's analytical estimate of the variance near the converged solution), two alternate states of nature regarding the size of the spawning biomass in 2009 were analyzed. In the high and low states, the 2009 spawning biomass amounts are roughly 1.25 standard deviations higher and lower, respectively, than the base case. These amounts were achieved through manipulation of the size of NWFSC survey biomass in 2008. Much additional exploration of uncertainty was performed prior to and during the STAR panel. Some of that exploration of other sources of uncertainty is provided below.

2.9.1 Sensitivity analysis

Sensitivity analysis was performed to determine the model behavior under different assumptions than those of the base case model. In the numerous sensitivity model runs that were explored before and during the STAR panel, the model provided generally consistent behavior between model and data assumptions with the exception of the choice of stock-recruitment relationship. Three sensitivity runs were done for the final base case model to examine the influence of using the Ricker stock-recruitment function, reducing the effective survey sample sizes by half, and removing all of the 2008 NWFSC survey data. Table 20 shows the results of the sensitivity runs compared to the base case, and Figure 66 shows the biomass trajectory for the sensitivity model runs.

The sensitivities show the following patterns (Table 20, Figure 66). First, the choice of the stock-recruitment relationship specified has a significant effect on the estimates of unfished spawning biomass and depletion. The Ricker stock-recruitment relationship results in a 43% lower estimate of unfished spawning biomass and an 83% higher depletion level than the Beverton-Holt stock-recruitment relationship. Removing the 2008 survey data resulted in more optimistic model results, while halving the effective sample sized for the survey composition data had minimal impact on model results.

2.9.2 Retrospective analysis

A retrospective analysis was conducted by running the model using data only through 2003, 2004, 2005, 2006, and 2007 (Table 21, Figure 67). The following retrospective patterns emerge. All of the retrospective model runs suggest that the unfished spawning biomass is about 25,000 mt. The current biomass (the beginning of the year spawning biomass after the last year of data) is higher for the retrospective runs using data up to 2004, 2005, 2006 and 2007, and lower when the data end in 2003, which shows a smaller biomass and the lowest depletion in 2004. Because the NWFSC survey had only one biomass estimate in 2003, this data point was removed, thus there are no biomass estimates from the NWFSC survey in that retrospective run. Overall, the current depletion is generally higher with the data up to 2007, but the inclusion of data up to 2008 (base case) leads the model to predict a downward trend in the recent spawning biomass. The declining trend in spawning biomass with the inclusion of the 2008 data is driven by the four consecutive years of downward trend in the NWFSC survey biomass index and by the observation of a higher proportion of smaller fish in the 2008 survey length and age-composition data.

2.9.3 Likelihood profiles

Likelihood profiles for steepness, natural mortality, and the NWFSC survey biomass catchability (q) were completed to investigate the uncertainty in the estimates of these parameters, as well as the effect of these parameters on the estimated status of the stock for the pre-STAR model. The pre-STAR model profile for female and male natural mortality suggested that the range of 0.12 to 0.23 for females was within the 95% confidence interval, with male natural moratlity consistenly being about 0.02 higher. The pre-STAR model steepness profile was symmetric and the 95% confidence interval is approximately 0.76–0.99.

Likelihood profiles for the NWFSC catchability (*q*) and steepness (*h*) from the final base case model are presented here. Profile results are shown in Figures 68. The profile on the NWFSC survey catchability shows that it is very unlikely for the estimate to be much larger than the current value or the lower that about 2 (Figure 68). The profile on *h* shows that h may range between about 0.84 and 1.

3. Rebuilding Parameters

Both the STAT team and STAR panel are suggesting that the SSC consider using reference point based on the model estimates of Bmsy rather than the standard Bmsy proxy reference points based on 40% of unfished spawning biomass. Since the SSC has not had the opportunity to consider this issue, the status of the petrale sole stock is yet to be determined.

4. Reference points

The abundance dropped below the $SB_{40\%}$ management target in 1949 and the overfished threshold in 1952. Beginning in 1980 the stock was around 10-12% of unfished spawning biomass and in 1988 the stock dropped below 10% of unfished spawning biomass (Figures 64-65). The estimated relative depletion level in 2009 is 11.6% (Tables 18-19, Figures 64-65). The estimated relative depletion level in 2009 is 11.6% (~95% asymptotic interval: ±4.8%, ~ 75% interval based on the range of states of nature: 9.4-13.8%), corresponding to 2937.6 mt (~95% asymptotic interval: ±832.7 mt, states of nature interval: 2407.8-3468.1 mt) of female spawning biomass in the base model (Table 18).

Fishing mortality rates in excess of the current F-target for flatfish of $SPR_{40\%}$ are estimated to have begun in the late 1930s and persisted through 2008 (Figures 69-70). Current relative exploitation rates (catch/biomass of age-3 and older fish) are estimated to have been 0.29 in 2008. Figure 71 shows a phase plot comparing the time series of estimated fishing mortality and relative depletion. Figure 72 shows a phase plot using the Fmsy and Bmsy reference points.

The equilibrium unfished spawning stock biomass was estimated to be 25,334 mt. The target stock size ($SB_{40\%}$) is therefore 10,134 mt which gives a catch of 2060 mt (Table 18). The estimates of unfished spawning biomass, and therefore the $SB_{40\%}$ reference points were very sensitive to the assumption of stock-recruitment relationship (see section 2.9.1). Model estimates of spawning biomass at MSY and MSY yield were more robust to the assumption of stock-recruitment relationship (see section 2.9.1). Maximum sustained yield (MSY) applying recent fishery selectivity and allocations was estimated in the assessment model at 2,376 mt, occuring at a spawning stock biomass of 4,796 mt (SPR = 0.20). Figure 73 shows the equilibrium yield curve from the base case model; note that the proxy Bmsy reference point (40% of unfished biomass) is very conservative in comparison to the model estimate of Bmsy.

5. Harvest projections and decision tables

The total OYs in 2009 and 2010 are 2433 and 2393 mt and the projections are based on the assumption that they will be reached. The exploitation rate for 2011 and beyond for the base model projection potential is based upon an SPR of 40% (Table 22). Selectivity and fleet allocations are projected at the values for the most recent year. The states of nature in the decision table are low and high 2009 spawning biomass scenarios (Table 23). Seven possible time series of catches are provided and include: 1) a minimal constant catch time series of 3mt, 2) ½ the catches from the 40-10 catch control rul, 3) the catches from the 40-10 catch control rule, 4) a constant catch of 500 mt, 5) a constant catch of 1500 mt, 6) a constant catch based on 2/3 of the estimate Fmsy, 7) a ramping down of catches from 2/3 Fmsy when the stock is as Bmsy to zero catch when the stock is at 50% of Bmsy. Since the STAR panel and STAT team are suggesting that the model estimate of Bmsy be used as a reference point two time series of stock depletion are provided for each combination of catch time series and state of nature. The first measure of stock depletion is based on the model estimate of unfished spawning biomass, the second measure of stock depletion is based on the model estimate of Bmsy.

6. Regional management considerations

The resource is modeled as a single stock. Spatial aspects of the coast-wide population are addressed through geographic separation of data sources/fleets where possible and consideration of residual patterns that may be a result of inherent stock structure. There is currently no genetic evidence that there are distinct biological stocks of petrale sole off the U.S. coat and the limited tagging data that describes adult movement suggests that movement may be significant across depth and latitude.

7. Research needs

Progress on a number of research topics would substantially improve the ability of this assessment to reliably and precisely model petrale sole population dynamics in the future and provide better monitoring of progress toward rebuilding:

1. The estimate of the NWFSC survey catchability in the base case model is higher than expected. This may be due to the use of the total area within each strata during the expansion of the survey data rather than the trawlable areas only, where petrale are most likely to be found. At this time there are no area estimates for trawlable and untrawlable areas. However the petrale sole population is most likely well surveyed by the trawl survey and expanding using areas that include untrawlable areas is probably not appropriate.
2. Expand the assessment to include the waters of British Columbia since petrale sole are likely a single stock that moves across the U.S. Canadian boarder.
3. Many assessments are deriving historical catch by applying various ratios to the total flatfish catch prior to the period when most species were delineated. While progress has been made in moving towards a comprehensive historical catch reconstruction it would be best if a complete catch reconstruction is available from each state for all flatfish species. This will make it possible to compile a best estimated catch series that accounts for all the catch and makes sense for both petrale sole and flatfish as a group.
4. Age data from the California fishery are needed.
5. Historical age data could be improved by obtaining new break and burn ages where structures are available.
6. The estimation of ageing error for the WDFW samples could be improved by doing break-and-burn cross reads with the CAP ageing lab.
7. Studies on recent biological data and stock structure. For example, due to inconsistencies between studies and scarcity of appropriate data, new data are needed on both the maturity and fecundity relationships.

8. Acknowledgements

This assessment draws heavily on the text and analyses in the 2005 petrale sole assessment as well as other groundfish assessments lead by I. Stewart and has benefited greatly from the efforts of all authors contributing to those analyses. Comments and suggestions from Jim Hastie and Stacey Miller improved the quality of this document.

Many people at various state and federal agencies assisted with assembling the data sources included in this assessment. Stacey Miller and John Devore assisted in identifying points of contact and acquiring Pacific council and other documentation. Beth Horness provided summary statistics from the NWFSC survey. John Wallace provided R code for generating GLMM-based indices of abundance from the triennial and NWFSC trawl surveys. Eliza Heery and Marlene Bellman provided discard data from the West Coast Groundfish Observer Program. Patrick McDonald and Teresa Tsou coordinated comparative ageing efforts and assisted in interpreting the results. Andre Punt provided software for the estimation of ageing imprecision and assistance in its use.

The members of the STAR panel and advisors to the panel, Robin Cook, Xi He, J.J. Maguire, Theresa Tsou, John DeVore, Dan Erickson, and Brad Pettinger provided a rigorous review of this work and provided insight into fishery. The members of the industry that attended the panel provided invaluable insights into the history of the fleet behavior as well as the historical context of the fishery.

Table 2. Recent trend in estimated total petrale sole catch and commercial landings (mt) relative to management guidelines.

Fishing year	ABC (mt)	OY (mt)	Commercial Landings (mt)	Estimated[1] Total Catch (mt) for the Annual Year	Estimated Total Catch (mt) for the Fishing Year
1999	2,700	2,700	1,520	1,617	1,591
2000	2,950	2,950	1,778	1,888	1,856
2001	2,762	2,762	1,838	1,975	1,934
2002	2,762	2,762	1,877	2,066	2,024
2003	2,762	2,762	1,686	1,786	1,809
2004	2,762	2,762	2,191	2,273	2,284
2005	2,762	2,762	2,854	2,948	2,960
2006	2,762	2,762	2,102	2,173	2,183
2007	3,025	2,499	2,329	2,372	2,376
2008	2,919	2,499	2,079	2,114	2,117

[1] Total annual catches reflect the commercial landings plus the model estimated annual discard biomass (commercial landings * retained catch/total catch). The total amounts of discard may differ from those reported in the NWFSC reports on total catch for some of these years.

Table 4. Summary of the tow data from the NWFSC survey.

Year	Number of tows	Number of Tows with Petrale	Percent of Tows with Petrale
2003	558	203	36.4
2004	497	225	45.3
2005	674	293	43.5
2006	652	250	38.3
2007	696	261	37.5
2008	685	260	38.0

Year	Number of tows with lengths taken	Percent Petrale tows with lengths taken	Number of male lengths	Number of female lengths	Number of unsexed lengths
2003	202	99.5	1,422	1,442	4
2004	222	98.7	1,875	1,633	1
2005	290	99.0	2,470	2,246	16
2006	250	100.0	1,989	1,752	4
2007	261	100.0	1,976	1,479	6
2008	260	100.0	1,620	1,444	5

Year	Number of tows with ages taken	Percent Petrale tows with ages taken	Number of male ages	Number of female ages	Number of unsexed ages
2003	177	87.2	392	389	0
2004	185	82.2	548	370	1
2005	248	84.6	396	397	1
2006	239	95.6	425	358	2
2007	200	76.6	384	320	0
2008	228	87.7	401	353	1

Table 5. Estimates of biomass (mt) and standard errors (of the natural log of biomass).

	Triennial			NWFSC		
Year	Estimate (B)	log(B)	SE(logB)	Estimate (B)	log(B)	SE(logB)

2008				13,532	9.51	0.1275

Table 6. Summary of the tow data from the Triennial survey.

Year	Number of tows	Number of Tows with Petrale	Percent of Tows with Petrale
1980	301	139	46.2
1983	479	250	52.2
1986	483	268	55.5
1989	440	275	62.5
1992	421	251	59.6
1995	441	209	47.4
1998	468	291	62.2
2001	466	256	54.9
2004	383	244	63.7

Year	Number of tows with lengths taken	Percent Petrale tows with lengths taken	Numberof male lengths	Number of female lengths	Number of unsexed lengths
1980	1	0.7	2	14	0
1983	2	0.8	20	10	0
1986	36	13.4	248	292	0
1989	141	51.3	642	773	4
1992	116	46.2	480	535	0
1995	145	69.4	565	804	0
1998	236	81.1	1,147	1,447	30
2001	254	99.2	1,453	1,559	4
2004	239	98	2,306	2,369	1

Table 7. The number of double read samples available for estimating ageing error for petrale sole. Shaded samples with the same number of reads between ageing method indicates a data set with triple or quadruple reads.

	Agency/Lab/Study					
Ageing Method	WDFW	Pre CAP (OR samples from before 1980)	Early CAP (OR samples from 1981-1999)	Recent CAP (OR and NWFSC samples 2000-present)	CDFW	Bomb Radiocarbon Study
BB v BB	590		7	199	0	333
BB v. Combo	590				0	
BB v. S		216	3	314	0	333
Combo v. Combo	156				0	
Combo v. S			142		0	
S v. S			338	362	0	333

Table 8a. The structure of the ageing bias and imprecision analysis for WDFW samples with the comparison(s) of interest for the assessment highlighted. The Radiocarbon ages are break and burn reads from a single reader from the bomb radiocarbon study that are known to be unbias. Therefore, these ages are used as the benchmark against which the other ageing methods are compared in the analysis.

	Radiocarbon v. BB	BB v. BB	BB v. Combo
Radiocarbon v. BB	**x**		
BB v. BB		**x**	
BB v. Combo			**x**

Table 8b. The same as table 8a except these are comparisons from the CAP laboratory.

	Radiocarbon v. BB	BB v BB	BB v. S	S v. S
Radiocarbon v. BB	**x**			
BB v BB		**x**		
BB v. S			**X**	
S v. S				**x**

Table 8c. The same as a except these are comparisons for a second tier analysis meant to estimate only the bias and imprecision of the combo ageing method (since the ageing error software can only handle three methods and the CAP data have four). In this case the BB method is set as the unbias benchmark and the bias estimated for the combo method is adjusted using the estimated bias for the BB samples from the tier 1 analysis

	BB v BB	BB v. S	S v. S	S v. Combo
BB v BB	**x**			
BB v. S		**x**		
S v. S			**X**	
S v. Combo				**X**

Table 9a. A subset of the different models fit to each CAP analysis #1 data set as well as the likelihoods, the model selected is highlighted. The bias options are 0 = unbias, 1 = linear, 2 = type 2. The standard deviation options are 1=constant CV and 2=increase in CV with age. There is one value specified for each age reading method in the analysis.

Model Run	Bias Options	Standard Deviation Options	Plus Group	Negative Log Likelihood
1	0,1,1	1,1,1	25	5956.49
2	0,1,1	1,1,1	30	Not Converged
3	0,1,1	1,2,2	25	Not Converged
4	0,1,1	2,2,2	25	Not Converged
5	0,1,2	1,1,1	25	Not Converged
6	0,1,2	1,1,2	25	Not Converged
7	0,2,2	1,1,1	25	Not Converged
8	0,2,2	2,2,2	25	Not Converged

Table 9b. The same as 9a but for the CAP analysis #2 data set.

Model Run	Bias Options	Standard Deviation Options	Plus Group	Negative Log Likelihood	Maximum Standard Deviation	Notes
1	0,1,1	1,1,1	25	5465.41	30	selected to limit the bias and standard deviation
2	0,1,1	1,1,1	25	Not Converged	10	Unreasonable huge bias at older ages
3	0,1,1	1,1,2	25	Not Converged	10	hit bound on maximum standard deviation
4	0,1,1	1,1,2	25	Not Converged	30	hit bound on maximum standard deviation
5	0,1,1	1,1,2	25	Not Converged	60	hit bound on maximum standard deviation
6	0,1,2	1,1,2	25	Not Converged	100	huge standard deviation

Table 9c. The same as 9a but for the WDFW data set.

Model Run	Bias Options	Standard Deviation Options	Plus Group	Negative Log Likelihood
1	0,1,1	1,1,1	25	Not Converged
2	0,1,2	1,1,1	25	3485.25
3	0,1,2	1,1,2	25	Not Converged

Table 10. The estimates of bias (mean observed age at true age) and imprecision (SD of observed age at true age) from the best fit models that are used for the various age reading methods in the assessment.

	Break and Burn		Surface		CAP Combo		WDFW Combo

Table 15. Time blocks

Block Pattern				
#1 (all fleets other than Winter-OR)	1973-1982	1983-1992	1993-2002	2003-2008
#2 (only fleet Winter-OR)		1983-1992	1993-2002	2003-2008

Table 16. Estimates of the growth parameters from the base case model. Age min is 2.83 and Age max is 15.83. Variability of the male estimates are not given because those parameters were estimated as offsets to female values.

Parameter	Value	SD
Females:		
Length at age min	17.3	0.43
Length at Linf	58.0	0.48
von Bertalanffy *K*	0.16	0.01
SD of length at age min	2.83	0.19
SD of length at age max	3.33	0.17
Males:		
Length at age min	16.7	–
Length at Linf	42.0	–
von Bertalanffy *K*	0.29	–
SD of length at age min	2.07	–
SD of length at age max	3.71	–

Table 17. Petrale sole catchability and productivity parameters.

Parameter	Value
Catchability:	
NWFSC survey catchability (*q*)	3.07
Triennial survey catchability (*q*) early, late	0.52; 0.72
Productivity:	
R_0	9.52
Steepness (*h*)	0.95
Female natural mortality (*M*)	0.15
Male natural mortality (*M*)	0.17

2019	1,870	1,794	16,482	8,740	34.5%
2020	1,917	1,838	16,850	8,991	35.5%

Table 23. Decision table of 12-year projections for alternate states of nature (columns) and management options (rows) beginning in 2011. There are two values for depletion, the first calculates depetion using the SB40% Bmsy proxy and the second calculates depletion relative to the model estimate of Bmsy. Relative probabilities of each state of nature are based on low and high values for the model estimate of 2009 spawning biomass with the 2008 NWFSC survey biomass estimate as the axis of uncertainty. Landings in 2009–2010 are 2433 and 2393 mt, respectively, for all cases. Selectivity and fleet allocations are projected at the 2008 values

			State of nature

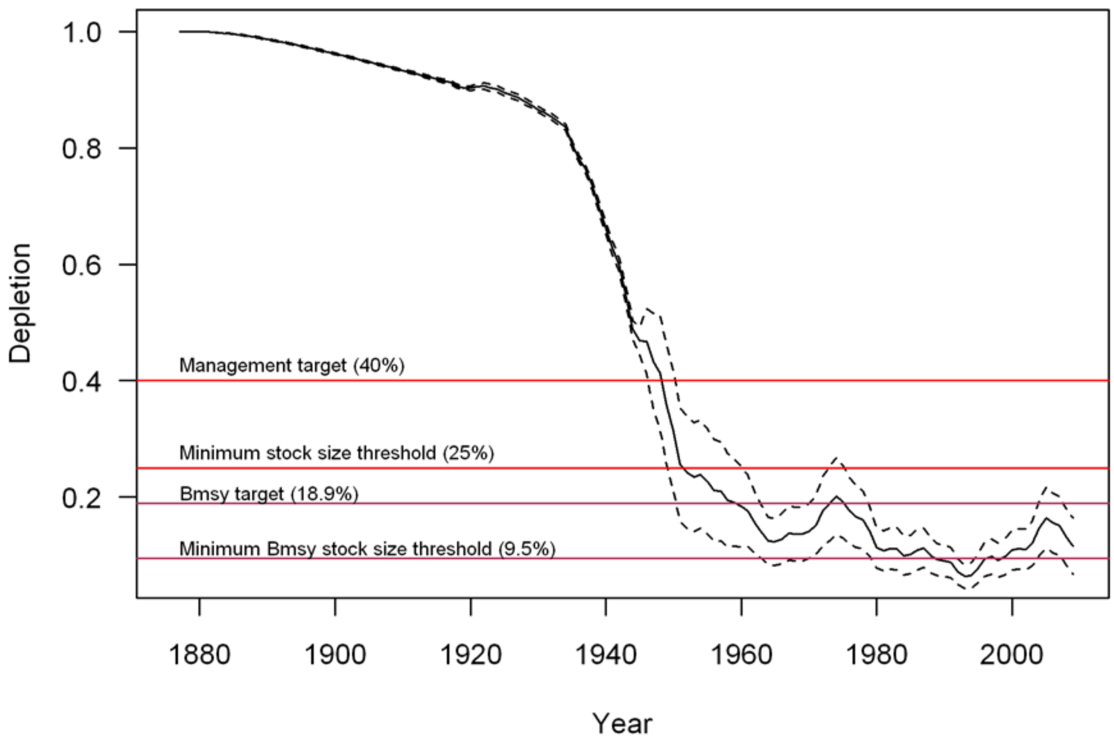

Figure 65. Time series of depletion level as estimated in the base case model (round points) with approximate asymptotic 95% confidence interval (dashed lines) and alternate states of nature (light lines).

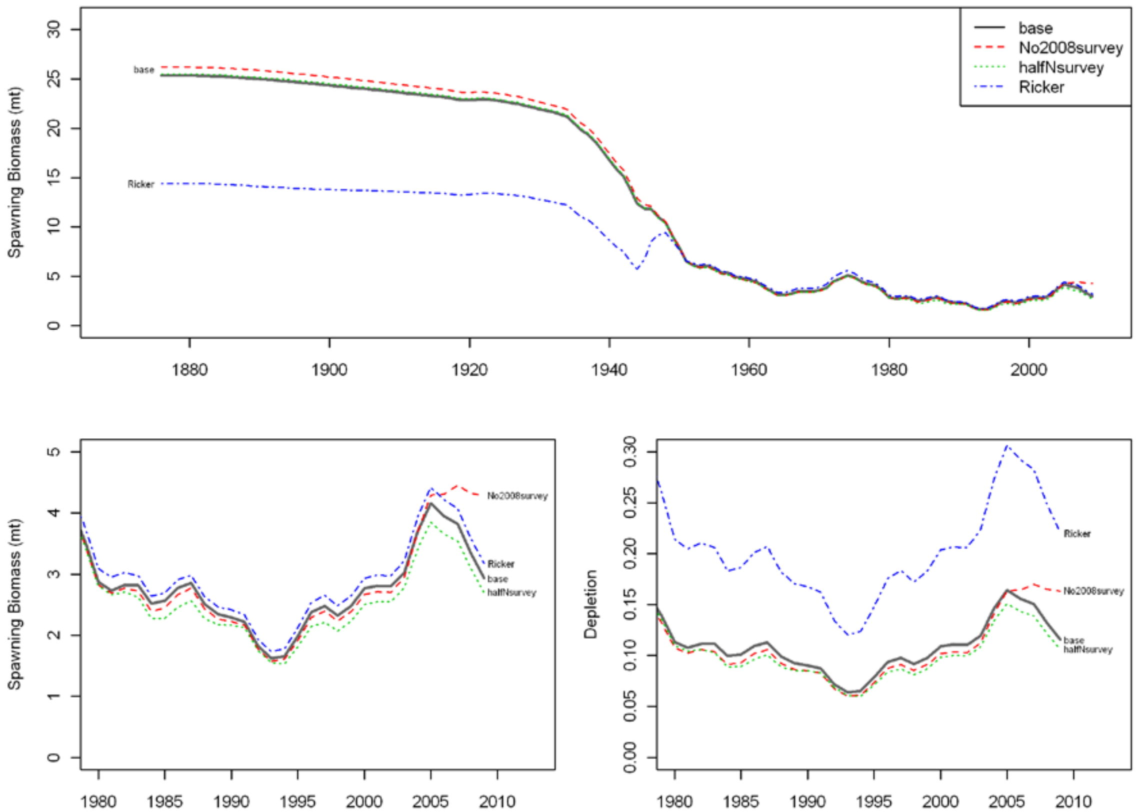

Figure 66. Plot showing sensitivity model runs.

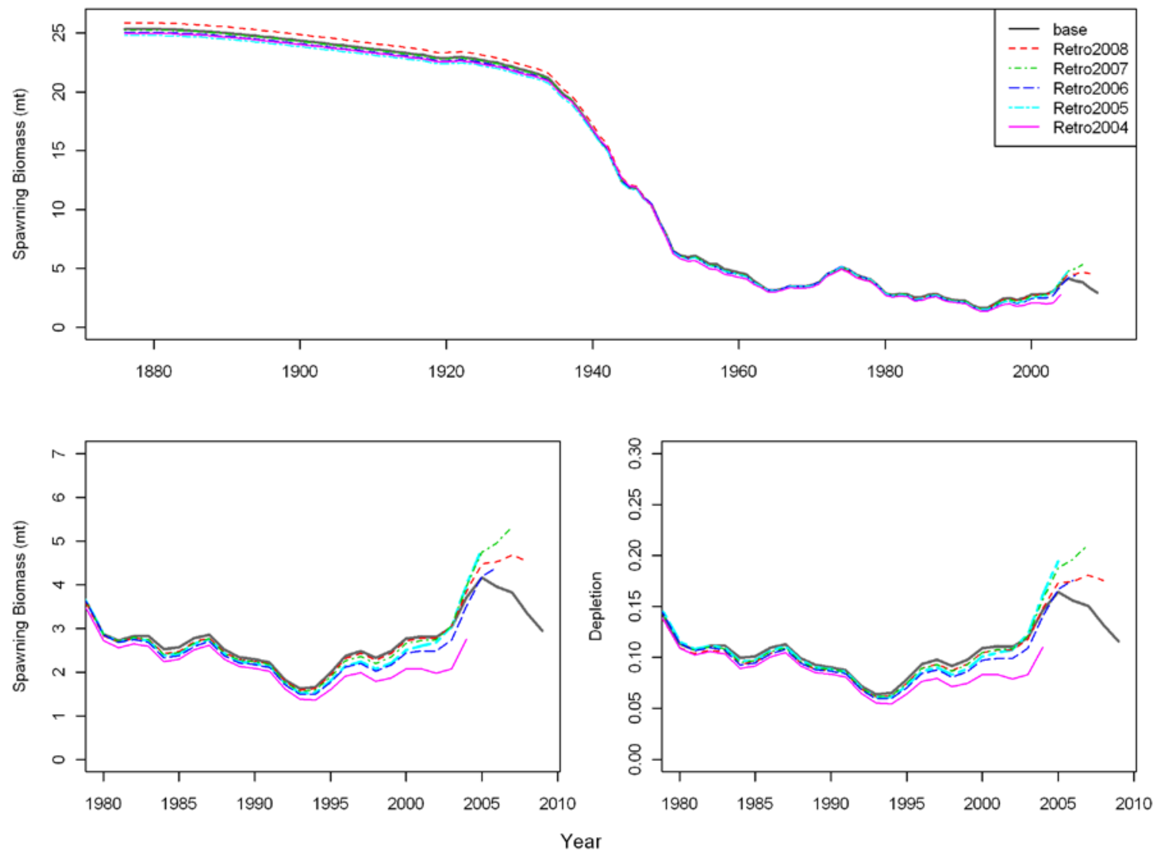

Figure 67. Results from a 5-year retrospective analysis. Each year of retrospective is performed as if the assessment were conducted in that year (i.e., retrospective in 2007 includes data through 2006).

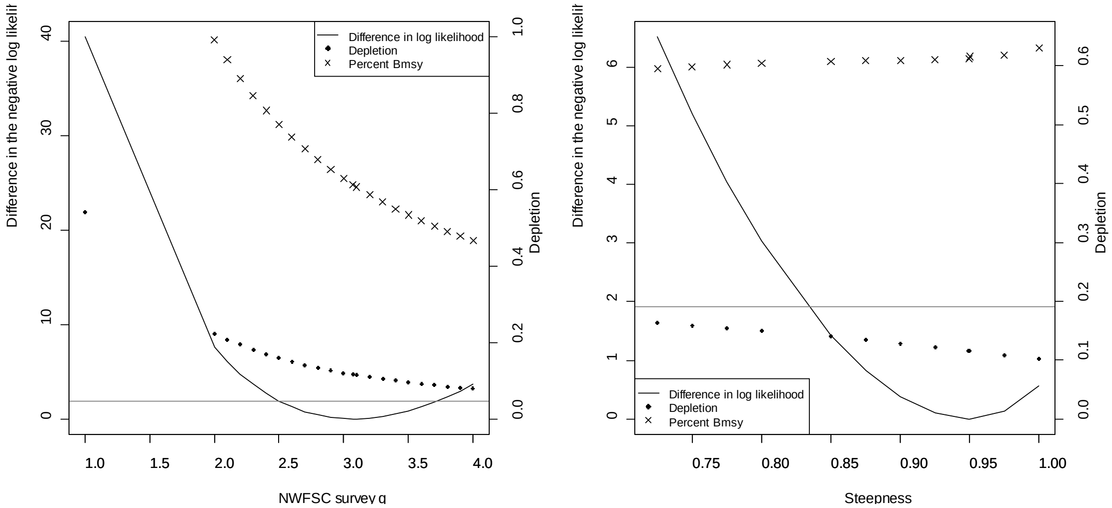

Figure 68. Individual likelihood profiles for the NWFSC survey catchability (q) and stock-recruitment steepness (h) parameters. The negative log likelihood is shown as a solid black line with a grey horizontal line indicating the approximate 95% confidence interval. Depletion (relative to unfished equilibrium biomass) is shown as dots and biomass in 2009 as a percentage of Bmsy is shown as an X's.

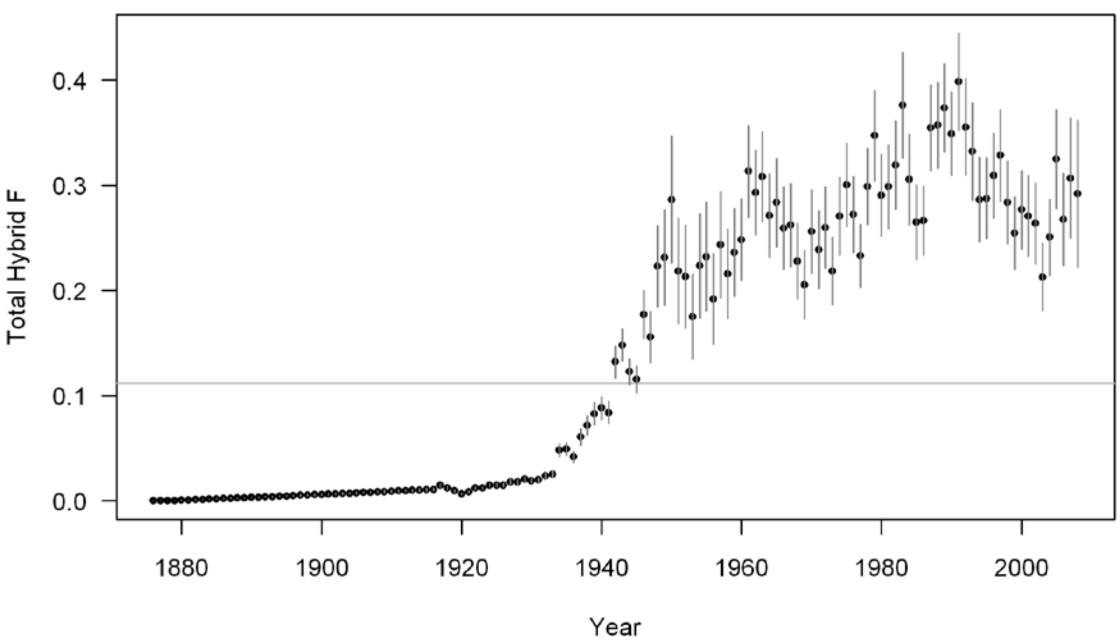

Figure 69. F time-series for all fleets combined.

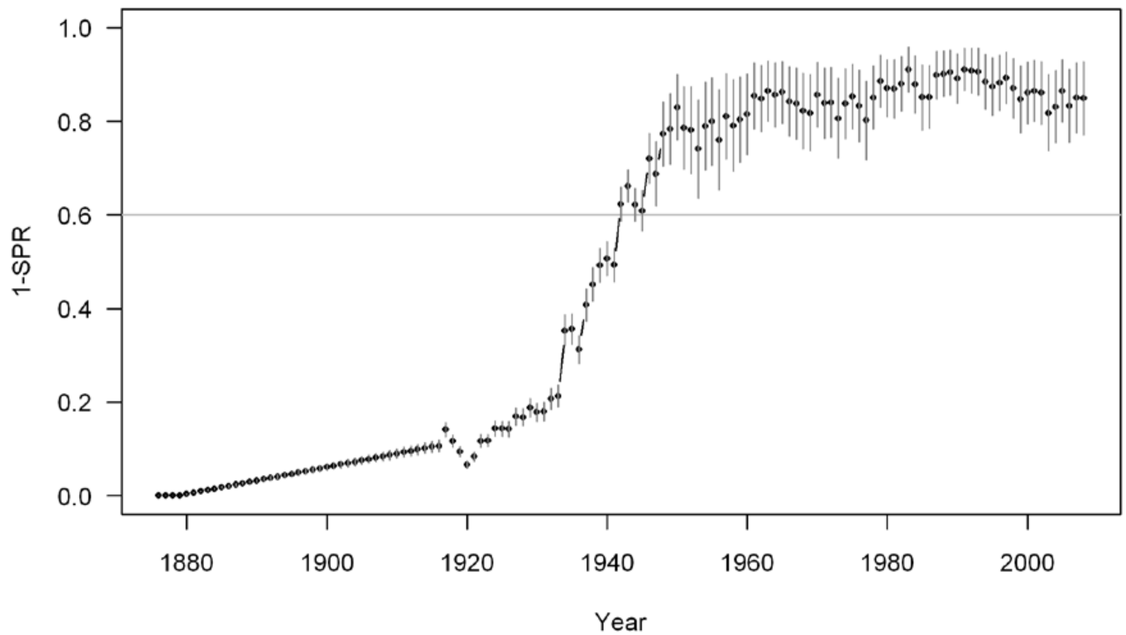

Figure 70. Time series of estimated spawning potential ratio (displayed as 1-SPR) for the base case model (round points). Values of SPR above 0.6 reflect harvests in excess of the current overfishing proxy.

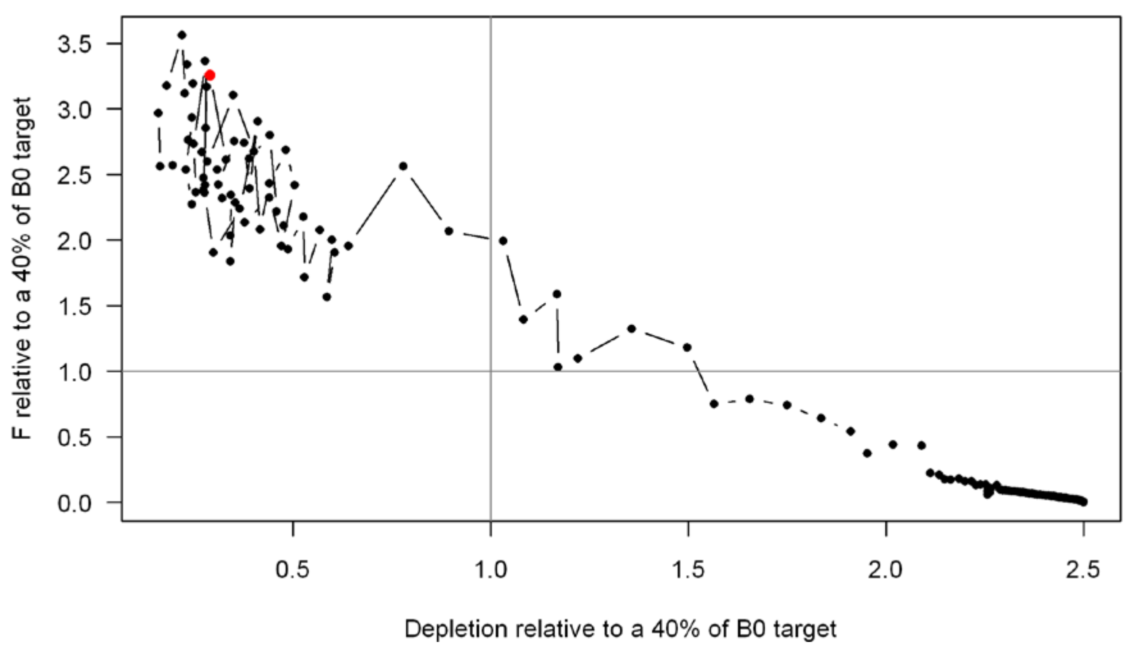

Figure 71. Phase plot of estimated fishing intensity vs. relative spawning biomass for the base case model. Fishing intensity is the relative exploitation rate divided by the level corresponding to the overfishing proxy (0.12). Relative spawning biomass is annual spawning biomass relative to virgin spawning biomass divided by the 40% rebuilding target.

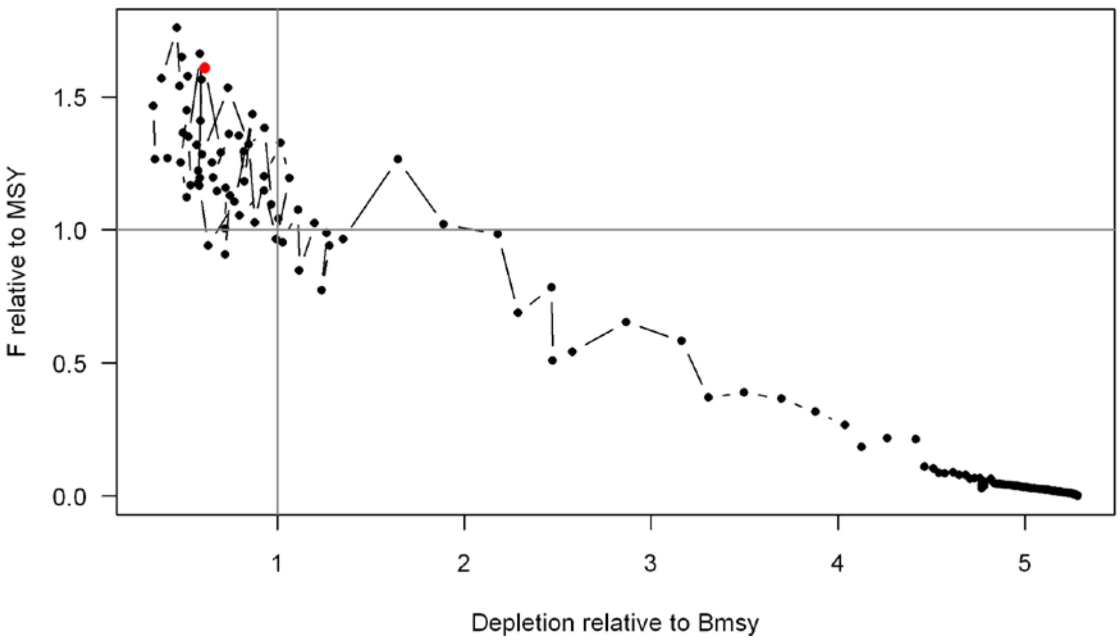

Figure 72. Phase plot of estimated fishing intensity vs. relative spawning biomass for the base case model. Fishing intensity is the relative exploitation rate divided by the level corresponding to Fmsy. Relative spawning biomass is annual spawning biomass relative to the model estimate of Bmsy. The red point is 2009.

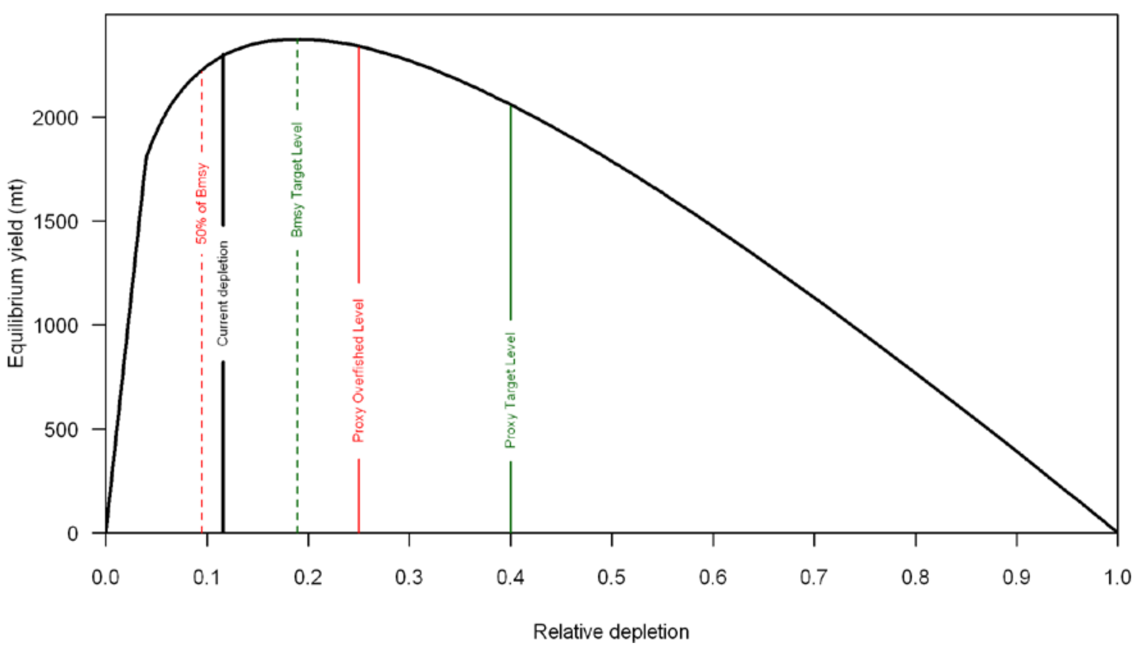

Figure 73. Equilibrium yield curve for the base case model. Values are based on 2008 fishery selectivity.

12. Appendix A: Post stratification of the Triennial and NWFSC surveys

The default stratification from the Triennial and NWFSC surveys is not necessarily the best stratification when analyzing the survey data for Petrale sole. The last Petrale assessment (Lai et al) post-stratified the Triennial survey data based on a Bayesian changepoint analysis of the length as a function of depth. The reasoning behind the changepoint analysis was that Petrale show an ontogenetic migration to deeper water. Therefore the mean length would increase with depth until some point when the slope of the relationship would decrease due to mixing of adult fish. Their results showed median changepoints of 114 m and 144 m for females and males, respectively, and they chose to post-stratify the survey data into three strata (50–100 m, 100–155 m, and 155–700 m).

We chose to revisit the post-stratification because the NWFSC survey was not analyzed in the 2005 assessment. Lai et al (2005) used Bayesian statistics with uninformative priors and MCMC sampling to calculate the posterior distribution. However, we used a frequentist approach since there is no prior information for any of the parameters, and the problem in the frequentist paradigm allows for quick point estimates which are used as guidance for the strata definitions.

Piecewise linear regression is similar to linear regression except that the data are split into two parts by a breakpoint, and separate linear relationships describe each part. In mathematical terms,

$$L = \alpha_1 + \beta_1 d \quad d \le \delta$$
$$L = \alpha_2 + \beta_2 d \quad d \ge \delta$$

Furthermore, because we are assuming that the fish are migrating to deeper water, the relationship at the breakpoint (δ) should be continuous. In other words, the relationships to the two pieces are equal at the breakpoint.

$$\alpha_1 + \beta_1 \delta = \alpha_2 + \beta_2 \delta$$
$$\alpha_2 = \beta_1 + \delta(\beta_1 - \beta_2)$$

Substituting in and rearranging the equations we arrive at the same model used by Lai et al. (2005).

$$L = \omega + \beta_1 (d - \delta) \quad d \le \delta$$
$$L = \omega + \beta_2 (d - \delta) \quad d \ge \delta$$

where $\omega = \alpha_1 + \beta_1 \delta = \alpha_2 + \beta_2 \delta$, or the length at the breakpoint. There are four parameters to estimate.

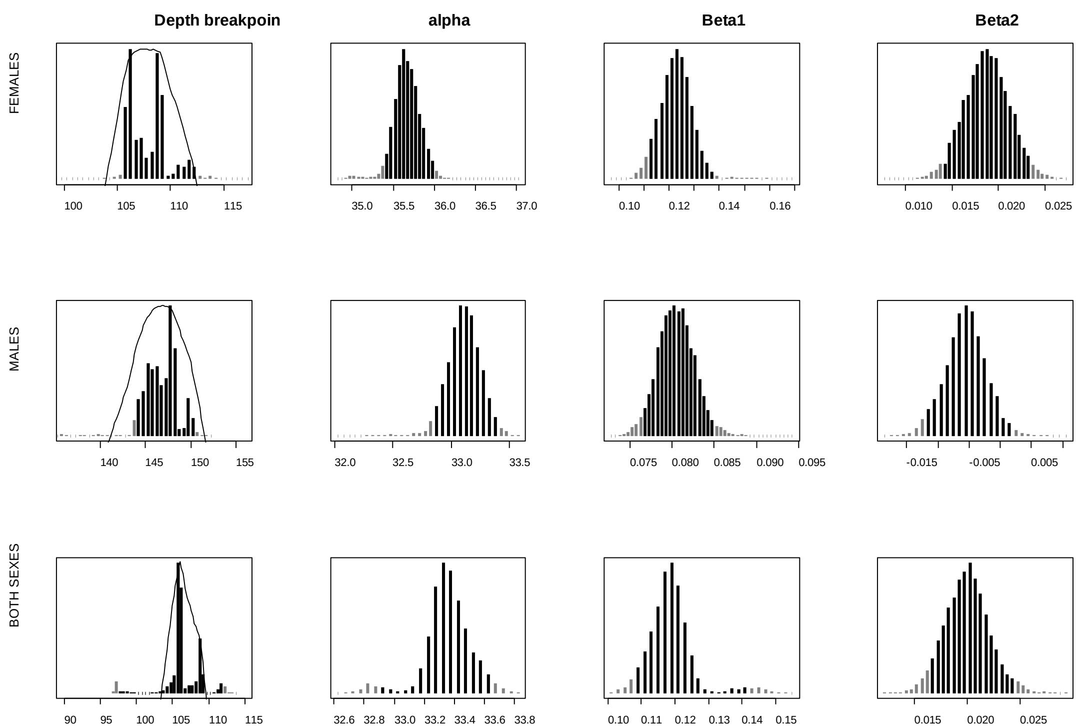
The parameters were estimated by minimizing the sum of the squared residuals and non-parametric bootstrapping was used to estimate the 95% confidence intervals.

Furthermore, likelihood profiles were compared with these confidence intervals after assuming that the residuals were normally distributed with equal variance.

The results here agreed with the analysis performed by Lai et al (2005), and we also chose a breakpoint at 100 m. A breakpoint around 110 m may be more reasonable, but strata specific values, such as stratum area, is more easily available with a breakpoint at 100 m.

Table A3: 95% confidence intervals of the breakpoint from the likelihood profiles and bootstraps for each survey.

	Triennial		NWFSC	
	Profile	Bootstrap	Profile	Bootstrap
Female	**104.2–112.2**	**105.2–112.1**	**105.2–121.2**	**104.3–120.4**
Male	**141.2–151.4**	**143.7–150.0**	**146.0–159.8**	**144.2–160.8**
Both	**103.6–109.4**	**97.0–112.0**	**112.6–120.8**	**112.8–120.4**



FigureA1: Plot of the Triennial survey bootstrap results from piecewise regression for each sex and all years combined. The line in the depth breakpoint plot is a likelihood profile (the 95% CI is where the profile crosses zero).

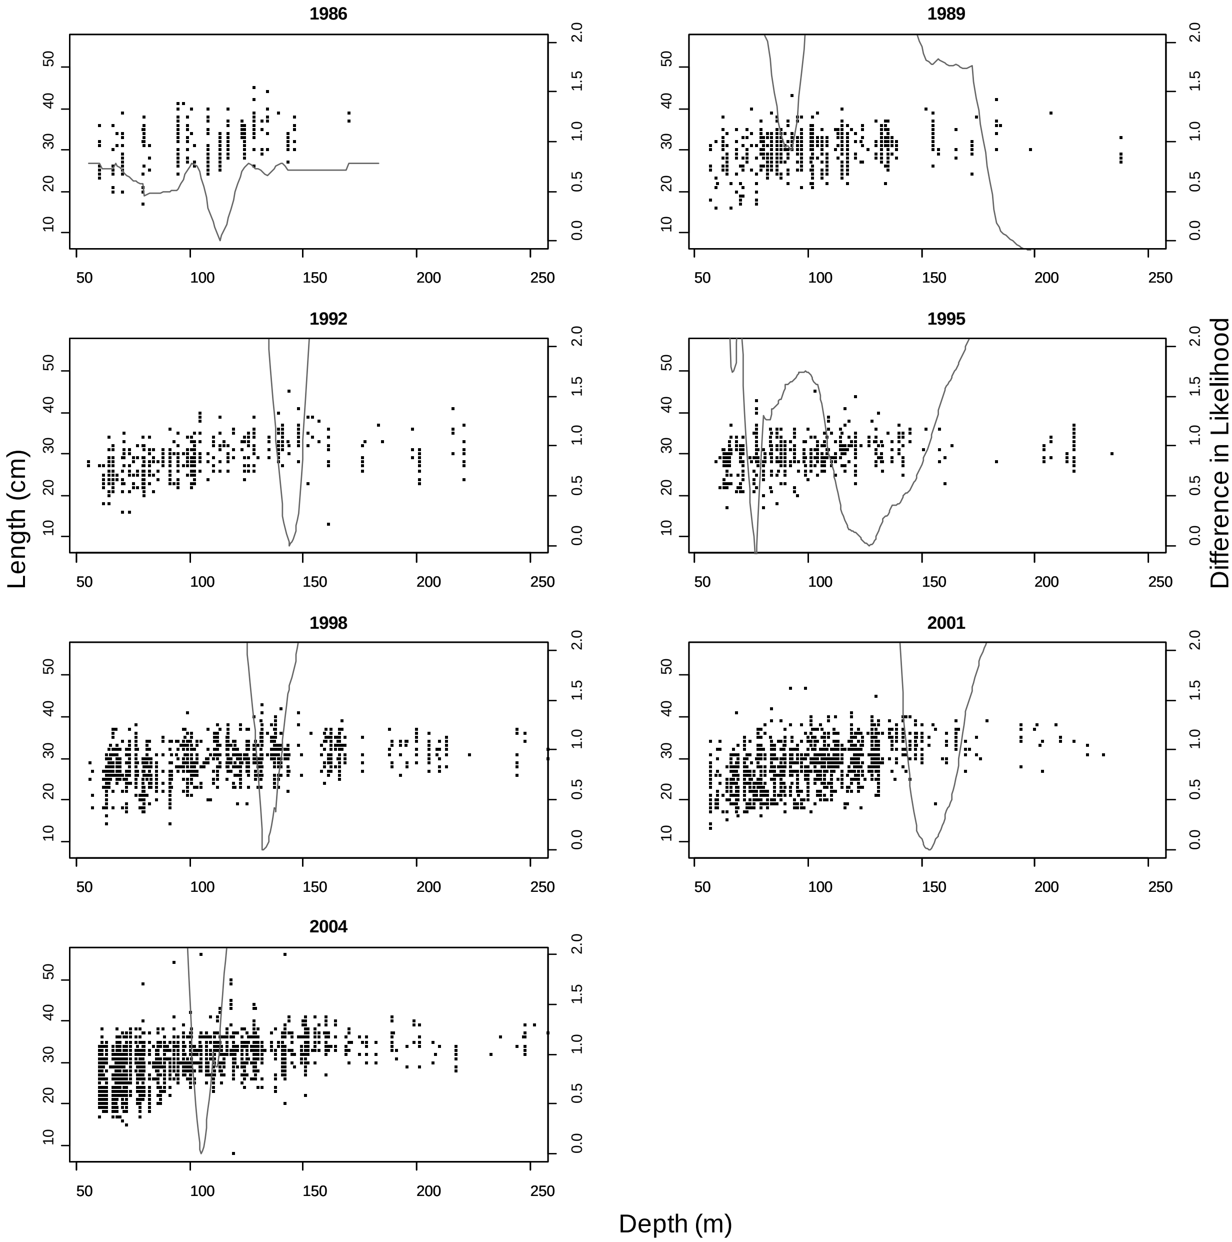


Figure A2: Plots of length vs depth from the Triennial survey for each year and males only with the likelihood profile of the breakpoint overlayed.

NWFSC Survey

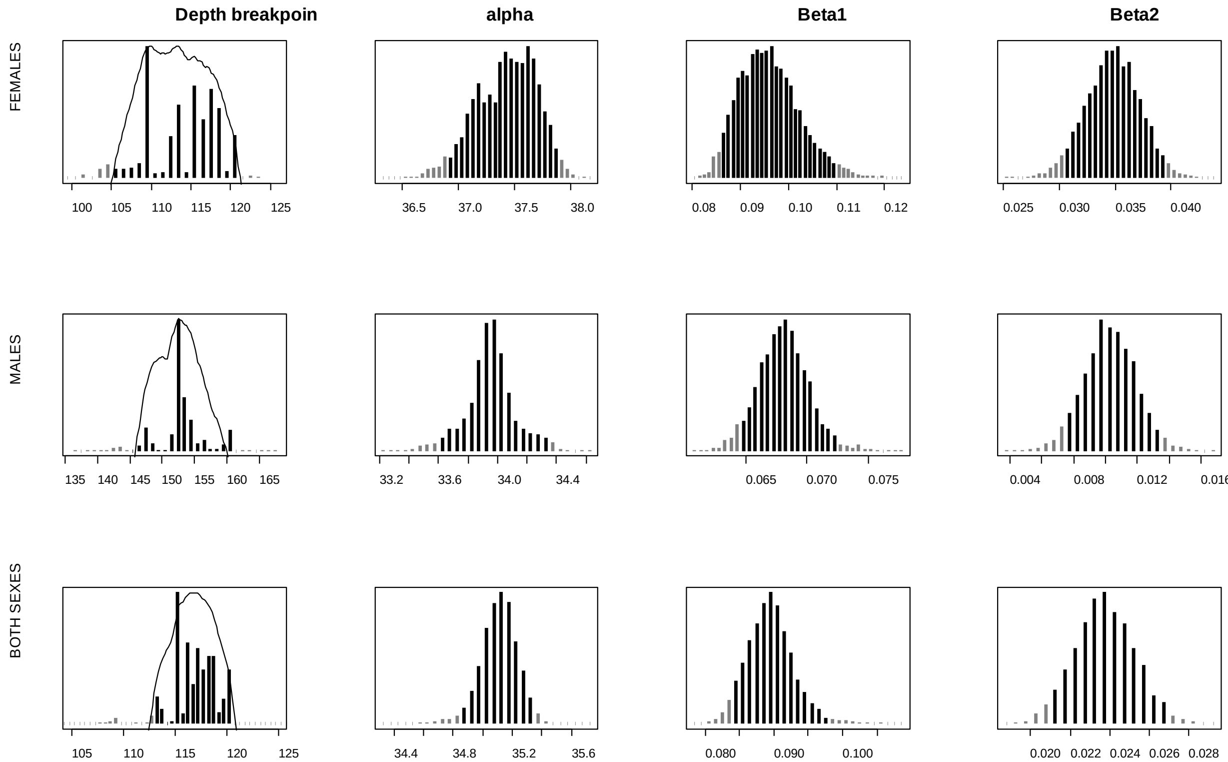

Figure A3: Plot of NWFSC survey bootstrap results from piecewise regression for each sex. The line in the depth breakpoint plot is a likelihood profile (the 95% CI is where the profile crosses zero).

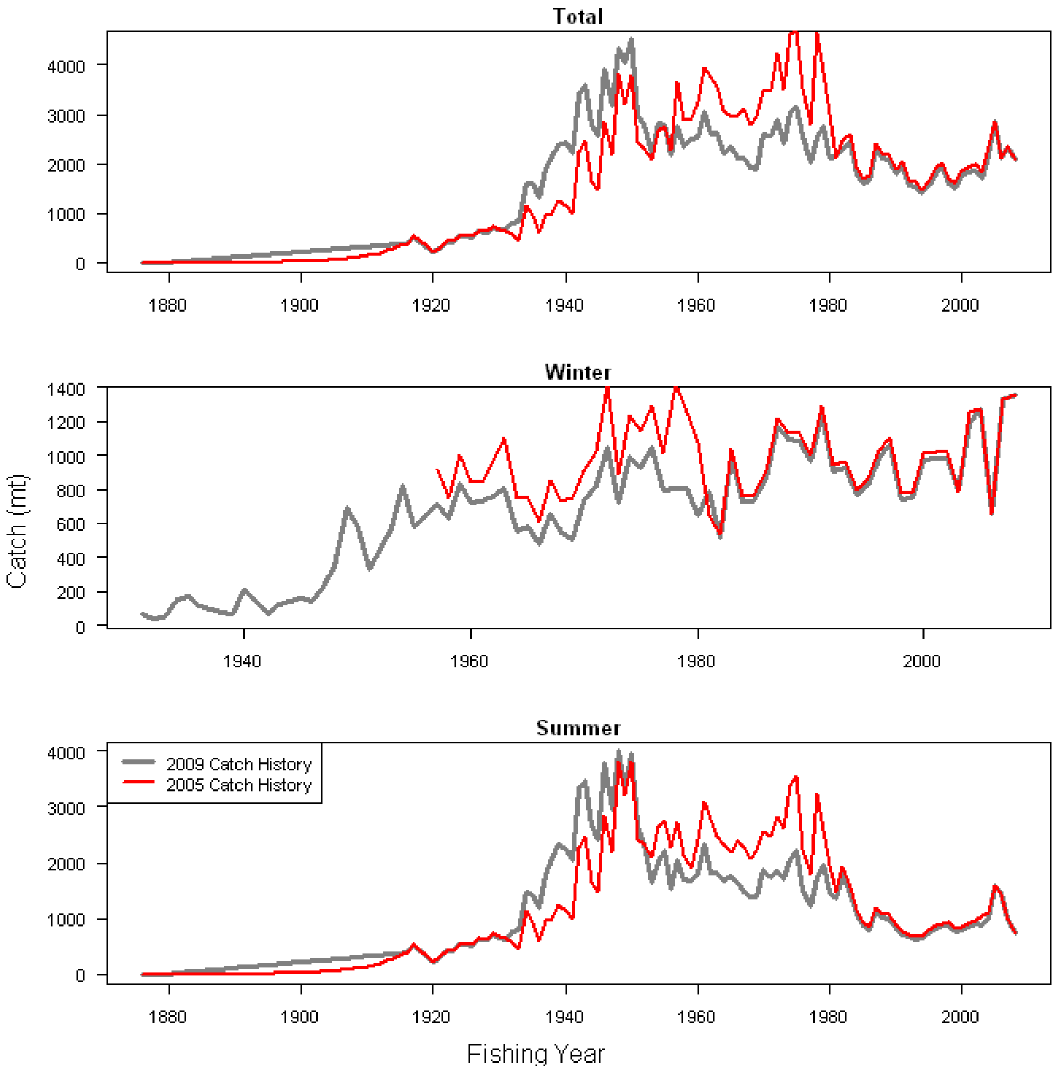
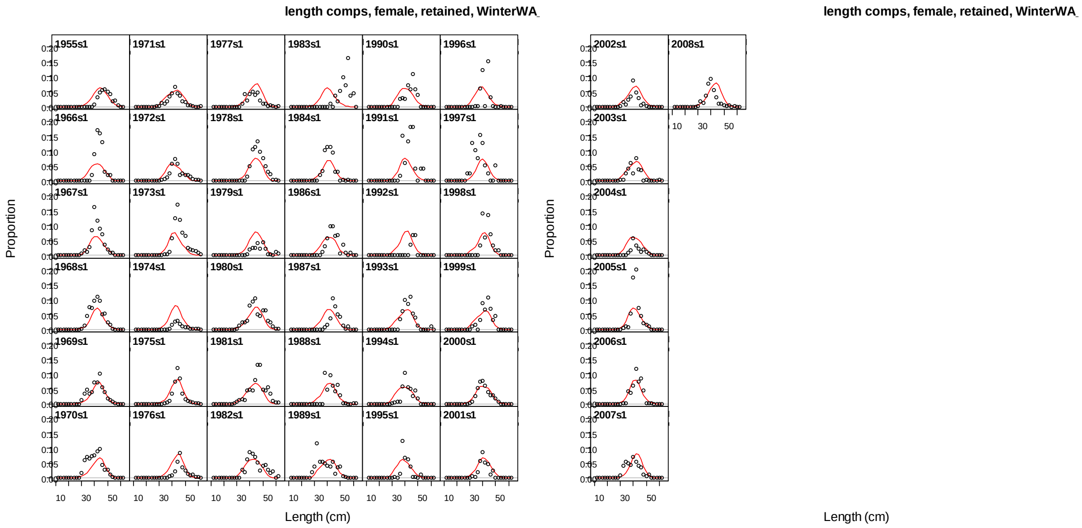
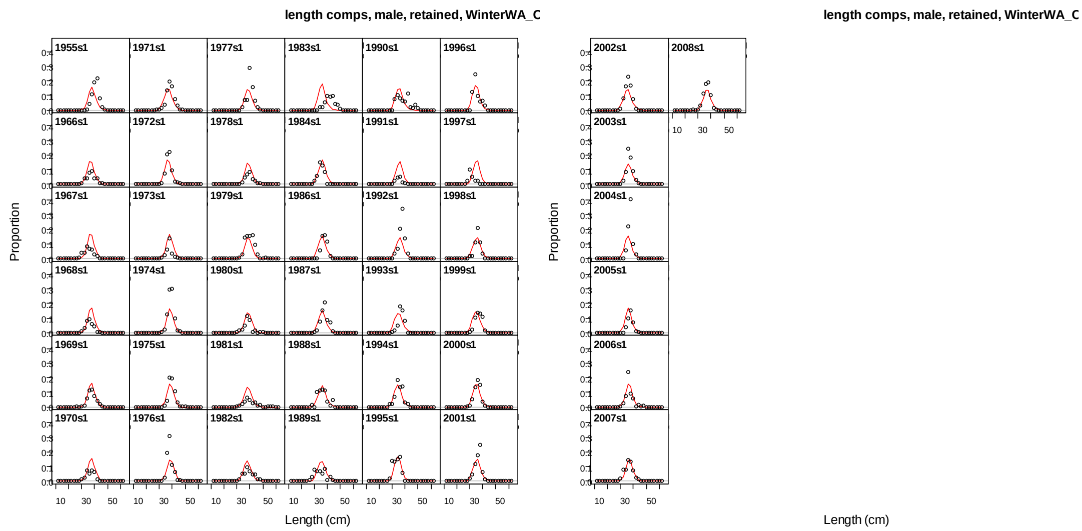
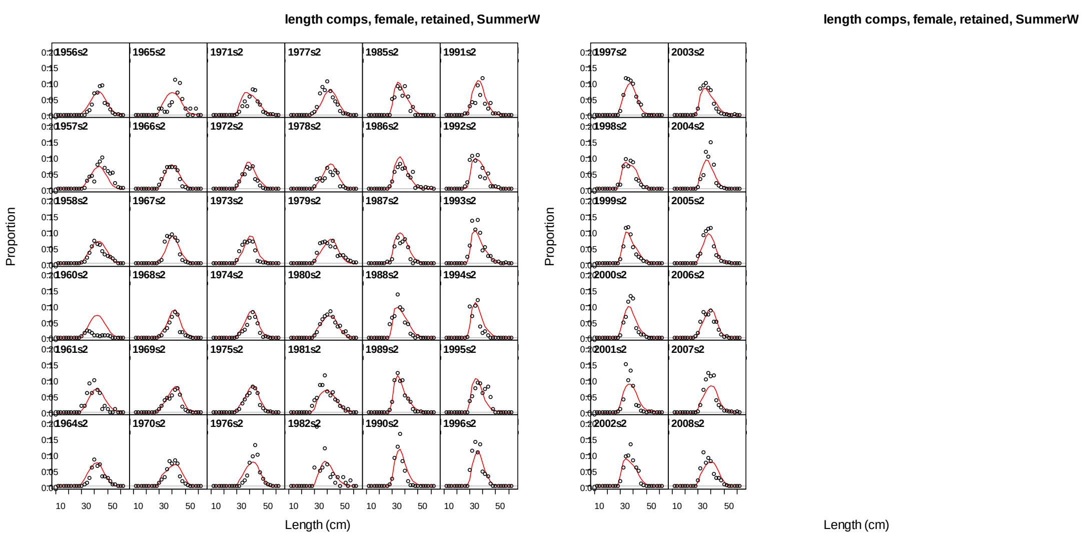
13. Appendix B: Comparison between the 2005 and 2009 catch histories.



14. Appendix C: Model fits and diagnostics for fishery age and length composition data.







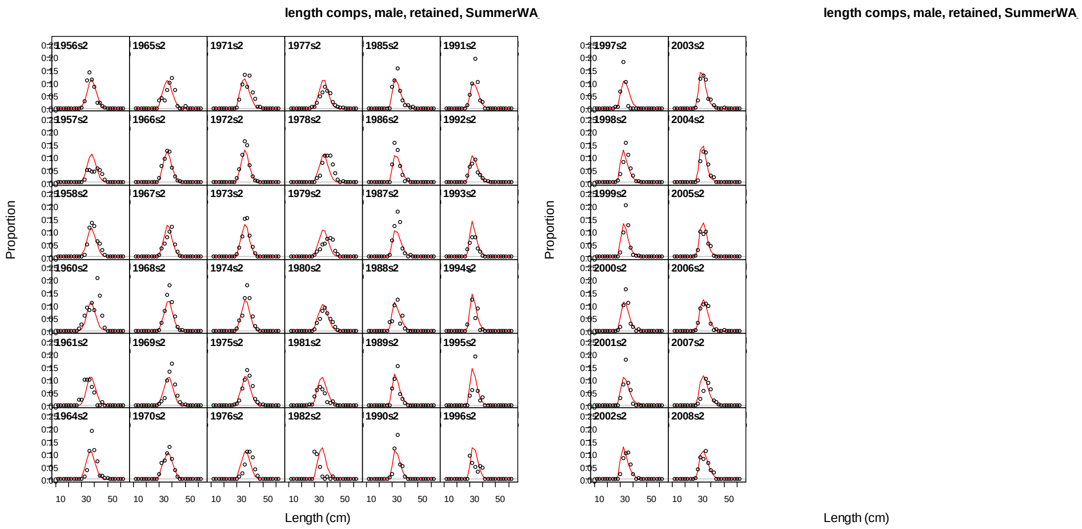


Figure C1. Fit to the Washington fishery length compositions.

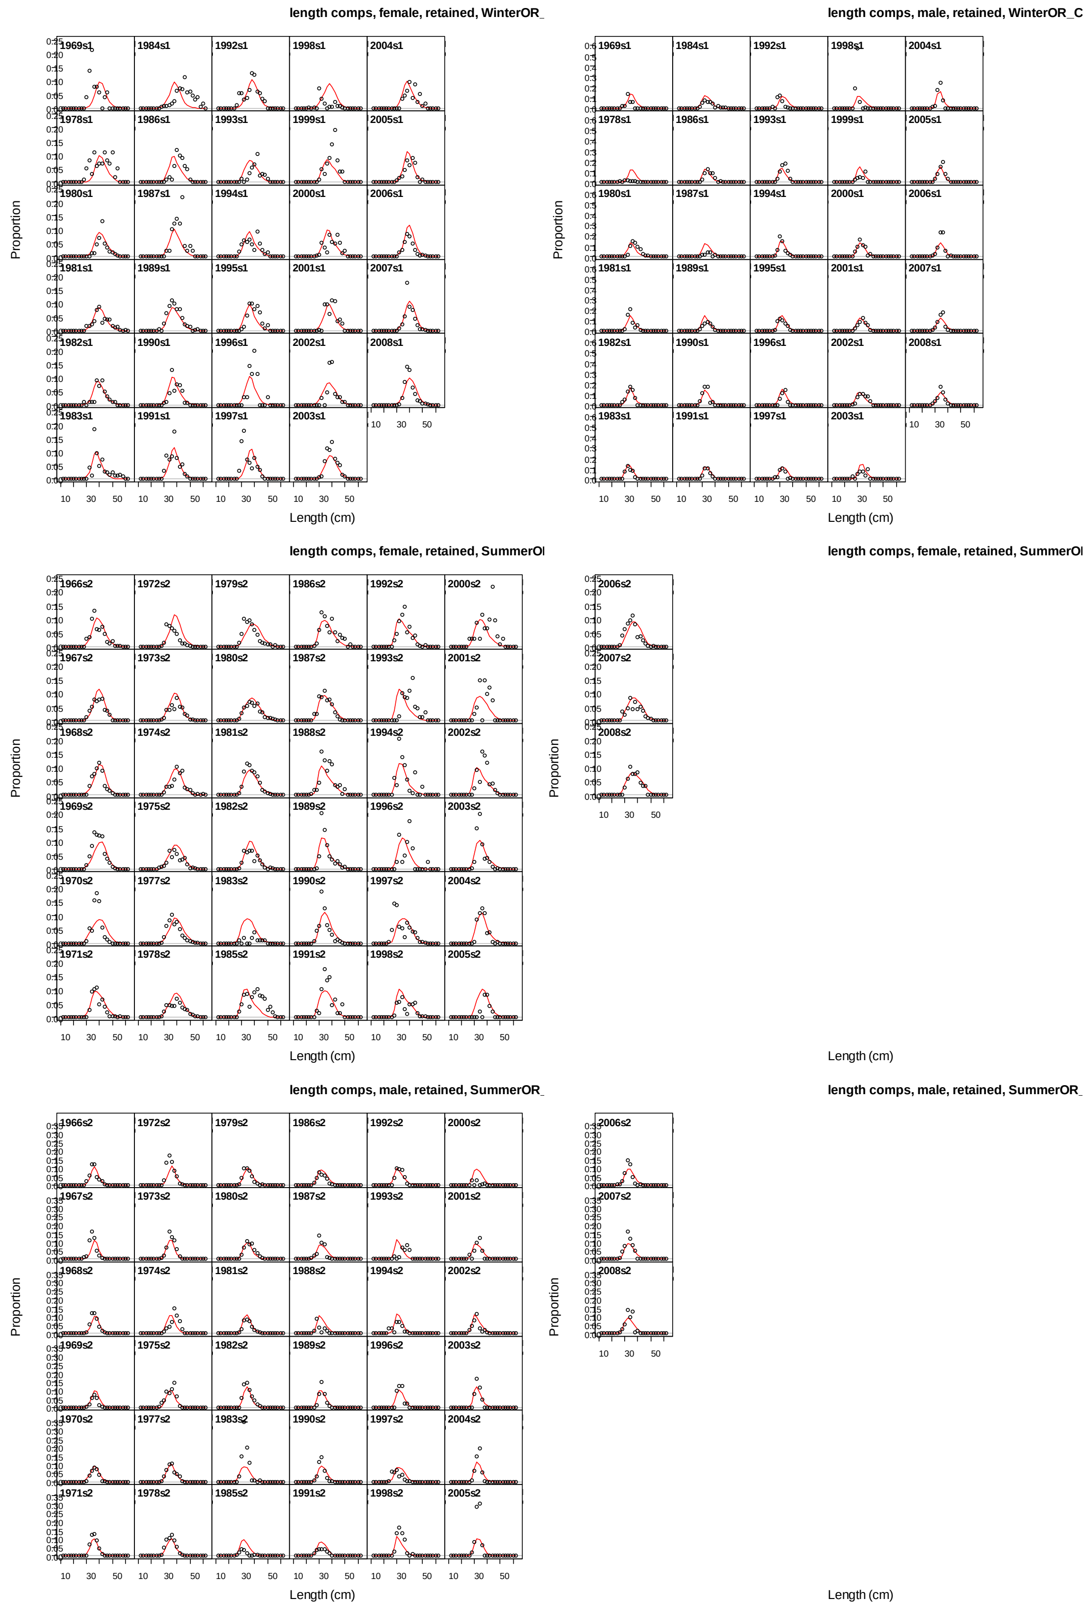

Figure C 2. Fit to the Oregon fishery length compositions.

16. Appendix E: Management Actions Potentially Impacting the Petrale Sole Fishery

Dan Erickson, ODFW Marine Resource Program, in collaboration with Brad Pettinger and members of industry compiled the following summaries of how management actions may have impacted the petrale sole fishery.

Major Management Shifts that could Impact Stock Assessments.

Effective October 18, 1982

- First trip limits established (widow rockfish and sablefish).

Effective January 1, 1992

- First **cumulative trip limits** for various species and species groups (widow RF; Sebastes complex; Pacific ocean perch; deepwater complex; non-trawl sablefish).

Effective May 9, 1992

- Increased the **minimum legal codend mesh size** for roller trawl gear north of Point Arena, California (40^o 30' N latitude) from 3.0 inches to 4.5 inches; prohibited double-walled codends; removed provisions regarding rollers and tickler chains for roller gear with codend mesh smaller than 4.5 inches.

Effective January 1, 1994

- Divided the commercial groundfish fishery into two components: the **limited entry** fishery and the open access fishery.

  A federal limited entry permit is required to participate in the limited entry segment of the fishery. Permits are issued based on the fishing history of qualifying fishing vessels.

Effective September 8, 1995

- The **trawl minimum mesh size** now applies throughout the net; removed the legal distinction between bottom and roller trawls and the requirement for continuous riblines; clarified the distinction between bottom and pelagic (midwater) trawls; modified chafing gear requirements;

Effective January 1, 1999:

- Dividing line between north and south management areas moved to 40^o 10'.

Effective January 1, 2000

- **chafing gear** may be used only on the last 50 meshes of a small footrope trawl, running the length of the net from the terminal (closed) end of the codend.

New rockfish categories in 2000.

- Rockfish (except thornyheads) are divided into new categories north and south of 40° 10' N. lat., depending on the depth where they most often are caught:

nearshore, shelf, or slope. New trip limits have been established for "minor rockfish" species according to these categories.

Nearshore: numerous minor rockfish species including black and blue rockfishes.

Shelf: shortbelly, widow, yellowtail, bocaccio, chilipepper, cowcod rockfishes, and others.

Slope: Pacific ocean perch, splitnose rockfish, and others

New Limited Entry Trawl Gear Restrictions in 2000.

- Limited entry trip limits may vary depending on the type of trawl gear that is onboard a vessel during a fishing trip: large footrope, small footrope, or midwater trawl gear.

  Large footrope trawl gear is bottom trawl gear, with a footrope diameter larger than 8 in. (20 cm) (including rollers, bobbins or other material encircling or tied along the length of the footrope).

  Small footrope trawl gear is bottom trawl gear, with a footrope diameter 8 in. (20 cm) or smaller (including rollers, bobbins or other material encircling or tied along the length of the footrope), except chafing gear may be used only on the last 50 meshes of a small footrope trawl, running the length of the net from the terminal (closed) end of the codend.

  Midwater trawl gear is pelagic trawl gear, The footrope of midwater trawl gear may not be enlarged by encircling it with chains or by any other means.

Effective during 2001:

- First conservation area was established (Cowcod Conservation Area)
- The West Coast Observer Program was initiated
- It is unlawful to take and retain, possess or land petrale sole from a fishing trip if large footrope gear is onboard and the trip is conducted at least in part between May 1 and October 31

Effective during 2002:

- Darkblotched Conservation Area was established.

Effective during 2003:

- Vessel buyback program was initiated (December 4, 2003)
- Yelloweye Rockfish Conservation Area was established
- Rockfish Conservation areas for several rockfish species were established.

Effective during 2004:

- Vessel Monitoring System (VMS) was initiated.

Effective during 2005:

- Selective flatfish trawl required shoreward of the RCA North of 40^{o} 10'.

Petrale Sole – First Major Regulations

Effective 1983
- First established coast-wide ABC limits for annual harvest of petrale sole.

Effective April 1, 1999 (April 16, 1999 for "B" platoon vessels)
- Limited Entry and Open Access *Sebastes* complex: north and south of Cape Mendocino, if a vessel takes and retains, possesses, or lands any splitnose or chilipepper rockfish south of Cape Mendocino, then the more restrictive *Sebastes* complex cumulative trip limit applies throughout the same cumulative limit period, no matter where the *Sebastes* complex is taken and retained, possessed, or landed.

Effective during 2000:
- For Limited Entry: large footrope trawl gear may be used to take………petrale sole from January 1-February 29 and November 1-December 31……., but these exceptions apply only on a trip that is conducted entirely during the periods in which use of large footrope gear is authorized. The presence of rollers or bobbins larger than 8 in. (20 cm) in diameter on board the vessel, even if not attached to a trawl, will be considered to mean a large footrope trawl is on board. Dates will be adjusted for the "B" platoon.

Effective during 2001:
- It is unlawful to take and retain, possess or land petrale sole from a fishing trip if large footrope gear is onboard and the trip is conducted at least in part between May 1 and October 31

Effective 2002:
- First cumulative trip limits for petrale sole

  In 2001, no restrictions except requirement for small footrope.

  In 2002, monthly limit of 15,000 pounds during July and August.

Effective 2003:
- Bimonthly cumulative trip limits for petrale sole were initiated.

Table E1. Annual RCA depth boundaries 2002 – 2009 (does not include in-season changes).

PETRALE SOLE

STAR Panel Report

May 4-8, 2009
Northwest Fisheries Science Center
Hatfield Marine Science Center
2032 SE Oregon State University Drive,
Newport, OR 97365

Reviewers:
Robin Cook, Center for Independent Experts
Xi He, Southwest Fisheries Science Center
Jean-Jacques Maguire, Center for Independent Experts
Theresa Tsou (Chair), Scientific and Statistical Committee (SSC) representative

Advisors:
John DeVore, Pacific Fishery Management Council (PFMC) representative
Dan Erickson, Groundfish Management Team (GMT) representative
Brad Pettinger, Groundfish Advisory Subpanel (GAP) representative

STAT Team Members present:
Melissa Haltuch, Northwest Fisheries Science Center
Allan Hicks, Northwest Fisheries Science Center

Overview

A draft assessment of the coastwide petrale sole (*Eopsetta jordani*) off the U.S. west coast was reviewed by the STAR panel during May 4-8, 2009. This assessment used the Stock Synthesis platform version 3.03a and incorporated a variety of data sources into the candidate base model. Data from commercial trawl fisheries included landings, discards, and age and length composition data. Abundance indices used in the model were a standardized CPUE index of the Oregon trawl fleets from 1987-1997 from Sampson and Lee (1999), the triennial shelf trawl survey (1980-2004), and the NWFSC shelf/slope trawl survey (2003-08). Biological information collected from both trawl surveys was also included.

Petrale sole was last assessed in 2005. Significant differences in data sources and model configuration between the 2005 and current assessment include:

- A coastwide model instead of separate north and south assessments in 2005;
- Reconstructed historical catches from California and Washington;
- An updated ageing error matrix;
- Incorporation of the NWFSC shelf/slope survey;
- Direct inclusion of discard information from Pikitch et al. (1988) and from the West Coast Groundfish Observer Program.

Multiple model runs were conducted and reviewed to examine model assumptions and structure, and to identify uncertainties in the assessment. The panel noticed that the estimates of B_0 and 2009 biomass are very sensitive to the assumption of the stock recruitment relationship and the 2008 NWFSC survey data. While the current stock status with reference to B_0 is notably different among model runs, the B_{MSY} estimate remains consistent. The panel is concerned that the 25% B_0 minimum stock size threshold (MSST or overfished threshold) proxy is highly uncertain because both B_0 and $B_{CURRENT}$ are highly uncertain in this assessment. Therefore, the panel recommends that reference points based on MSY are investigated as an alternative MSST. . The Panel notes that catches since 1951 have been fluctuating around MSY. The spawning biomass has largely been in the precautionary zone since about 1958 with the exception of a few years above B_{MSY} in the mid-1970s, and a series of years below B_{MSY} between the late 1980s to mid-late 1990s.

The STAR panel concluded that the petrale sole assessment was based on the best available data, and that this new assessment constitutes the best available information on petrale sole off the U.S. west coast. The STAR panel thanks the STAT team for their willingness to respond to panel requests and their dedication in finding possible solutions to difficult assessment problems.

Analyses requested by the STAR panel

1. **Split the triennial survey due to changes in starting date.**
   <u>Rationale</u>: The difference in the timing of the surveys, approximately one month later since 1995, is expected to result in a change in catchability of petrale sole because of its seasonal onshore-offshore migrations.

Response: Splitting the survey improved the fit marginally and the resulting catchability coefficients (q) were 0.51 for the early time series of the survey and 0.71 for the later time series of the survey. The selectivity curves for the NWFSC shelf/slope survey also changed marginally.

2. **Plot the biomass trends from the 1999, 2005 and current assessments to compare the differences.**
Rationale: This is a standard request to put the results of the current assessment in the context of previous ones. This was seen as particularly important for petrale sole given the changed perception in stock status.
Response: The biomass trajectories in the 1999, 2005 and the current assessments for 1980 to 2000 period are very similar and the confidence intervals for B_0 estimates in the 2005 and current assessments overlap. The 1999 and 2005 assessments suggested that biomass was increasing at the time of each assessment; while the current assessment indicates that biomass peaked in 2005 and has been decreasing since. The ratio of $B_{current}$ to B_0 (depletion) was higher in the 1999 assessment because the estimate of B_0 was smaller, largely due to the fact that historical catches back to 1976 were incorporated in the 1999 assessment and historical catches back to 1876 were incorporated in the 2005 and current assessments. The estimated 2005 depletion from the 2005 assessment is within the confidence interval of the estimated 2005 depletion from the current assessment.

3. **Remove all data related to 2008 NWFSC shelf/slope survey.**
Rationale: The objective of this request was to evaluate the influence of the 2008 NWFSC survey data.
Response: Removing the 2008 NWFSC survey data significantly increased the estimate of current biomass, decreased the estimated recruitment strength of the 2005 year class, and increased the recruitment strength of the three previous year classes from lower than average to average recruitment by losing the signal for the 2005 year class. The estimated current depletion changed from 0.14 to 0.24 due to a higher estimated 2008 biomass.

4. **Use a Ricker stock and recruitment relationship.**
Rationale: The Beverton-Holt stock recruitment curve is the standard choice for most assessments but there is no specific evidence to support this model over others for petrale sole. This species is an ambush predator and it could be hypothesised that the habitat available for young petrale sole to settle could become limited at high adult stock size. There is a high potential for density dependence, though no direct evidence for it. This request is to test and evaluate the influence of the assumed stock-recruitment relationship.
Response: Assuming a Ricker relationship provides a very similar fit to the Beverton-Holt assumption for the 1954 to 2008 time period, but the B_0 estimate is substantially lower. Because of the lower B_0, the ratio of $B_{current}$ to B_0 was higher. MSY estimates were very consistent under both stock-recruitment assumptions.

5. **Start assessment in 1939 and estimate initial F/depletion.**
   Rationale: Catch estimates prior to 1939 are more uncertain than those since. Size information is scarce before the 1960s and reliable fishery-independent abundance estimates start in 1980. Also, 1939 was the earliest reliable estimate for catches in Washington.
   Response: Three ways of doing this were explored: 1) start with an equilibrium catch and estimate initial equilibrium Fs; 2) start with an equilibrium age structure and estimate a multiplier on initial recruitment; and 3) start at a virgin, equilibrium state. All 3 options showed similar trends. The panel concluded that the current biomass trends were similar and MSY estimates were robust across these assumptions. Because the starting year did not make a difference in the results, the panel decided to initiate the assessment in 1876 when the first historical catches of petrale sole were documented.

6. **Allow selectivity functions to deviate without assuming blocks.**
   Rationale: The panel wanted to evaluate patterns and / or trends in fishery selectivity over time rather than using blocks.
   Response: Allowing smooth changes in fishery selectivities using annual blocks seemed to chase recruitments. The panel initially thought that time blocks on fishery selectivities were not necessary, but, under a no-time block structure, patterns in residuals appeared worse and the Hessian matrix did not invert. The panel finally decided on ten-year blocks starting in 1973. Results from a five-year blocking structure starting in 1973 were more variable and less parsimonious.

7. **Profiling on the length at minimum age.**
   Rationale: The panel wanted to test the influence of size at minimum age and investigate the effects of external estimates of growth.
   Response: The model-estimated length at minimum age seemed to explain the data better. Externally-estimated L_{MIN} resulted in a larger B_0 estimate and a lower current depletion of 4%. The model fit was degraded and the data did not support externally estimated parameters.

8. **Plot summer fishery CPUE and NWFSC survey biomass on same graph.**
   Rationale: The panel requested this plot to make it easier to directly compare these indices.
   Response: When plotted on the same graph and scales, the correspondence was seen to be very similar in recent years, especially for the Washington portion of the catch. There was a slight time shift in the peak values for Oregon and California fisheries CPUE compared with the survey. The panel concluded that future exploration of the Summer CPUE series as an index of abundance may be warranted.

9. **Provide the actual catch values for the big tows in NWFSC survey.**
   Rationale: The panel wanted to get an appreciation for the magnitude of petrale sole tows during the survey.
   Response: The STAT presented the top ten tows in the surveys, which ranged from 76 to 747 kg resulting in density estimates of 4 357 to 53 085 kg/km^2.

10. **Provide the data informing the length at maturity relationship.**
Rationale: The panel wanted to get an appreciation for how well the maturity model from Hannah et. al (2002)[1] fitted the macroscopic and microscopic observations of maturity.
Response: The panel was satisfied that the data supported the length at maturity relationship used in the model.

11. **Provide the historical Washington catch data used to interpolate historical catches during the 1930-1950 period.**
Rationale: The reconstruction of historical Washington catch estimates is one of the reasons for the difference between the 2009 and the 2005 assessments. The panel wanted to see if different interpolations could have been possible.
Response: The data were presented and the panel concluded that sensible catch interpolations had been done.

12. **Plot the catch series used in the 2005 and current assessments.**
Rationale: The panel requested these plots for direct comparison of catch histories used in these assessments.
Response: The panel could not evaluate the catch data directly; however, it was concluded that the new catch series should be used.

13. **Check the maximum length in surveys and compare with the maximum length in the winter fishery.**
Rationale: The commercial length frequencies seemed to show more larger fish than captured in trawl surveys and this could have implications for estimated fishery selectivities.
Response: A plot of the proportions at lengths greater than 50 cm showed that the maximum lengths in the surveys and winter fisheries were similar.

14. **Reduce effective sample sizes for survey data.**
Rationale: The panel wanted to see the effect of giving less weight to survey data.
Response: Reducing the effective sample sizes of survey data by half did not significantly affect selectivities nor other results.

15. **Provide the estimated growth parameters from other studies or assessments.**
Rationale: The panel was concerned that estimated growth parameters in the model and fishery selectivities could potentially be confounded, i.e. it could be growth rather than selectivity that varied over time..
Response: Estimated growth parameters from other studies were provided and were similar to those estimated in the model. The panel therefore concluded that there was no reason to assume alternative growth functions from other studies.

---

[1] Hannah, R.W., S.J. Parker and E.L. Fruth. 2002, Length and age at maturity of female petrale sole (Eopsetta jordani) determined from samples collected prior to spawning aggregation. U.S. Fish. Bull. 100:711-719.

16. **Explore the areal expansion used to expand survey results to estimate biomass.**
    Rationale: The panel was concerned that the areal expansion may have included areas where petrale sole are not found.
    Response: The habitat areas used by petrale were not available. The petrale sole densities are therefore expanded to the entire area surveyed which may contain habitats that are not suitable for petrale sole.

17. **Plot recruitment deviations in log space without error bars since 1939 for the base model and under requested sensitivity runs (i.e., no time blocking of fishery selectivities and start the fishery in 1939).**
    Rationale: The panel wanted to see how the various runs compared to understand the sensitivity of recruitment estimates to assumptions regarding time-varying fishery selectivity and the historical catch prior to 1939.
    Response: This graph was provided for all requested runs and showed a similar pattern of recruitment deviations, especially from 1970 to present.

Description of base model and alternative models used to bracket uncertainty.

The final base model uses data from the beginning of the fishery in 1876. The model estimates separate selectivity curves for 1876 to 1972, 1973-1982, 1983-1992 and 2003-2008, splits the triennial survey in 1995 into two series and assumes a Beverton-Holt stock recruitment relationship. A sensitivity run assuming a Ricker stock-recruitment relationship showed very similar trends in biomass estimates from the early 1950s to 2008, but a substantially smaller B_0. This resulted in a higher ratio of $B_{current}$ to B_0. A second sensitivity run excluded the 2008 NWFSC survey data, which resulted in a markedly higher biomass estimate for 2008 and, consequently, a higher $B_{current}$ to B_0 ratio. A final sensitivity run assigned half the effective sample size to the survey length composition data, which resulted in no significant change to the base model results.

Comments on the technical merits

The current assessment and the 2005 assessment provide similar biomass and depletion trajectories, with overlapping confidence intervals and similar estimates during the 1980-2000 periods. The 2005 assessment suggested that biomass was generally increasing through 2005 while the current assessment indicates that the stock has been declining since the peak biomass in 2005. While the 2005 assessment indicated that the stock was not overfished in 2005 and that overfishing was not occurring it did show that the stock had been below the minimum stock size threshold (MSST) for much of the previous three decades and had only increased above the MSST during the previous 1-3 years. Both the current and 2005 assessments agree that that stock declined below the B40% reference point during the 1950s to an all time minimum stock size during the early 1990s, followed by increases in the stock up to 2005.

The petrale assessment was thorough, with no major flaws, and well investigated with all requested sensitivity runs provided. The document was clear and well written.

Explanation of areas of disagreement regarding STAR panel recommendations:

A. Among STAR panel members (including concerns raised by GAP and GMT representatives); and

There were no areas of disagreement among STAR panel members, though concerns were raised regarding the estimated *q* value for the NWFSC shelf/slope survey. The panel regards the *q* value as a scaling factor and noted that biomass was expanded to the whole survey area in the depths petrale occur while it is unlikely the whole area represents petrale habitat. Potential differences in growth between the northern and southern substocks may need further exploration given that the 2005 assessment estimated higher growth rates for the southern substock than for the northern substock. However, there are no recent age data available from California fisheries to better explore these potential differences.

B. Between the STAR panel and STAT team:

There were no areas of disagreement between the STAR panel and the STAT

Unresolved problems and major uncertainties

The choice of an assumed stock-recruitment relationship is uncertain in the petrale sole assessment. While there are theoretical reasons to expect a Ricker stock-recruitment relationship, there is insufficient evidence to choose between Ricker and Beverton-and-Holt, and the panel defaulted to the more commonly used B&H relationship. Choosing a Ricker relationship, however, would result in a lower B_0 estimate and thus higher $B_{CURRENT}$ to B_0. The difference in perception is smaller if MSY – based reference points are used.

The q estimated for the NWFSC shelf/slope is approximately 6 times higher than that for the AFSC triennial surveys. Higher catch rates were observed in the NWFSC survey when compared to the Triennial survey, and even though some of the difference can be explained by gear design and the NWFSC survey ability to move around rocks, further investigation is needed

The model is sensitive to the 2008 survey data and removing the 2008 survey data results in a markedly higher 2009 biomass estimate.

While the STAT addressed aging errors, uncertainties in age-composition remain important.

Management, data, or fishery issues raised by the GMT or GAP representatives

The history of key management changes was provided and was useful in ground-truthing historical catch reconstructions and time-blocking fishery selectivities. The details regarding development of the fishery were provided and important events were identified.

Prioritized recommendations for future research and data collection.

- The comprehensive catch reconstructions currently underway in Washington and Oregon need to be completed. The mixing of U.S. and Canadian catches is of particular concern for the Washington fleet. The break-and-burn aging technique is recommended for determining petrale ages because it was estimated to be less biased than surface-read ages through a bomb radiocarbon age validation study.

- The current assessment platform (SS3) is structurally complex, making it difficult to understand how individual data elements are affecting outcomes. The panel recommends investigating simpler, less structured models, including statistical catch/length models, to compare and contrast results as data and assumptions are changed.
- Expand the stock assessment area to include Canadian waters to cover the entire biological range of petrale sole.
- The abundance vs. survey depth plot suggests that the highest summer densities of petrale sole are inshore of the survey area. Expanding the survey area inshore or implementing a new nearshore survey is recommended.
- A winter shelf/slope survey would be particularly valuable for a stock like petrale with seasonal onshore-offshore migrations.
- A management strategy evaluation is recommended for petrale sole because the estimates of B_0 and $B_{current}$ are sensitive to the assumed stock-recruitment relationship, making these reference points more uncertain, while B_{MSY} estimates are consistent among all the model run results. The usefulness of the Summer CPUE series as an index of abundance should be evaluated.

August 21, 2009

This document addresses the requests made on July 8 after the SSC review of the petrale assessment at the June 2009 PFMC meeting. The SSC requests were prepared under two general headers (1) Parameter confounding and (2) Use of model-based BMSY vs. the Council proxy for management advice with multiple deliverables under each heading. This document is structured by the deliverables requested with a note showing which main SSC request contained each deliverable.

1. **MCMC results for the base model and sensitivity model run with the steepness prior** SSC (1 & 2)

There were some bugs in Stock Synthesis with regard to the treatment of the recruitment deviations when conducting MCMC that were completely resolved on August 10. Due to a power shut down August 15-16 at the Montlake Lab the correct set of MCMC model runs for the petrale assessment were not started until August 17 and are currently running. These results are not included in this document but will be presented to the SSC groundfish subcommittee meeting during August 31 to September 2.

Specific items requested include:
Provide bi-variate plots of MCMC draws of NWFSC q, natural mortality, and stock recruit parameter of steepness and Rzero.
Characterize uncertainty in B_0, B_{MSY}, F_{MSY}, stock depletion, and $B_{40\%}$.
Use the asymptotic STdevs and the MCMC output
Annual SS3 SSB estimates and their variances from MCMC output.

2. Comparison of US and Canadian landings and size/age composition data
SSC (1)

The recent Canadian stock assessments of petrale sole (Fargo and Starr 2004, Fargo 2006) both suggest that Canadian landings of petrale sole in the B.C. trawl fishery averaged around 3000 mt annually between the late 1940s and the late 1950s. U.S. trawlers fishing in Canadian waters also landed substantial amounts of petrale sole during this period. However, the landings time series in these assessment models begins during 1956 (2004) and 1966 (2006), and do not include the peak removals of petrale sole in B.C. that occurred during the 1940's and early 1950's. The landings data from the Canadian stock assessments are available only in summarized form. Landings from 1966 to 1978 are summarized based on the calendar year while 1979-2006 are based on a fishing year beginning on April 1 and ending on March 31. The monthly Canadian landings data were requested in mid-July but are not available at this time. The lack of monthly landings data results in a mismatch between the seasonal structure of the US fleets in the US petrale sole stock assessment and the available Canadian landings data. To use the Canadian landings in the US petrale sole stock assessment the yearly Canadian data were allocated to the winter and summer fleets based on the seasonal proportions of catches from the Washington fleet.

While the Canadian assessments do not include the peak fishery removals during the 1940s and early 1950s both assessments note that by the mid-1960s landings had decreased (Figure 1) and petrale sole abundance had declined substantially (Ketchen and Forrester 1966). Both Canadian assessments concur that the petrale stock was at low abundance during the 1980s and 1990s and a TAC of 497 mt was established for this species in 1997 (Fargo and Starr 2004, Starr 2006). The TAC has increased to 600 mt in recent years (Star 2006).

The WDFW provided internal documents by Alverson and Chatwin (1957) that have area specific information on historical petrale sole landings in Canadian waters from 1938-1955. These landings are of the same order of magnitude suggested by the two previous Canadian petrale sole stock assessments, except for the peak catches in 1948 at around 6200 mt, which is coincident with the period of peak landings recorded in the US. A second grey literature document from WDFW (Anon. 1956) records landings from the period 1942-1949 of similar magnitude but the landings in this document are not used due to a lack of area specific information (it is not possible to separate US and Canadian catches from Canadian waters) and the shorter time series. Alverson and Chatwin (1957) also report results from petrale sole tagging experiments that record petrale sole moving as much as 350 miles. Since petrale sole are known to have the ability to move such long distances all landings in Canadian waters (PSMFC areas 3C, 3D, 5A, 5B, 5C, 5D, and 5E), with the exception of those from the Strait of Georgia, are included in the Canadian landings history used as a sensitivity model run in the US petrale sole stock assessment. In summary the Canadian landings data are taken from the following sources:

1. 1938-1955 Alverson and Chatwin (1957)
2. 1956-1978 2004 assessment
3. 1979-2009 2006 assessment
4. 2006-2008 assumed equal to TAC of 600 mt

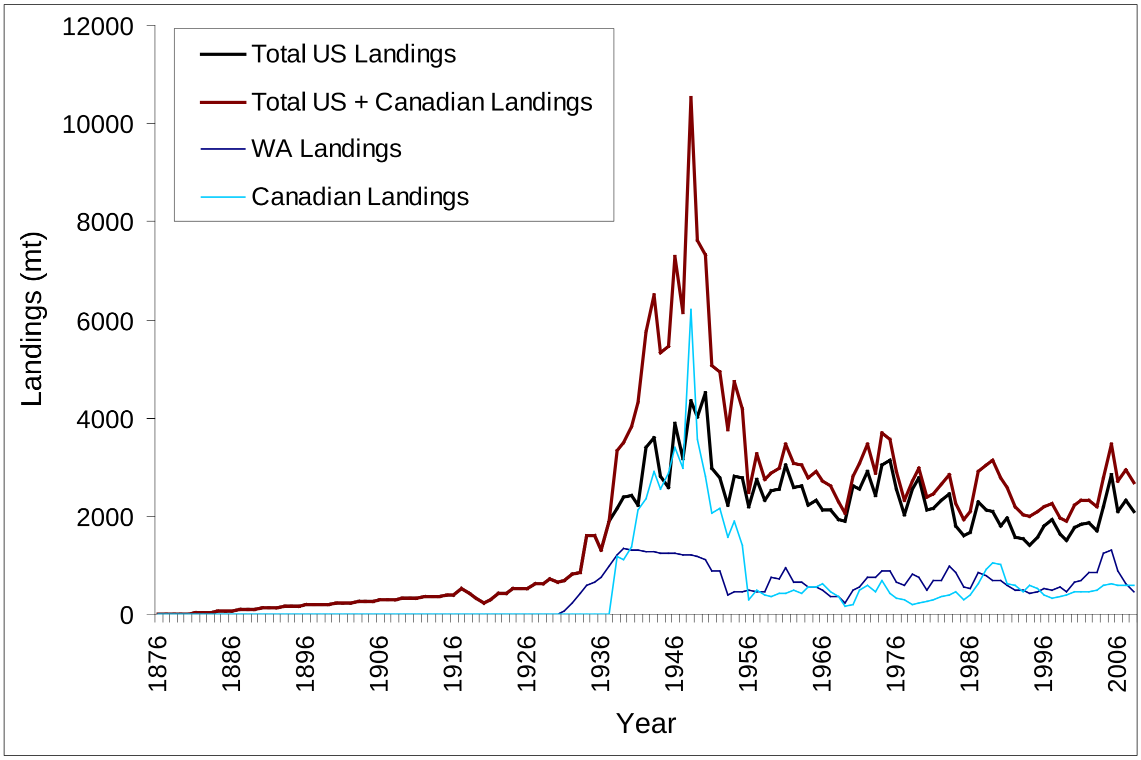

Figure 1. Landings of petrale sole from Washington, Canada, total US, and combined US and Canadian waters.

The two previous Canadian stock assessments used delay difference models due to sparse fishery data with low sample sizes and spatially limited research samples from the early 2000s that are not representative of the stock (Fargo and Starr 2004, Starr 2006). However, we received the raw Canadian age- and length-composition data on August 10 and present these data. The age and length compositions discussed below are expanded by the total weight for each sample but are not expanded by the total catch for each area. Where data are sparse the compositions are presented annually using the fishing year (November – October) as described in the 2009 petrale sole assessment. The data presented seasonally use the same seasons as the 2009 petrale sole stock assessment.

Petrale sole begin to be observed in both the Canadian and Washington petrale sole fisheries around 4 years old, although the Washington fishery has more frequent observations of 2 and 3 year old fish (Figures 2-3). However, the maximum ages observed in the Canadian commercial data are greater than the ages from the Washington commercial data (Figures 2-3). Male petrale sole aged greater than 20 years are routinely present in the Canadian commercial age data whereas the Washington fishery rarely takes male petrale sole older than 10 years. Similarly female petrale sole aged greater than 20 years, and up to 40 years, are commonly observed in the Canadian fishery, while female petrale sole taken in the Washington fishery are rarely older than 15 years. The marked difference in ages between petrale sole observed in the commercial fisheries in US and Canadian waters suggest a more lightly exploited stock in Canada.

Comparisons between the US and Canadian commercial length-composition data suggest that both fisheries start to routinely take petrale sole around 30 cm (Figures 4-5). The Canadian fishery observations generally take larger petrale sole (males 50 cm, females 65 cm) compared to the US fishery (males 45 cm, females 55 cm) (Figures 4-5).

Canadian age data from research samples are very sparse and do not cover the full range of the stock. It is also difficult to compare the US survey data and Canadian research samples since these samples do not cover the same period of time (Figure 6-7). Therefore we do not try to draw conclusions from these data. The same patterns persist between the US and Canadian length-composition data from survey/research samples as those described above for the commercial samples (Figure 8-9).

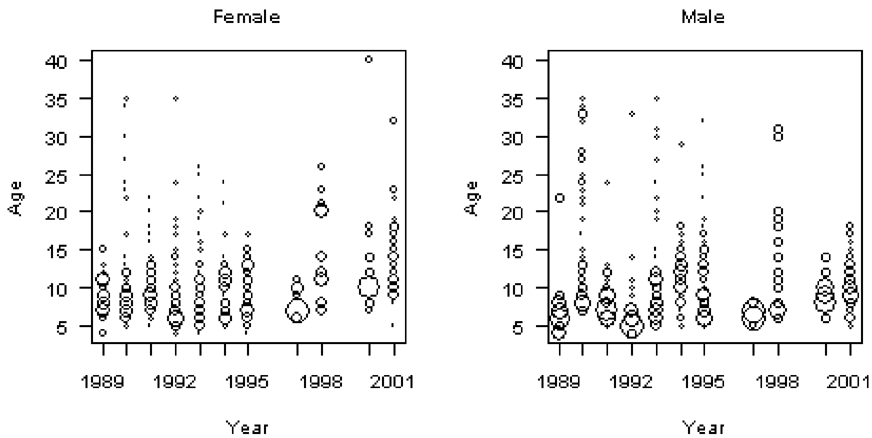

Figure 2. Canadian petrale sole commercial age compositions, observed ages range from 4 to 40.

3. **Model sensitivity with Canadian data** (SSC 1)

The Canadian landings are included in the base model using multiple methods. The first method adds the Canadian landings directly to the Washington landings. Method 1 was not successful, the model was poorly behaved, took about 10 hours to run, and clearly did not converge. The second method includes the Canadian landings as catches from a separate fleet and then mirrors the Canadian fleet retention and selectivity to the Washington fleet. Similarly to method 1, method 2 was poorly behaved, did not converge, and took a very long time to run. Both of these methods implicitly assume that the Canadian 'fleet' shares the same characteristics as the Washington fleet. This assumption is less than satisfactory for the following reasons:

1. In order to correctly remove the catch from the population (to estimate selectivity) the model needs length and/or age data from the catch. Furthermore, the time blocking on selectivity is based upon management actions that affected the behavior of the US fleets and does not necessarily impact the Canadian fleet, particularly since 1977.
2. In order to account for discarding the model needs estimates of discard rates from the Canadian fleet as well as length and/or age compositions of the discard (to estimate retention. While discard practices may have been more similar in the pre1977 fisheries more recent regulations have likely impacted discard practices in the Canadian fleet.
3. The survey indices that are currently in the model are spatially inconstant with the area covered by the Canadian fleet in the model. To do this properly requires a survey index from Canadian waters.
4. The NWFSC survey is the main source of information for estimating growth in the assessment model. However the survey does not extend into Canadian waters so the growth must be assumed to be the same between the US and Canada, which may not necessarily the case.
5. While the Canadian ages are break and burn reads and likely to have low levels of bias and imprecision it is unclear what, if any, information exists to estimate the correct ageing error bias and imprecision associated with the age data for inclusion in the model.

A third method for including the Canadian catches allowed the free estimation of selectivity curves for the Canadian fleet, did not estimate a retention curve, and did not use the time blocks that were used for the Washington fleets. This model also failed to converge and had extremely long run times. The results from these model sensitivity runs are not presented under deliverable 4 since there were obvious problems with lack of convergence.

Given the points above and the multitude of problems with including only the Canadian catches in the model the STAT feels that it is necessary to include all of the appropriate Canadian data to evaluate the impact of the Canadian fleet on the petrale sole population ranging from B.C. to California. This is a substantial undertaking that would result in an essentially new assessment for petrale sole. A joint US-Canadian assessment will require buy-in from staff at the Canadian Department of Fisheries and Oceans since considerable collaborative effort between US and Canadian stock assessors will be needed to complete a joint assessment. The management implications of such an assessment should also be considered prior to such an undertaking.

4. **Model sensitivity runs** SSC (1)
    a. steepness prior of Pleuronectids in Meyers (1999), mean = 0.794, standard deviation = 0.093.
    b. a more informative prior on female M, mean 0.2, standard deviation 0.0125
    c. Canadian landings (not included, see point 3)

The full comparison of the requested model sensitivities with the base case model is shown in Table 1 below. The model sensitivity with the Meyers (1999) pleuronectid prior on h has a marginally higher negative log likelihood but essentially fits the data equally well. The estimate of h decreased from 0.95 to 0.91 and the estimate of M increased from 0.15 to 0.17. The unfished biomass decreased and the current biomass increased to produce a final stock status of 13% depletion rather than 12% depletion (Figure 10). The model sensitivity with a more restrictive prior on M has a worse fit to the data. This model produces a higher estimate for female M (0.18) and a lower estimate of h (0.86). The unfished biomass decreased and the current biomass increased to produce a final stock status of 14% depletion rather than 12% depletion (Figure 10). It is notable that the depletion relative to the estimated Bmsy remains the same across both the h and M model sensitivity runs (Table 1).

5. **Sensitivity of Bmsy to selectivity patterns and the distribution of catch among fleets** SSC (2)

The original SSC request was to examine the impact of selectivity patterns on the estimates of the MSY spawning biomass. However, the STAT feels that the distribution of catch between fleets, particularly as the fishery shifted from the summer to the winter season, is potentially more important than changes in selectivity. The intent was to present results for both changing selectivity and catches between fleets. Unfortunately the STAT discovered a bug in the SS forecast report for seasonal models shortly before this meeting. The program is not changing the selectivity patterns, regardless of the choice of years specified for averaging selectivity over in the forecast.SS file. The program does correctly use the distribution of catches between fleets provided in the forecast.SS file. Therefore, the STAT provides a set of MSY reference points for six scenarios, whereby all of the catch is taken by each fleet in turn. The STAT feels that this will provide some information on the range of plausible MSY reference points.

The results are presented for MSY based management quantities for the average catches between fleets during each of the selectivity time blocks as well as for all catches being taken evenly between either the summer or winter fleets given the 2003-2008 selectivity patterns (Table 2a). The results of each of the six petrale sole fleets taking all of the catch given the 2003-2008 selectivity patterns are shown in Table 2b. These scenarios are meant to bound the range of potential values for the reference points. Table 3 shows the management quantities from the base model for comparison. When the catches are taken only during the summer and winter the MSY reference points are more variable (Tables 2a and 2b). The estimates of MSY spawning biomass range between a low of 4,277 mt and a high of 5,010 mt when all of the catch is taken by an individual fleet (Tables 2a and 2b). The current base model estimate is 4,796 mt (Table 3). The stock depletion as a fraction of the estimate Bmsy is ranges between 57%-69% (Tables 2a and 2b). Depending upon the distribution of catches between fleets the MSY catches range between 2,148 and 2,740 mt.

Table 2a. MSY based biological reference points from the 2009 petrale sole stock assessment base case model considering the time blocks on fishery selectivity as well as the distribution of catches between fleets.
**Only the distribution of catches between fleets, not selectivity patterns, are changing in this table due to the SS bug discussed above.

6. **State the case for using either revised proxy reference points or species specific estimates of Bmsy from the assessment model** SSC (2)

The STAR panel review report and the 2009 petrale sole stock assessment provide results regarding the reliability of the estimated reference points presented in the 2009 petrale sole stock assessment. The choice of approached for quantifying reference points, either the current 40% Bmsy proxy, the estimate of Bmsy, or some revised proxy based on a value such as Bmsy/B0, should be independent of the acceptance of the assessment. Below, the STAT summarizes the STAR report, assessment results, and further investigations requested after the June 2009 SSC meeting regarding the reliability of the Bmsy estimates from the 2009 petrale sole stock assessment that can inform this management choice.

- The STAR panel notes that annual catches since 1951 have been fluctuating around the estimated MSY. The MSY-based reference points from the 2009 assessment suggest that the spawning biomass has largely been between the estimated Bmsy and 50% Bmsy, since about 1958 with the exception of a few years above B_{MSY} during the mid-1970s, and a series of years below B_{MSY} between the late 1980s to mid-late 1990s.
- The estimates of Bmsy as a fraction of B0 from recent flatfish assessments on the west coast that report Bmsy, petrale sole, English sole, and arrowtooth flounder, are consistently around 20% B0. The estimated Bmsy reported in the 2005 Dover sole assessment is roughly 25% of B0. These are much less than the proxy management target of 40% B0. Flatfish generally have higher natural mortality, grow faster, and mature earlier than many rockfish, making them more productive, which is illustrated by the typical estimates of 20-25% of B0 for flatfish assessments.
- The choice of an assumed stock-recruitment relationship is uncertain in the petrale sole assessment. While there are theoretical reasons to expect a Ricker stock-recruitment relationship, there is insufficient evidence to choose between Ricker and Beverton-and-Holt, and the panel defaulted to the more commonly used B&H relationship. Choosing a Ricker relationship, however, would result in a lower B_0 estimate and thus a higher ratio of $B_{CURRENT}$ to B_0. The difference in perception between the two assumptions is smaller if MSY based reference points are used. Therefore, the panel recommended that reference points based on MSY are investigated as an alternative MSST.
- Both the current and 2005 assessments agree that the stock declined below the B40% reference point during the 1950s to an all time minimum stock size during the early 1990s, followed by increases in the stock up to 2005. The current flatfish proxy reference points (40% B0 and 25% B0) suggest the stock has been below the current overfished threshold since the 1950s and that catches in excess of F40% have been occurring for nearly this entire time period. However, the petrale sole stock is productive enough to have maintained stable catches over the past approximately 50 years and has shown

large recruitments at low stock sizes, resulting in increases in abundance since the early 1990s.

EXECUTIVE SUMMARY

Stock

This assessment reports the status of the bocaccio rockfish (*Sebastes paucispinis*) off of the west coast of the United States, from the U.S.-Mexico border to Cape Blanco, Oregon (representing the Conception, Monterey and Eureka INPFC areas). Although the range extends considerably further north, there is some evidence that there are two demographic clusters of bocaccio, centered around southern/central California and the west coast of British Columbia, with a relative rarity of bocaccio (particularly smaller fish) in the region between Cape Mendocino and the Columbia river mouth. This is supported by apparent differences in growth, maturity and longevity, although genetic evidence seems to indicate a single west coast population. Within the stock area, there is also evidence of limited demographic separation, which is treated through some separation of fleets and data. These and other issues related to stock identification and relative levels of demographic mixing and isolation remain important research questions for future assessments.

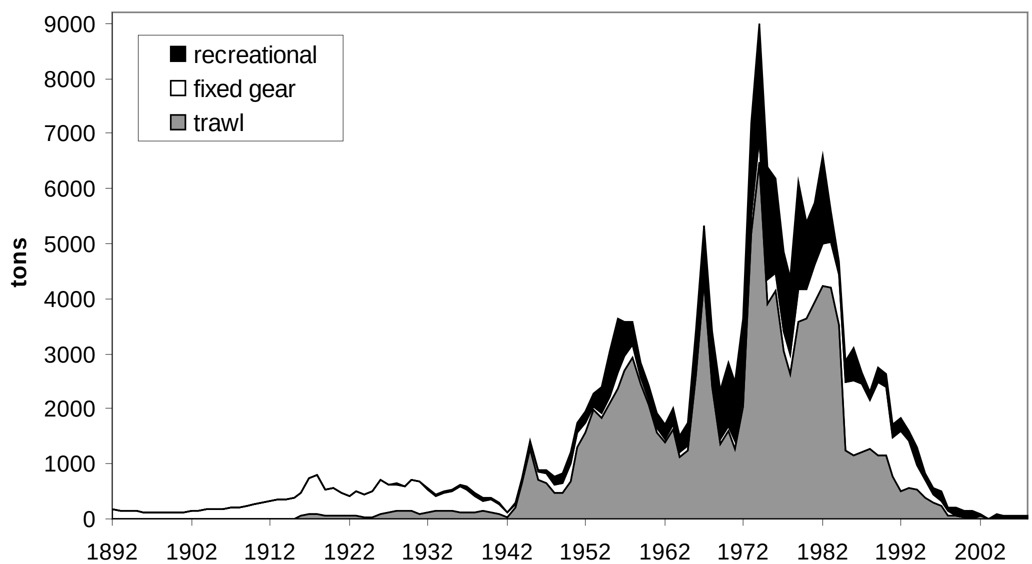

Figure E1: Catch history of bocaccio rockfish (in metric tons) in the assessment area from 1892-present

Catches

Bocaccio rockfish have long been one of the most important targets of both commercial and recreational fisheries in California waters, accounting for between 25 and 30% of the commercial rockfish (*Sebastes*) historical catch over the past century. However, this percentage has declined in recent years as a result of stock declines, management actions and the development of alternative fisheries (particularly the widow rockfish fishery in the early 1980s). The catch history for this assessment begins in 1892, a major shift from recent assessments which began in 1951, and relies heavily on the catch reconstruction efforts and products recently developed for historical California groundfish landings. Although the recent (post-1950) catch history has changed only modestly, the revised catch history prior to 1950 has a substantial impact on the perception of stock status.

Table E1. Recent catches (in metric tons) of bocaccio rockfish south of Cape Blanco

	trawl south of 38° N	trawl north of 38° N	hook and line	setnet	rec south of 34.5° N	rec north of 34.5° N

Data and Assessment

The last full assessment of bocaccio rockfish was done in 2003 in Stock Synthesis 1, and subsequently updated (with the same software) in 2005 and 2007. This assessment uses the Stock Synthesis 3 (version 3.03a), expands the area modeled from Cape Mendocino, CA to Cape Blanco, OR, and begins the model at 1892 rather than 1950. This model includes catch and length-frequency from six fisheries, two trawl fisheries (north and south of 38° N), a hook and line fishery, a set net (gillnet) fishery and recreational fisheries south and north of Point Conception, CA. No age data are used in this model. Fisheries dependent relative abundance (CPUE) indices, unchanged from the last assessment, are used for the trawl fishery and the two recreational fisheries; a recruitment (age-0) index based on recreational pier fishing is also included, revised since its removal from the 2003 assessment. Fisheries independent data used in the last assessment and continued here include the CalCOFI larval abundance time series and the triennial trawl survey index; new fisheries independent indices include a GLMM index based on the NWFSC combined survey index, the new NWFSC Southern California Bight hook and line survey, and the revised (coastwide) pelagic juvenile index. A recruitment index based on power plant impingement data is described but not included in the base model, as are point estimates of spawning and total biomass in the Southern California Bight based on larval production. The most significant parameter change includes the estimation of a steepness value of 0.57 in the base model; the natural mortality rate is unchanged from recent assessments (0.15). Growth is estimated within the model and results are consistent with past assessments.

Stock spawning output

The spawning output was estimated to be very slightly below the estimated unfished levels in the beginning of the modeled period, due to very moderate fishing pressure that began no later than the 1850s. The spawning output trajectory continues a very moderate decline until about 1950, but is estimated to have declined steeply from the early 1950s through the early 1960s as catches rose from several hundred to several thousand tons. The biomass increased sharply thereafter, as a result of one or several very strong recruitment events in the early 1960s, exceeding the mean unfished biomass level through the early 70s, when catches again began to climb rapidly to their peak levels, associated with high fishing mortality rates and a rapid drop in spawning output. Fishing mortality remained high throughout the 1980s and 1990s, even as catches, biomass and spawning output declined rapidly. Fishing mortality declines towards the end of the 1990s, in response to severe management restrictions, and coincident with a series of several strong year classes (following a decade of very poor recruitment) that began in 1999. Since the early 2000s, spawning output has been increasing steadily. The base model estimates a current (2009) depletion level of 28%, a 2008 SPR of 0.950, with the forecast under constant harvest rates indicating a continued increase in spawning output.

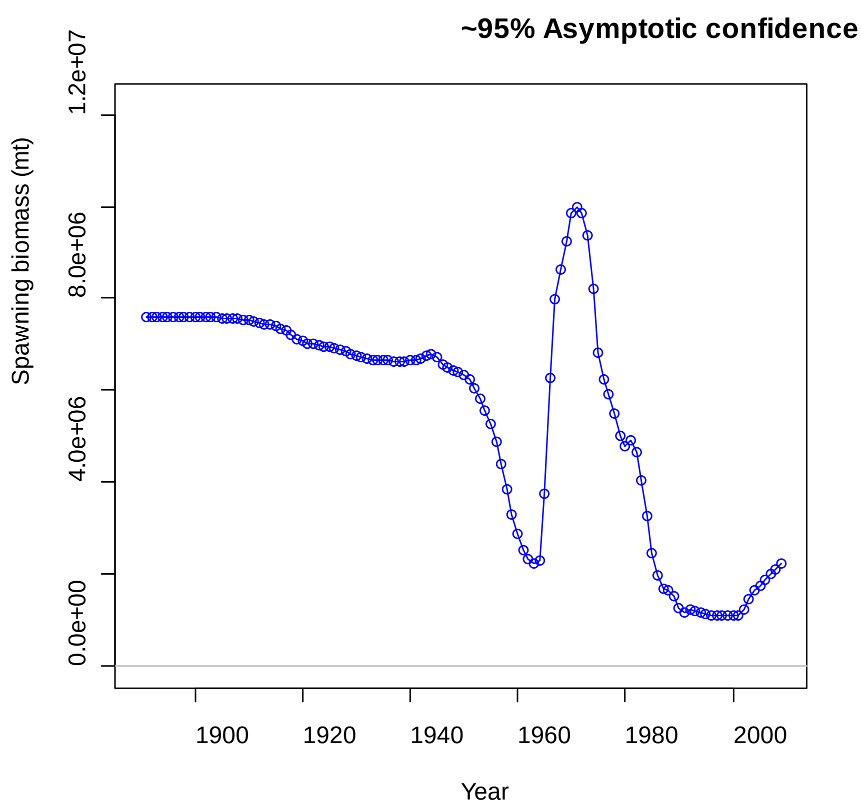

Figure E2. Estimated spawning output time series (1892-2008) for the base case model with approximate asymptotic 95% confidence interval.

Table E2. Recent trends in estimated spawning output and relative depletion level

Year	Spawning Output	Confidence interval (~95%)	Depletion	Confidence interval (~95%)
1999	1091300	(803600 - 1379000)	13.88%	(0.09 - 0.17)
2000	1087600	(792900 - 1382300)	13.84%	(0.09 - 0.17)
2001	1094600	(792340 - 1396860)	13.93%	(0.09 - 0.18)
2002	1225700	(884940 - 1566460)	15.59%	(0.10 - 0.20)
2003	1453900	(1046540 - 1861260)	18.50%	(0.12 - 0.24)
2004	1628200	(1169340 - 2087060)	20.72%	(0.14 - 0.27)
2005	1733900	(1239080 - 2228720)	22.06%	(0.15 - 0.28)
2006	1848700	(1313540 - 2383860)	23.52%	(0.16 - 0.3)
2007	1980000	(1400300 - 2559700)	25.19%	(0.17 - 0.33)
2008	2103200	(1480260 - 2726140)	26.76%	(0.18 - 0.35)
2009	2209900	(1546440 - 2873360)	28.12%	(0.18 - 0.37)

Recruitment

Recruitment for bocaccio is highly variable, with a small number of year classes tending to dominate the catch in any given fishery or region. Recruitment appears to have been at very low levels throughout most of the 1990s, but several recent year classes (1999, 2003, 2005) have been relatively strong given the decline in spawner abundance, and have resulted in an increase in abundance and spawning output. The juvenile cruise index suggests low recruitment in 2007 and 2008, years in which length composition data are not indicative of above average recruitment . Estimated recruitments and confidence intervals for those values are shown in Table E3 and Figure E3.

Table E3. Estimated recruitment with 95% confidence interval, 1999-2009

Year	Recruits (x1000)	Confidence interval (~95%)
1999	8067	(5647 - 10487)
2000	268	(22 - 514)
2001	318	(74 - 562)
2002	1250	(714 - 1786)
2003	3952	(2660 - 5244)
2004	566	(232 - 900)
2005	3642	(2368 - 4916)
2006	433	(129 - 737)
2007	838	(308 - 1368)
2008	850	(0 - 1742)
2009	3428	(0 - 10336)

Figure E3. Estimated recruitment of bocaccio rockfish with 95% asymptotic confidence intervals, from 1892-2009 (freely estimated only from 1954-2008).

Reference Points

Reference points are presented in Table E4, which presents the unfished summary biomass, unfished spawning output, mean unfished recruitment and the proxy estimates for MSY based on the $SPR_{50\%}$ rate, the fishing mortality rate associated with a spawning stock output of 40% of the unfished level, and MSY estimated based on the spawner/recruit relationship. The corresponding yields for these three estimates vary by a relatively minor amount, ranging from 1250 tons based on the spawning output proxy and 1270 tons based on the MSY estimate. However, the relative impact of the higher harvest rate on spawner abundance is results in a significantly lower equilibrium spawning output and summary biomass with both the SPR proxy and the estimated MSY rate, relative to the spawning output reference point. Additionally, estimates of the different MSY proxies are based on the relative proportion of total catches by fishery in 2008 (which in no way are intended to imply a de facto sector allocation), and will change modestly depending upon allocation among fisheries with differing selectivity curves.

Table E4. Summary of reference points for bocaccio rockfish from the base model

Unfished Stock	Estimate	95% Confidence Limits Lower	Upper
Summary (1+) Biomass	44070	36029	52111
Spawning Output	7860000	6426040	9293960
Equilibrium recruitment	5060	4129	5991

	Yield reference Points		
	$SSB_{40\%}$	SPR proxy	MSY est.
SPR	0.512	0.500	0.461
Exploitation rate	0.066	0.069	0.078
Yield	1250	1258	1270
Spawning output	3140000	3031020	2651890
SSB/SSB_0	0.40	0.39	0.34

Exploitation Status

The 2009 spawning output is estimated to be at 28.3% of the unfished spawning output, significantly lower than the target levels, but slightly above the minimum stock size threshold (Figure E5). The draft base model indicates that the exploitation rates for bocaccio rockfish has remained at low levels since the turn of the millennia, and the population has been increasing accordingly (Table E5, Figures E5-E6).

Table E5. Base model estimated exploitation rate and spawning potential ratio (SPR)

Year	Exploitation rate	SPR rate
1999	0.034	0.754
2000	0.023	0.825
2001	0.018	0.912
2002	0.010	0.988
2003	0.001	0.922
2004	0.008	0.906
2005	0.010	0.949
2006	0.005	0.949
2007	0.005	0.941
2008	0.006	0.950

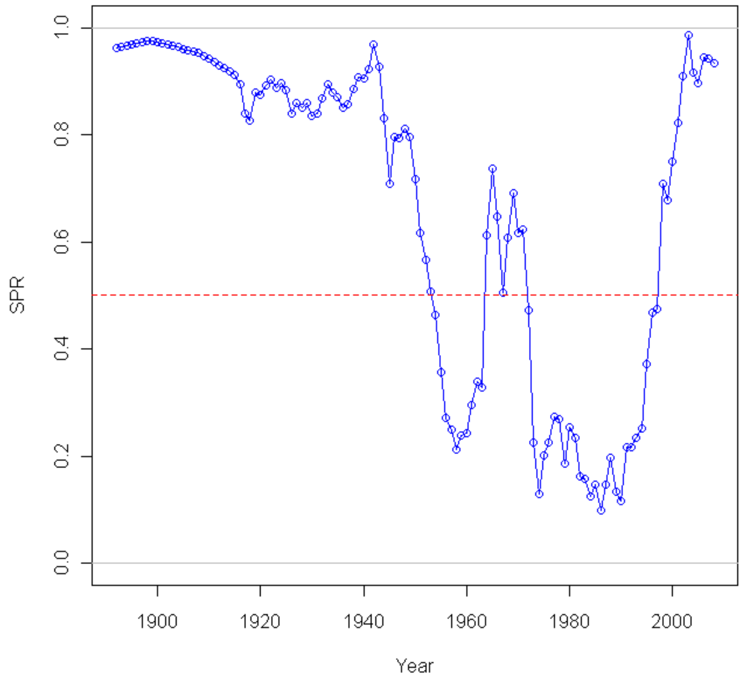
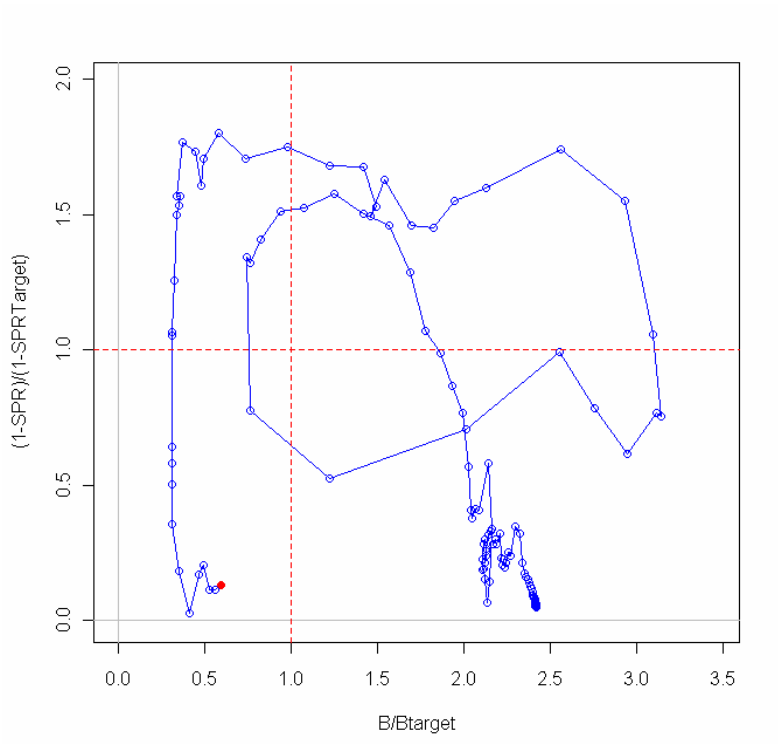
Management Performance

Bocaccio rockfish were formally designated as overfished in March of 1999, after the groundfish FMP was amended to incorporate the mandates of the Sustainable Fisheries Act reauthorization to the MSFCMA. The rebuilding policy adopted by the PFMC held the rebuilding OY constant at 100 MT for the years 2000-2002, with the intention of switching to a constant fishing rate policy beginning in 2003. However, due to an extremely pessimistic 2002 assessment, the 2003 OY was set to 20 tons OY. A more optimistic assessment in 2003 led to a 2004 OY of 199 tons. The OY has been set at a range of values between 218 and 307 tons since then (Table E6), with actual catches (including discards) estimated to be less than half of that amount in most years since 2003.





Figures E5- E6. Spawner potential ratio (SPR) over time (top), with reference proxy for *Sebastes* (0.5) and phase plot of SPR rate plotted against SSB, against target levels (bottom).

Table E6. Management performance

	commercial catches	recreational catches	ABC	OY
1999	73	124	230	230
2000	28	112	164	100
2001	22	109	122	100
2002	49	41	122	100
2003	5	7	244	20
2004	19	66	400	199
2005	27	81	566	307
2006	19	41	549	306
2007	9	53	602	218
2008	44	34	618	218

Unresolved problems and major uncertainties

Although much of the parameter uncertainty is reported, natural mortality (M) is treated as fixed, as are several important selectivity parameters. Consequently, the reported asymptotic confidence intervals underestimate the true parameter uncertainty. Although the data seem to be relatively informative with respect to steepness, the lack of age data lead to a potentially misleading interpretation of the sensitivity to alternative values of natural mortality. There is clear tension in the model between several key indices, particularly the CalCOFI index and the southern recreational CPUE index, which tend to reflect a more optimistic view of stock status, and the trawl cpue and triennial survey index, which tend to reflect a more pessimistic view of stock status. This tension is explored further in the decision table. The manner in which selectivity is estimated for the triennial trawl survey continues to be problematic, as it has for past assessments, although the application of a GLMM index seems to result in a more plausible index. Despite other sources of parameter and model uncertainty, and the potentially confounding impacts of management actions in both reducing the availability of data in recent years, there appears to be clear signs that the stock is rebuilding at a relatively rapid rate. Data from relative recent, short term surveys do not yet appear to be informative with respect to trends in abundance, although they are informative with respect to cohort strength.

Table E7. Forecast of bocaccio ABC, OY, spawning biomass and depletion for the base model based on the SPR= 0.777 fishing mortality target (OY) from the previously adopted rebuilding plan, and $F_{50\%}$ overfishing limit/target (ABC).

Year	ABC (mt)	OY (mt)	Age 1+ biomass (mt)	Spawning output	Depletion
2009	831	267	12,808	2,209,950	28.11%
2010	744	251	12,618	2,228,890	28.35%
2011	714	246	12,671	2,206,150	28.06%
2012	753	265	13,018	2,199,380	27.98%
2013	824	299	13,605	2,252,490	28.65%
2014	894	339	14,340	2,352,740	29.93%
2015	950	377	15,151	2,481,040	31.56%
2016	992	413	15,991	2,625,210	33.39%
2017	1025	445	16,833	2,777,630	35.33%
2018	1051	474	17,663	2,933,000	37.31%
2019	1074	500	18,472	3,087,910	39.28%
2020	1094	517	19,256	3,239,680	41.21%

Decision Table

As both the STAT and the STAR Panel identified the major sources of uncertainty in the model as relating to the tension between two generally pessimistic indices (both derived primarily from north of Point Conception, California) and two optimistic indices (both derived primarily from south of Point Conception). Consequently, the two alternative states of nature sequentially increased the emphasis on each of these groups to bracket uncertainty (Table E8). The low abundance scenario (State 1) was obtained by upweighting ($\lambda = 10$) the triennial and southern trawl CPUE indices, while the high biomass scenario (State 2) was obtained by upweighting the southern recreational CPUE index and the CalCOFI indices. Thus, these scenarios also provided useful contrast between an apparent, but poorly understood, spatial dimension to relative abundance trends, as the data suggest that recovery may be taking place more rapidly in the south, and recovery in the central/northern California region may be dependent on an influx of fish from the southern area.

Table E8: Decision Table for the bocaccio assessment, where State 1 has the triennial and trawl CPUE indices emphasized, and State 2 emphasizes southern rec CPUE and the CalCOFI indices.

Research and Data Needs

Stock structure for bocaccio rockfish on the West Coast remains an important issue to consider with respect to both future assessments and future management actions. Although a reanalysis of the genetic evidence done for this assessment suggests no significant differentiation among the major oceanographic provinces in the California Current, the apparent differences in growth, maturity, and longevity, are indicative of moderate demographic isolation. Although an area model could be a worthy approach for addressing some of these questions, the lack of mixing or movement data would make such an effort challenging, and questions regarding the appropriate scale of such models remain largely unresolved.

The potential to develop defensible aging criteria for bocaccio in the southern area should be evaluated further, particularly if such criteria could be developed in a coordinated effort among workers along the west coast. Although production aging is likely to remain a challenge, future aging efforts would likely improve the ability to adequately inform natural mortality rates, growth and variability of size at age, and possibly contribute to an improved understanding of differences in life history parameters and rates in different regions of the West Coast.

With respect to both time varying growth and a more comprehensive evaluation of the interaction between climate and fecundity, additional research into the consequences of poor environmental conditions in affecting bioenergetic allocation patterns should be explored in greater detail. Efforts underway to investigate these questions, which should ultimately improve the interpretation of the CalCOFI larval abundance data as well as better inform efforts to model time-varying growth.

Since large scale area closures and other management actions were initiated in 2001, the spatial distribution of fishing mortality has changed over both large and small spatial scales. Not only has this effectively truncated several abundance indices (recreational CPUE indices), this confounds the interpretation of survey indices as well as fishery dependent and independent length frequency data. This is a problem for virtually all west coast groundfish, and should be addressed accordingly.

The application of juvenile indices to inform future recruitment remains an area ripe for additional investigations. Such indices have successfully captured the magnitude of some large recruitment events in the past, although they have missed others. Given the high recruitment variability observed in bocaccio, even indices with high uncertainty are likely to be an improvement over recruitment predicted from the spawner-recruit relationship. However, a better appreciation of the strengths and weaknesses of these indices is an important research priority.

C. INTRODUCTION

The name bocaccio is derived from the Italian for "bigmouth," bocaccio were also often called "bocacc" by early Italian fishermen, "merou" by Portuguese fishermen, "jack" by some American fishermen, "andygumps" by some British Columbia fishermen, "tomcod" for young bocaccio caught around wharfs, salmon grouper, and longjaw and many others (Love et al. 2002). The genus, *Sebastes*, is Latin for magnificent of course, and the species name, *paucispinis*, is a reference to the paucity of head spines relative to most other species of *Sebastes*. The body shape is best described as an elongate, laterally compressed fish with a very large mouth (thus the name) and a protruding lower jaw with a prominent knob at the end of their lower jaw. The upper jaw (maxillary) also extends to beyond the eye, distinguishing bocaccio from the often co-occurring chilipepper rockfish (Miller and Lea 1972). Underwater, subadult and adult bocaccio appear pink, pink-brown, gray or red; upon capture most appear a brighter reddish or salmon color mixed with brown, however considerable variation in colors and mottled patterns have been reported (Love et al. 2002). Both juvenile and adult stages grow rapidly, although growth slows considerably in mature adults; maximum reported sizes are 91 cm and to approximately 8 kg. In an extensive review of phylogenetic relationships among *Sebastes*, Hyde and Vetter (2007) found that bocaccio were most closely related to both chilipepper (*S. goodei*) and shortbelly (*S. jordani*) rockfish, although that lineage dated back approximately 6 million years. Adult systematics are described in more detail in Phillips (1957; 1964) and Love et al. (2002); larval distribution and descriptions are provided by Moser (1967; 1996) and pelagic juvenile life history stages and growth are described in Woodbury and Ralston (1991).

C.1 Management History

As the management history is closely linked to the history of many of the past assessments, highlights from previous modeling approaches are included in this section, and the assessment history section focuses on the transition from the 2003 assessment (and subsequent updates) to this assessment. Together with chilipepper rockfish (*Sebastes goodei*), bocaccio have long been one of the most important rockfish species in California commercial fisheries, particularly off of central and southern California (development of fisheries and trends in landings in the historical period are discussed in great detail in the catch reconstruction section). Throughout most of this period, domestic groundfish fisheries were managed by state management agencies, and in California waters there were few restrictions on harvest other than prohibitions on trawl fishing in state waters (within 3 miles of shore) and minimum mesh size requirements. Foreign fisheries caught significant volumes of some groundfish (Rogers 2003; also discussed in the landings section) in offshore waters of the west coast from 1966 through 1976, at which point harvest was limited by passage of the Magnuson-Stevens Fishery Conservation and Management Act (MSFCMA), which extended U.S. control over living marine resources within 200 miles of the coastline. The Pacific Fishery Management Council (PFMC) assumed management responsibility for west coast groundfish when the Groundfish Fishery Management Plan (FMP) became effective in September 1982.

From 1983 through 1990 the PFMC routinely adopted an acceptable biological catch (ABC) for bocaccio of 4,100 MT for the Monterey INPFC area and 2,000 MT for the Conception area from 1983 through 1990. Landings in other areas were considered too small to warrant a separate

ABC. These ABCs were based solely on historical (domestic) landings during selected periods; however actual landings were a (declining) fraction of the allowable landings throughout this period. In response to concerns about bocaccio stock conditions, an assessment was conducted in 1990 (Bence and Hightower 1990). The assessment results initially resulted in a recommendation for an 800 metric ton (mt) ABC for the combined Conception-Monterey-Eureka INPFC areas (for both commercial and recreational fisheries) for 1991; however, a harvest guideline of 1,100 mt was ultimately adopted for both 1991 and 1992. During those two years, actual harvest exceeded the harvest guideline by 300-500 mt (Figure 1; Table 1). Management measures used to constrain catches were primarily effort controls, with trip limits for commercial fisheries (trawl and fixed gear) and daily bag limits of rockfish in recreational fisheries. Trip limits were implemented for all rockfish species as a complex through 1990, generally limited to 40,000 lbs per trip. Species-specific trip limits began to be implemented in 1991, when trip limits were constrained to 25,000 lbs per trip of which no more than 5,000 lbs could be bocaccio. However, these limits were relaxed to 50,000 lbs per trip of which no more than 10,000 lbs could be bocaccio in 1992.

In 1992 the PFMC reviewed a new assessment for bocaccio (Bence and Rogers 1992). The ABC estimated from that assessment, based on strict adherence to the target fishing mortality rate at that time ($F_{35\%}$), was 1,540 mt. The assessment also projected that spawning and total biomass were expected to continue to decline under status quo harvest rates, and recommended that the 1,100 mt ABC be maintained. However, the PFMC adopted the 1,540 ton ABC (with the harvest guideline the same) for 1993 and 1994. The new assessment had also accommodated some expected discard in the trawl and set net fisheries that often fished to the trip limits. In 1994 the Council determined that few trips were being impacted by trip limits, such that the discard-based reduction was unnecessary and the ABC and harvest guideline was adjusted to 1,700 mt for 1995 and 1996. During this period, trip limits were replaced by monthly catch limits, which fluctuated in values throughout the year in response to efforts to achieve, but not exceed, harvest guidelines. Actual catches of bocaccio during this period were far below harvest guidelines, presumably in response to declining availability associated with continued harvest and ocean conditions that led to a long period of very poor recruitment.

A stock assessment conducted in 1996 (Ralston et al. 1996) indicated that the stock was in severe decline, and the PFMC drastically reduced the ABC to 265 mt in 1997, and to 230 mt with adoption of an $F_{40\%}$ policy in 1998 and 1999. In March of 1999 the stock was formally designated as overfished, after the groundfish FMP was amended to incorporate the mandates of the Sustainable Fisheries Act reauthorization to the MSFCMA. Later that year, an assessment by MacCall et al. (1999) estimated that the southern stock was only 2.1 percent of the unfished spawning output. Perhaps ironically, both the management regime and the climate regime shifted almost simultaneously; the decade-long string of poor recruitments ended in 1999 with early indications of a strong 1999 year class. The rebuilding policy adopted by the PFMC held the rebuilding OY constant at 100 mt for the years 2000-2002, with the intention of switching to a constant fishing rate policy beginning in 2003. Trip limits for trawl and fixed gear fisheries were reduced substantially during this period, in recreational fisheries a two-fish daily bag limit was imposed for bocaccio, and additional time-area closures were implemented in 2002 to reduce the recreational catch of bocaccio.

The 2002 assessment (MacCall 2002) utilized more information, particularly recreational fisheries CPUE indices and recruitment indices, and examined both a California-wide model as well as individual models for the areas north and south of Point Conception. The regional models provided a more optimistic perspective of stock status in the southern region, and a more pessimistic perspective of the central/northern California region, due to the absence of evidence for the strong 1999 year class in fisheries data from the northern area. However, the review panel recommended that a single, coastwide model be used to provide management advice. This model recognized the importance of the 1999 year class, but estimated that the stock spawning output was at only 4.8% of the unfished level, and the subsequent rebuilding analysis estimated that the stock would take nearly 100 years to rebuild to target levels (40% of the unfished output). The results of this assessment, combined with pessimistic assessments of other rockfish species coastwide, contributed to severe management constraints in 2003, including significant area closures and a near total cessation of recreational and commercial fisheries in shelf and shelf break waters. The estimated total catch of bocaccio declined to approximately 11 mt in 2003, roughly 10% of the total catch in 2002 and less than 1% of the catch ten years prior. Total mortality in 2003 fisheries was restricted to a 20 mt OY as a means of conserving the stock while minimizing adverse socioeconomic impacts to communities.

The 2003 bocaccio assessment differed greatly from the 2002 assessment. Both the CalCOFI time series and the recreational CPUE indices showed increasing trends as a result of the strong 1999 year class. However, the recreational CPUE indices were adjusted to account for regulatory changes (principally bag limit changes), and all of these indices were in conflict with the triennial trawl survey time series. The most recent triennial survey data was from 2001 and showed little evidence of an increase in abundance (although the length frequency data was indicative of a strong 1999 cohort). The STAR Panel recommended the use of two assessment models, each of which excluded the conflicting data, as a means of bracketing uncertainty from the very different signals between the recreational CPUE data and the triennial survey. However, the STAT Team was not in full agreement with this approach, and for the purposes of management decisions developed and presented a third "hybrid" model (STATc) that incorporated the data from all of the indices to the PFMC SSC. The SSC recommended and the Council approved the use of this third modeling approach. This resulted in modest improvement in estimated stock size, but had very significant impacts on the estimated productivity of the stock and rebuilding scenarios. These results were more optimistic with respect to the rebuilding outlook for bocaccio, suggesting the stock could rebuild to B_{MSY} within 25 years while sustaining an OY of approximately 300 mt in 2004. The 2004 OY was set at 199 mt.

The 2003 assessment was updated in 2005 (MacCall 2006). The assessment used the original Stock Synthesis model (SS1), and did not develop an equivalent new Stock Synthesis 2 (SS2) version of the assessment. In addition to new length frequency data, new data points were included from both the triennial survey and the CalCOFI larval abundance index, both of which suggested an increasing upwards trajectory for the stock. Importantly, the updated triennial trawl survey index (updated with a 2004 data point, now the last point in that time series) was now consistent with the increase in abundance suggested in the 2003 model with the recreational CPUE and CalCOFI indices. The updated base-case (STATc) model continued to forecast a slow increase in biomass (spawning output), with depletion (current spawning output divided by unfished spawning output) increasing from a current value of 10.7 percent to approximately 20 percent over the coming decade. The 2006 OY was ultimately set at 218 mt. The 2003 assessment was updated again in 2007 (MacCall 2008) without a major change in the perception of stock status. The only significant differences in the 2007 model were slight revisions to historical catches and updates of catch, length frequency, and the CalCOFI time series; the latter was the only time series of relative abundance that continued from the 2003 assessment. OY values have been maintained at 218 mt since 2007, with actual catches (including discards) estimated to be less than half of that amount.

C.2 Stock Distribution and Life History

The distribution of bocaccio has been described as ranging from Stepovak Bay on the Alaskan Peninsula (as well as Kodiak Island, Alaska) to Punta Blanca, Baja California (Miller and Lea 1972; Eschmeyer 1983; Love et al. 2002). It is abundant off southern and central California, uncommon between Cape Mendocino and the Oregon/Washington border, and moderately abundant from the Oregon-Washington border into Queen Charlotte Sound and Hecata Strait, British Columbia. The southern U.S. stock (the stock evaluated in past assessments) was petitioned for listing under the U.S. Endangered Species Act (ESA) in 2002. Although this petition was denied, bocaccio have been listed as a “Species of Concern” by the NMFS since 2002, and a more recent petition has proposed listing the population of bocaccio in the Georgia Basin Ecosystem under the ESA.

The U.S. stock assessment has traditionally assessed bocaccio from the U.S./Mexico border to either Cape Mendocino (MacCall 2002; MacCall 2003 and recent updates), or through the Eureka INPFC area (Ralston et al. 1996; MacCall et al. 1999). This has been based on a conceptual model of two centers of population density, one around southern and central California and another from Queen Charlotte Sound through the northwest coast of Washington State. Both historical and recent catch statistic and surveys suggest low relative abundance levels of bocaccio between approximately Cape Mendocino and the Columbia River mouth (essentially, the Eureka and Columbia INPFC areas; Figure 2). Moreover, most of the bocaccio observed in this region tend to be very large (Figure 3a), suggesting the possibility that there is little or no localized recruitment in this region and the animals that are observed are likely to be slowly dispersing or diffusing adults. Similarly, a summary of bocaccio catches in Russian trawl surveys conducted off of the U.S. west coast from 1963 to 1978, prior to what has been estimated to be the greatest period of depletion of this stock or stocks, is consistent with a pattern of low abundance from north of Cape Mendocino through Oregon, with higher catches in southern and northern regions (Figure 4).

There is a fair amount of data and information on the status of bocaccio in Canadian waters, where landings have ranged from several hundred to over 1000 mt per year in recent decades. In 2002, the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) listed bocaccio as threatened (COSEWIC 2002) based on an apparent population decline of more than 95% over a two decade period, and the stock is under consideration for listing under the Canadian Species at Risk Act (SARA). A stock assessment was performed on this stock in 2004 (Stanley and Starr 2004), in which most evidence suggested that bocaccio had been widespread over their habitat and stable in abundance since the mid-1990s, a period in which total catches (primarily from bottom trawl) ranged from 300 to 330 mt; however, the magnitude of the decline over the preceding decades was unclear. That assessment was based on observed trends in spatial distribution, and irregular catch rates from bottom trawl surveys. Interestingly, one of these surveys was described as suggesting a peak relative abundance in the 1980s, noting that the abundance levels observed in that period might not be appropriate rebuilding targets (Stanley and Starr 2004).

More recent work in Canada includes the preparation of a stock assessment (Stanley et al. in prep.; pers. com.) and a recovery potential assessment (DFO Canada, Canadian Science Advisory Secretariat, in press) to provide scientific advice for the recovery strategy in Canadian waters. The recovery potential assessment (DFO Canada, Canadian Science Advisory Secretariat, in press) is based on the results of a Bayesian surplus production model fitted to one fishery-dependent and six fishery-independent abundance indices and a reconstructed catch history that stretched back to 1935. In their reference case model, the biomass was estimated to demonstrate a monotonic decline from the 1930s through the early 2000s, with the steepest decline taking place from the mid-1980s through the mid-1990s and some suggestion of a flattening of the biomass trend since the late 1990s. The model estimated a posterior median for the estimated 2008 biomass of 2,324 mt (posterior mean of 3,022 mt), with the posterior median relative stock size (B_{08}/B_{MSY}) of 0.111 (posterior mean 0.155). In general, the recovery potential assessment indicates that contemporary Canadian catches of approximately 150 mt per year will not place the population in short-term jeopardy, but that reductions in harvest will be necessary to implement the probability of future population increases.

There is also what is currently described as a discrete population segment (DSP) of bocaccio rockfish in the Georgia Basin ecosystem (Puget Sound plus the Strait of Georgia), spanning the inland waters of the U.S. (Washington State) and Canada (Southwestern British Columbia). The National Marine Fisheries Service (NMFS) recently issued a proposed rule (and request for comment) to list this DSP of bocaccio as endangered (at high risk of extinction) under the Endangered Species Act (ESA).[1] This proposed rule came about as a result of a petition to enlist this and several other population units of rockfish in this region (the other four species were canary, yelloweye, greenstriped and redstriped rockfish), of these five only bocaccio is proposed to be listed as endangered, while yelloweye and canary are proposed to be listed as threatened and greenstriped and redstriped were found not to be at risk of extinction. This petition follows an earlier petition to list three other species of rockfish (among other species), although the initial petition was ultimately denied (Stout et al. 2001).

The proposed rule is based on the evaluation of abundance trends, spatial structure of the populations, and the suite of somewhat unique threats in these ecosystem. Among the factors related directly to bocaccio are the rapid decline and current total absence of bocaccio in recreational rockfish catches within the Georgia Basin (consistent with a substantial overall decline in the catch rates of all rockfish, but of a greater magnitude), the highly variable nature of bocaccio recruitment, and the observation that historical length composition data were indicative of multiple strong cohorts (interpreted as evidence that fish present in the ecosystem were unlikely to be infrequent strays from the coastal population). Specifically, from 1975-1979

[1] Proposed rule published in the U.S. Federal Register, Vol. 74, No. 77, Thursday April 23, 2009. Proposed rule and supporting background documents, including the Biological Review Team (BRT) report are available at http://www.nwr.noaa.gov/Other-Marine-Species/Puget-Sound-Marine-Fishes/esa-PS-rockfish.cfm.

bocaccio accounted for an average of 4.6% of the total catch, from 1980-1990 they represented 0.24% of the catch, and no bocaccio have been observed from 1996 through 2007. The total absence of bocaccio from observed catches or surveys since 1996 was noted as being of particular concern, indicative of at least some possibility that the population has already been extirpated. Among the more general observations that support the conclusion that the bocaccio DPS may be at high risk is the unique and relatively isolated nature of the Georgia Basin ecosystem, the cumulative impact of various anthropogenic threats to habitat in this ecosystem (including contamination from pollutants, declines in oxygen levels, habitat impacts, and impacts of harvest) and the observations that multiple studies have found evidence that rockfish (and several other finfish species) inhabiting geographically isolated areas have been demonstrated to have genetic differentiation from coastal populations (Stout et al. 2001).

Although the southern/central California "stock" and the British Columbia "stock," as well as the more recently described Puget Sound/Georgia Basin stock, are treated independently by their respective management entities, an accurate understanding of stock structure both among and within these regions remains unclear. Wishard et al. (1980) described electrophoretic patterns in a series of samples collected between the Southern California Bight and Cape Mendocino. Although the PGI-1 and ADH loci were polymorphic and heterozygosity was high, there was no genetic differentiation among the samples at these or three other loci. However, no samples were collected and evaluated north of Cape Mendocino. Results of genetic research conducted in conjunction with the 1999 assessment (MacCall et al. 1999) suggested genetic differentiation between bocaccio collected off southern California and fish from Washington, but that fish from southern California and Monterey Bay do intermix genetically (MacCall et al. 1999). In that study, a lack of samples from intermediate locations did not allow geographic identification of genetic stock boundaries or possible areas of limited mixing.

Matala et al. (2004) used likelihood tests of homogeneity of allele frequencies at seven highly polymorphic microsatellite loci to evaluate population connectivity along the west coast. Samples were divided into eight regions: Queen Charlotte Island and Vancouver Island in British Columbia, Monterey Bay in Central California, four locations in the Southern California Bight (Point Conception, Tanner Banks, Santa Barbara Channel, and Santa Monica Bay), and Punta Colnett, Mexico. Unfortunately, there were no samples evaluated from Northern California, Oregon or Washington, nor from the Puget Sound/Georgia Basin region. Analysis based on fixation index (F_{ST}) values revealed no statistically significant geographic divergence, or evidence for isolation-by-distance (Matala et al. 2004). However, an ad hoc method for partitioning the samples based on genetic and geographic homogeneity could not reject the possibility of some population structure related to geographic location. These patterns appeared to be related to oceanographic features, possibly suggesting limited gene flow between British Columbia and California, as well as limited flow around Point Conception, California. However, a re-analysis of the same data (D.E. Pearse, FED/SWFSC, pers. comm.) using the Bayesian partitioning program STRUCTURE 2.0 (Pritchard et al. 2000), found no support for the presence of population genetic structure among the samples of bocaccio analyzed by Matala et al. (2004; Figure 5). This most recent analysis suggests that from a population genetic perspective, all bocaccio from British Colombia, Canada to Baja, Mexico, should probably be considered to be a single, panmictic unit.

As Waples et al. (2008) and Berntson and Moran (2009) suggest, demographic independence does not necessarily require strong evidence of genetic isolation. As pointed out by Waples et al. (2008), population genetic analyses typically have considerable power to identify separate populations connected only by low levels of migration, but struggle to identify differentiation at the level of connectivity that would indicate demographically coupled stocks. Similarly, Berntson and Moran (2009) suggest that while relatively few migrants per generation will typically result in low F_{ST} values, indicative of a single evolutionary genetic population, such low levels of migration would likely not be sufficient to result in rebuilding stocks in regions where there might be a wide disparity in abundance. Thus, although the failure to identify clear evidence of population genetic structure among bocaccio populations in the Canadian/Northern U.S. region and the southern/central California region suggests that some migratory connectivity exists, the apparent differences in growth rates, size (and presumably age) at maturity, and longevity suggest that some level of demographic independence is likely.

We maintain the tradition of distinguishing the southern bocaccio population unit from the northern unit in this assessment. However, in evaluating commercial length frequency data and landings trends (described later), we suggest that the fish in the Eureka INPFC area are likely to be most closely linked with the southern subpopulation, and we include this region in this assessment. Consequently, the geographic range of the southern bocaccio stock is assumed to correspond to the waters south of Cape Blanco, Oregon (the northern boundary of the Eureka INPFC area). This is consistent with the suggestion of a break in population distribution based on both historical and recent abundance data, the paucity of data in the northern part of the range, and a long history of previous assessments.

Even less is known about the abundance and distribution of bocaccio at the southern end of their range. MacCall (2003) used the CalCOFI larval abundance data from the 1950s and 1960s (CalCOFI cruises ceased to sample Mexican waters in the 1970s) to estimate that the historical distribution of spawning abundance over the assessment range. He found that approximately 4.6 percent of larvae were encountered in Mexican waters, 46 percent in southern California waters, and 50 percent in central/northern California waters (from Pt. Conception to Bodega Bay). No information is available on catches or stock status and trends of bocaccio in waters off northern Baja California; and although there is presumably population connectivity between the Southern California Bight and Baja California, we are constrained to treating the stock as distinct north of the U.S./Mexico border. As Mexican oceanographers have begun occupying the historical CalCOFI stations off of the Baja Penninsula in recent monitoring efforts, the potential to include or analyze data from these efforts should be revisited in the future.

Genetics and effective population size

Narum (2007) evaluated the evidence for reduced effective population sizes for eighteen species of rockfish, most at multiple sites, using microsatellite data from the published literature. Although such analyses are sensitive to the estimates of mutation rate and life history characteristics, most species identified as having low effective population sizes were those that have been heavily exploited by marine fisheries, including bocaccio, copper (S. *caurinus*) and quillback (*S. maliger*). For bocaccio, Narum (2007) interpreted the results as indicative of recent bottlenecks (dramatic reductions in population size) across all locations. However, bottlenecks of sufficient magnitude to result in such low effective population sizes are in all likelihood much more extreme events than the past assessments might suggest. The most recent assessment (MacCall 2007) estimated that at its lowest point the mature female population was represented by a population on the order of five million mature and spawning females. Nonetheless, as highlighted by Berntson and Moran (2009), there are several examples in which effective population sizes have been demonstrated to be several orders of magnitude lower than actual abundance (e.g. red drum, Turner et al. 2002; darkblotched rockfish, Gomez-Uchida and Banks 2006).

C.3 Life history, habitat preferences and movement patterns

Like all *Sebastes*, bocaccio are primitively viviparous and bear live young at parturition. They copulate during September-October, although fertilization is often delayed, and embryonic development takes at least a month to complete, with larvae hatching internally (Moser 1967). Parturition occurs during the winter months (Wyllie Echeverria, 1987) and larvae eventually metamorphose into pelagic juveniles (Moser and Boehlert, 1991). The combined larval and juvenile pelagic phase typically lasts about 150 days, consequently the spatial dispersal of larvae and juveniles likely links populations among fairly broad regions. This might be particularly true as bocaccio appear to orient higher in the water column than juveniles of most other winter-spawning rockfish species (Ross and Larson 2003), and propagule dispersal tends to be greater at shallower depths (Peterson et al., in press). The rapid growth of bocaccio is initiated at the juvenile stage; Woodbury and Ralston (1991) describe linear species-specific growth rates (and interannual variability in the same) for juvenile rockfish in approximately the first 50 to 150 days of life, in which those for bocaccio ranged from 0.56 to 0.97 mm/day, the highest rate amongst the species evaluated. Settlement to littoral and demersal habitats begins in late spring and extends throughout the summer months.

Pelagic bocaccio young-of-year typically recruit to shallow habitats, and subadult bocaccio are more common in shallower water than adults, with average size becoming notably larger at greater depths (Figure 3b). Strong year classes frequently lead to high densities and high catches of young bocaccio from piers and other shore structures from the early summer through winter of the first year of life; data describing such events are discussed in greater detail in the section on the pier fishery survey data. Adult bocaccio are typically described as occurring in a broad range of habitats and depths, including developing large midwater aggregations, high densities tend to be more associated with more complex substrates. As with many other shelf species of rockfish, there is a clear trend towards larger fish at greater depths as well as towards higher latitudes (Figures 3a-b).

In southern California, juveniles often recruit to oil platforms, often in large numbers during strong recruitment years. For example, in 2003 Love et al. (2006) estimated a minimum of 430,000 juvenile (age ~0.75 yrs.) bocaccio recruiting to just 8 oil platforms in the Santa Barbara Channel. They estimated that this represented approximately 20% of the average number of juveniles in any given year, and estimated further that densities of juveniles around oil platforms that year tended to be greater than the density of juveniles over nearby shallow habitat areas more typically considered juvenile habitat. Their results also suggested very high patchiness in the distribution of juvenile bocaccio; over 80% of the total estimated number of juveniles recruited to just one platform (Grace), two other platforms in the immediate vicinity accounted for another 10% of the total numbers of recruits, but at widely disparate densities. Although they acknowledge that considerable uncertainty exists with respect to the potential role of platforms in providing recruitment habitat, Love et al. (2006) suggest that bocaccio and other rockfish that recruit to these structures likely represent production that would have been lost to the population in the absence of these structures. Love et al. (2005) also estimated higher densities of adult bocaccio at platform habitat relative to the densities on nearby natural reefs, suggesting that platforms could represent a source of subadults to neighboring natural habitats

In considering habitat preferences more generally, we obtained data on over 2800 bocaccio observations from 14 years of submersible surveys of southern California habitats from M. Love (University California at Santa Barbara) and colleagues. These surveys have been used to assess the abundance of rockfish and other species on oil platforms (as described in the preceding paragraph), to develop absolute abundance indices for other species of rockfish (e.g., Yoklavich et al. 2007) and to characterize assemblages of rockfish communities (Love et al. 2009); details of the survey methods and results can be found in those publications and others. We evaluated rockfish densities by size and habitat, although rather than use complex habitat types, we simply described habitat as low, moderate, or high relief (for each dive, this rating is given to a primary habitat type, as habitats often vary within dives, a secondary habitat type is also ascribed). We grouped fish size data at 5 cm increments and looked at mean densities of fishes by size and by year over different habitat types (Figure 6). In general, there was a clear trend towards greater densities of fish of all sizes over high relief habitats, such that 30-40 cm fish over high relief habitats were found at roughly 2-3 times the abundance levels at moderate relief habitats, and roughly 9 times the abundance at low relief habitats. For larger fish (50 cm and greater) this discrepancy was even greater; virtually no large fish were seen in low relief habitats and 4-5 times as many large bocaccio were seen in high relief habitats relative to those with moderate relief. Interestingly, when the mean densities by habitat type are compared by year, it is seen that the greatest number of fish were seen in low relief habitat in the year 2000, following the strong 1999 year class, a year in which densities in all habitats were notably greater. This could reflect either, or both, a tendency for smaller, younger fish to occupy less optimal habitat particularly in years of high abundance due to strong recruitment pulses. Moreover, if there are density-related habitat preferences, such that less suitable habitat is occupied only during periods of relatively high abundance (over either short- e.g., recruitment pulses, or long, e.g., low frequency trends in abundance), then traditional trawl surveys may be less likely to provide unbiased estimates of stock abundance.

With respect to movement patterns, the evidence for most rockfish suggests that the bulk of the adults are highly sedentary, with some ontogenetic movement to greater depths common for most shelf and slope species. However, some rockfish have shown fairly extensive movements, usually of late juvenile and early adult stages. For example, Hartmann (1987) reported the results of tagging studies of nearly 25 species of rockfish from over 10,000 fish tagged in the Southern California Bight (olive, blue, widow, bocaccio, kelp and copper rockfish comprised over 90% of both the fish tagged and recaptured). The total number of recaptures was 696, of which 606 were recaptured at or very near to the site of tagging. Of the remaining 90 only 12 (of four species) moved greater than 10 km. Most of these were juvenile bocaccio, which moved as far as 150 km. By contrast no movement was observed in adult bocaccio, although relatively few were tagged. Lea et al. (1999) found no movement for bocaccio rockfish, although they only had three tags returned (out of 56 deployed). However, in a movement study using fish captured and surgically implanted with acoustic transmitters, most spent only a small fraction of their time in the 12 square kilometer study area, with frequent small scale movements in both horizontal and vertical planes (Starr et al. 2001). By contrast, six greenspotted rockfish tagged in the same study exhibited substantially lower movement rates.

Although there are no quantitative food habits studies of this species, they have long been described as primarily piscivorous, consistent with their name. Phillips (1964) stated that even before completing their first year of life, young bocaccio (which, as previously mentioned, tend to recruit to shallow, nearshore waters late in their first year of life) prey on other young-of-year rockfish, surfperch, jack mackerel and other small inshore species. Adults in deeper waters feed on small rockfish and sablefish, anchovies, mesopelagic fishes, and squids such as the California market squids. Pelagic juveniles feed primarily on copepods, juvenile (and other stages) of euphausiids, and other fish larvae; while their diet was found to be highly similar to other pelagic juveniles of winter-spawning species, there is some suggestion that that bocaccio fed on larger prey than the other species (Reilly et al. 1992). Pelagic juveniles are preyed upon by a wide range of predators, including seabirds, salmon, lingcod, and marine mammals (Merkle 1957; Sydeman et al. 2001). Predators of larger adults are likely limited to larger piscivorous fishes and marine mammals, although few studies have identified rockfish prey to the species level.

C.4 Growth, Maturity, Fecundity and Natural Mortality

Growth

The stock synthesis approach uses the Schnute (1981) parameterization of the von Bertalanffy growth equation (Methot 2009). Bocaccio have long been described as having very rapid growth during the early years of life, more so than most other *Sebastes*, which can be tracked by the progression of strong cohorts in fisheries length frequency data. Due to the problems associated with ageing of bocaccio rockfish (described in greater detail below, in the section on natural mortality), past assessments have typically estimated the growth coefficient (K) internally, while fixing L_{min} and L_{max} based on the length frequency data (MacCall et al. 2002; MacCall 2003). The 2003 assessment (and subsequent updates) fixed values for L_{min} at 27 cm (for an age of 1.5 years) and L_{max} at 65.6 and 75.9 cm for males and females, respectively, with K estimated as 0.184 and 0.210 for females and males, respectively. The forthcoming Canadian bocaccio assessment estimated a L_{inf} of 78.32 and 69.98 for females and males, with corresponding von-Bertalanffy growth parameters (K values) of 0.163 and 0.108 respectively. This suggests that bocaccio in Canada tend to grow larger and slower than fish in the southern/central California region; consistent with observations regarding apparent greater longevity and age at maturity, as discussed later in this section.

We explored several options for modeling growth, including the approach used in the last assessment, freeing all of the growth parameters, and fixing L_{min} at 0.16 at an age (A_{min}) of 0.75 yrs. The latter was based on the observed length frequencies from recreational pier and shore fisheries, which show the modal progression of recently settled age 0 juveniles (Figure 7; length data pooled among all available years). However, this parameterization, as well as freely estimating all of the primary growth parameters, often led to problems in which growth was unrealistically slow (essentially shifting the strong recruitment years to the left) or in which male and female L_{min} values were dramatically different. Consequently, we maintained an approach by which L_{min} was treated as a fixed value for age 1.5.

To confirm that a reasonable value could be derived, we examined wave-specific length frequency data from recreational fisheries in which age-1 fish were caught in high abundance. Modal progression of strong year classes was easily discernable in many such datasets, particularly in the southern California recreational fisheries. As the 1970s CPFV observer program collected the greatest number of length frequency observations (over 77,000 in four years of collections), and the 1977 year class was among the strongest observed historically, we evaluated the size frequency of the 1978 length frequency data from this fishery to confirm a plausible size at age 1.5. Figure 8a shows the length frequencies from this fishery by wave in 1978 with a bin resolution of 1 cm (where waves are the 2-month intervals used in RecFIN statistics; although note that calendar dates for each observation are available for this dataset), with the maximum size of the 1977 cohort estimated visually from the data and larger sizes removed from the dataset. When these larger sizes are removed, the wave 3 and 4 data (May-August) have a mean of 25.98 cm, a median of 25.95 cm, and a standard deviation of 2.73 cm, leading to a CV of 0.105 (n = 1330). Over all waves, the same data have a mean of 27.87 cm, a median of 27.39 cm, a standard deviation of 37.14 and a CV of 0.136 (n = 3908).

Although few other years included comparable numbers of measured fish during the summer period (as rockfish tend to be a more important recreational target during the winter months, when more desirable warm-water species are unavailable), these results are consistent with RecFIN data for the size distribution of other strong cohorts at age 1.5, such as the 1984, 1988, and 1999 cohorts. Consequently, we fixed L_{min} for both sexes at 26 cm at age 1.5. The CV for L_{min} was set at 0.10, based on the described analysis and an evaluation of changes in the model likelihood with different combinations of CVs; there was a clear improvement in fit when the CV of L_{min} was raised from 0.08 to 0.1, and an equally significant improvement when the CV of older fish was decreased from 0.1 or 0.12 to 0.08 (the fit began to degrade again at lower values). More evaluation of this issue is included in the section on model sensitivity. Similarly, as past assessments have noted, periods of consistent variability in expected length at age, which may be attributed to climate-modulated variability in growth rates, leads to an exploration of time-varying growth in this assessment (see the model-sensitivity section).

The length-weight relationship was re-estimated using a total of 5,050 weight and length observations from the triennial trawl survey, the NWFSC combined trawl survey, the SWFSC groundfish ecology cruise dataset and the NWFSC hook-and-line survey in the Southern California Bight (Figure 9). Estimates were based on bias-corrected data from a log linear regression between fork length (cm) and weight (kg). The estimated values for a and b were a = 7.355 E-06, b = 3.11359, which are very similar to the values carried over from the 1996 assessment (then based solely on several hundred fish from the triennial survey) of 6.19 E-06 and 3.1712 for a and b, respectively.

Maturity

We compare results from four previous studies that describe the proportion of female bocaccio that are mature as a function of body length. To facilitate comparison, we standardized all lengths to centimeters fork length using the equations from Echeverria and Lenarz (1984). Phillips (1964) found that 50% of females from statewide samples in California were mature by 40.4 cm, and indicated a few were mature by 34.9 cm. Gunderson et al. (1980) examined 84female bocaccio from 34°08' to 40°26' N latitude (central California), finding that 50% were mature by 48.2 cm. Wyllie Echeverria (1987) estimated length at 50% maturity as 46.5 cm based on samples from central and northern California. Wyllie Echeverria reports interannual differences in size at maturity, although the reported lengths at 50% maturity differ by only 1 cm for bocaccio. No significant regional differences (north and south of Point Arena) were detected in the latter study. Thus, the estimated proportion of mature females at length differs among studies (Figure 10a). As Phillips only reported the length of 50% maturity, the curve based on his results uses the slope equal to that of Love et al. (1990). The curve shown for Love et al. (1990) is fitted to a fork length of 35.3 cm at 50% maturity and 43 cm at 99% maturity.

Differences in maturity at length among these studies may be due to spatial or temporal variation (including density dependence) in length at maturity, or changes in methodology such as determination of maturity stages. Love et al. (1990) report a larger proportion of fish maturing at smaller sizes relative to the other studies, based on samples from the Southern California Bight (SCB). Phillips (1964) combined statewide samples from CA, reporting a higher proportion of mature females at a given length relative to Love et al (1990). Wyllie Echeverria (1987) and Gunderson (1980) based their maturity estimates on fish captured north of Point Conception, and both studies estimated larger lengths at 50% maturity than were reported for the studies that included SCB data. However, temporal changes in maturity at length may have caused the observed differences among studies, and there is insufficient overlap in the timing of the surveys to eliminate either possibility. Regarding definitions of maturity stages, it is important to recognize the difficulty in distinguishing ovaries of immature rockfish (those that have never spawned) from ovaries of mature individuals in early stages of vitellogenesis or resting periods (Wyllie Echeverria, 1987). Errors in assignment of rockfish maturity stages are most likely to occur during non-spawning seasons (Wyllie Echeverria, 1987).

We obtained maturity data for female bocaccio from four studies conducted off the west coast of North America: 1) CalCOM, 2) the NMFS Southwest Fisheries Science Center Groundfish Ecology cruise conducted by the Fisheries Ecology Division, 3) the west coast triennial trawl survey, and 4) the Department of Fisheries and Oceans, Canada (R. Stanley, DFO, pers. com.).

CalCOM maturity data are collected by port samplers in California, who have recorded maturity stages of female bocaccio landed by commercial vessels since 1993. Sample sizes vary considerably over time (1993-2008) and by port complex. Central California port complexes have the highest number of observations, and sample sizes decrease in the more northern California ports. Very few samples are available from ports south of Pt. Conception (25 fish), and all of these southern specimens were mature; moreover, 90% were caught during the non-reproductive season for bocaccio (July – September). Consequently, we excluded CalCOM samples taken south of Pt. Conception or during the months of July through September from our analysis.

The SWFSC Fisheries Ecology Division collected rockfish maturity data from 2001-2007 in central California (Monterey area). We removed samples from the non-reproductive season (61 out of 343 observations). The majority of samples were collected during peak spawning season for bocaccio (January-April). Maturity samples from the west coast triennial survey were available for 1977, 1986, 1989, 1992, 1995, and 1998. We excluded samples from the non-reproductive season for bocaccio (July-September), leaving data from 1995 and 1998 only. Maturity data from Washington and Oregon were collected during non-reproductive months for bocaccio, so these data are excluded from our analysis. Most survey years exclusively contained samples during the non-reproductive period, so the triennial data in our final analysis are samples from central California in 1995 and 1998. Starting latitudes for each trawl tow were used to assign fish to regions roughly consistent with the CalCOM port complexes. Data from Canadian waters were provided by DFO, Canada (R. Stanley, pers. comm.) and used to evaluate evidence of latitudinal changes in size at maturity and seasonality of reproduction for bocaccio, as such trends have been reported for many rockfish species (Haldorson and Love, 1991). The DFO data were collected from 1967-1971, 1978-1980, 1988-1991, and 2002-2007.

The number of maturity stage observations among port complexes is not consistent over time (Table 2). Analysis of interannual changes in maturity at size were therefore limited to regional subsets of the data (e.g., Morro Bay from 1993-1998 and Monterey in 1993 and 2000-2004). Our evaluation of regional differences in size at maturity does not account for temporal trends due to minimal overlap among regions with larger sample sizes.

We considered all observations taken in U.S. waters during the reproductive season for the final analysis, classifying individual fish as either immature (0) or mature (1) using the maturity stage data supplied with each study. All fish assigned to the early vitellogenic maturity stage (stage 2) were excluded to minimize the number of classification errors. We define all stage 1 ovaries as immature. Fish with ovaries in late vitellogenic stages, with fertilized eggs or eyed larvae, or spent and recovering stages were classified as mature. We model the proportion of individuals that are mature at a given length using generalized linear models (GLM) with binomial error structures and logit link functions. The response variable is binary (immature=0, mature=1), and covariates examined include fork length, port complex, and year. The simplest model for maturity at length pools all data across years and areas (Figure 10b). The combined model estimated lengths at 50% and 95% maturity as 39.9 and 48.1 cm fork length, respectively (corresponding slope parameter is -0.359). These estimates were used in the draft assessment.

Interannual differences in maturity are confounded with differences in spatial coverage among studies. We restricted our analysis of temporal effects to individual regions and studies with adequate sample sizes. Models fit to Groundfish Ecology data from Monterey suggest that a larger fraction of females were mature at larger lengths in 2004 (ogive shifted to the right) relative to other years. No interannual differences were detected in the CalCOM data for Morro Bay. Regional difference in length at maturity have been reported in previous studies (Haldorson and Love, 1991). No consistent latitudinal trend in length at maturity is evident among the data sets we examined; however, the data suggest that differences in maturity exist among regions (Table 3). Fish from Canadian waters appear to mature at larger sizes, based on the DFO data (pooled across areas and years). Lengths at 50% and 95% maturity for the bocaccio from Canadian waters were estimated at 49.2 cm and 57.3 cm, respectively, consistent with published accounts of increasing size at maturity in northern latitudes. Proportions of fish that are mature at length also appear to vary by data source (CalCOM, triennial survey, or Groundfish Ecology survey), even after accounting for variability among regions (Table 3).

Although the length compositions of mature fish do not vary considerably among studies, there are differences in the distribution of lengths for immature fish, which may provide evidence of differences in gear selectivity (Figure 11a). Selectivity differences are expected between the samples from scientific surveys and commercial landings, but smaller differences were also detected between the triennial and Groundfish Ecology surveys. If fish landed by the commercial fisheries are generally larger than the survey fish, then it is possible that a bias may be introduced into maturity estimates based on commercial samples because smaller (possibly mature) fish are not caught in the fishery. Methodological differences among studies may also introduce variability in maturity estimates. Given the effect of data source on maturity estimates, we examined an alternative data set that did not include the samples from the commercial fishery. A binomial GLM fit to these data indicates that fish from Morro Bay differ significantly from those in Monterey, San Francisco, and Bodega. However, we chose to group the data among regions because a number of strata lack observations (unbalanced data), and all regions are within central California. Estimated lengths at 50% and 95% maturity from the combined survey model are 37.7 and 44.4 cm fork length, respectively (Figure 11b), approximately 2.2 and 3.7 cm less (respectively) than the combined model. This estimate, as well as the values used in previous models, was evaluated in a sensitivity analysis.

Fecundity

Bocaccio stock assessments since 1996 have used a linear model for relative fecundity as a function of weight developed by Ralston (1996) from data reported by Phillips (1964). Dick (2009) estimated relative fecundity as function of weight for 40 species of *Sebastes* using a hierarchical linear model for relative fecundity. His results for bocaccio are similar to that of Ralston, with a slightly steeper slope (Figure 12). The relationship used in this assessment is that of Dick (2009):

$$\frac{E}{W} \quad 192.5 \quad 49.3W \qquad (1)$$

where E is number of eggs and W is weight in kilograms.

Natural Mortality

Although age determinations of bocaccio are known to be imprecise, Ralston and Ianelli (1996) reported that the maximum known age of bocaccio is 45 years. Piner et al. (2006) used radiocarbon levels measured in otoliths from fish taken off the coast of Washington state to confirm that bocaccio can live up to at least 37 years. Andrews et al. (2005)used lead-radium dating in an attempt to independently age bocaccio otoliths, but found that measured levels of lead and radium were among the lowest in the literature, resulting in poor age resolution. Their results were consistent with a longevity of 30-40 years. The Canadian assessment (Stanley et al., in prep, pers. comm.) documents age frequencies for over 900 aged bocaccio, in which the maximum ages were 57 for males and 52 for females (99% ages were 52 and 46 for males and females respectively). Based on those ages they used the Hoenig (1983) relationship with the bias correction suggested by MacCall (2003) to derive estimates of total mortality of 0.097 and 0.086 for females and males respectively. The difficulties encountered in ageing bocaccio, which may be greater in the southern part of the range, are discussed in greater detail in the section on age data.

In 1996, Ralston and Ianelli (1996) reviewed the information relating to the natural mortality rate of bocaccio and used a natural mortality rate of 0.15 in their model. Due to computational problems in the then-current SS1 program (subsequently fixed), MacCall (1999) was unable to develop a model with the 0.15 mortality rate and developed a model with M set to 0.2, which was adopted as the base model. In the 2002 assessment, MacCall examined both M=0.15 and M=0.25, but retained M=0.2 as the base model because it was consistent with the previous assessment and rebuilding analysis. During discussions following the 2002 STAR Panel, it was generally agreed that M=0.2 was probably too high, and lower values of natural mortality rate should be considered. MacCall (2003) used the Hoenig (1983) method to estimate a total mortality rate of 0.092 for the maximum age of 45, but noted that this estimate is a geometric mean, and estimated that a bias-corrected total mortality rate should be approximately 0.1. However, the 2003 STAR Panel recommended a natural mortality rate of 0.15, and this value has been used in subsequent updates (MacCall 2005; MacCall 2007).

It might be noted that the maximum age of 45 was from fish in the northern part of the range, for which the maximum age has more recently been estimated as 57 (as above). Of the more than 1300 fish aged using break-and-burn methods for the 1996 assessment (fishery-dependent samples from 1988, 1991 and 1994), the oldest was 37 years. This would correspond to a total mortality (Z) of approximately 0.121 (with the bias adjustment), still quite below the rate of 0.15 used in past assessments (particularly given the high fishing mortality rates known to have been taking place in the decades preceding sample collection). Despite this, in the absence of convincing evidence for a different value, we maintain this estimate; and sensitivity to this estimate is evaluated and discussed in the section on model sensitivity.

D. ASSESSMENT

D.1 DATA

D.1.a. Catch History

One of the most significant changes to this assessment is consideration of the catch history of bocaccio. Together with chilipepper rockfish (*Sebastes goodei*), bocaccio have long been described as one of the dominant rockfish species for both commercial and recreational fisheries throughout California. Although landings of many California groundfish are typically reported in single species market categories, group market categories have been the most common approach for sorting rockfish catches in California, with a trend towards single species categories in recent years due to regulatory constraints.

Commercial Catches

In order to obtain reliable estimates of species-specific landings, a sampling program for commercial fisheries, the California Cooperative Groundfish survey (CCGS) was implemented in 1978 by the California Department of Fish and Game, the Pacific States Marine Fisheries Commission and the National Marine Fisheries Service. The primary objective is to collect species composition data for rockfish landed under various market categories, as well as biological information and samples (sex, maturity, length, weight, and ageing structures) to help manage commercial fisheries. Detailed descriptions of the sampling framework and program are provided in Sen (1984), Pearson and Erwin (1997), and Pearson et al. (2008). Commercial landings of bocaccio from 1978 through 2008 are based on this program, and landings from 1969 to 1977 are based on applying the species composition of market categories in the sampled period to the reported catches by market category in that period.

The most recent catch estimates for bocaccio for the period from 1968 to the present have changed modestly from those used in the 2007 assessment in response to slight revisions to the estimation procedures (correcting minor errors such as mis-specified port or gear codes and invalid market categories) reported in Pearson et al. (2008). The recent commercial and recreational catch estimates relative to those used in the 2007 assessment are reported in Figures 13a-e and are discussed in more detail below. Pearson et al. (2008) also developed an index (largely subjective) of the reliability of landings estimates by species, based on the potential for misidentification, sorting requirements, the percentage of landings based on port samples, and other criteria. Landings estimates for bocaccio from 1969 to the present are considered to be very reliable, as this is one of the most commonly caught species of rockfish, landings are usually reported into the bocaccio market category (required since 1991), and problems associated with misidentification are minimal as bocaccio are likely to be confused only with relatively uncommon species such as silvergrey (*S. brevispinis*) and Mexican (*S. macdonaldi*) rockfish (Pearson et al. 2008).

For the 2007 model, estimates of historical catches from 1950 through 1968 had been largely unchanged since the 1996 assessment (although the 2002 assessment used the methodology developed in the 1996 assessment to apportion catches north and south of Point Conception in separate area models). The 1996 assessment had apportioned the total California rockfish catch based on total rockfish catches (as reported in CDFG Bulletins) and the percentage of total rockfish catch estimated to be bocaccio by region based on early species composition samples reported by Nitsos (1965) and other sources. Following the PFMC recommendation to evaluate historical catches as part of the "off-year" science activities, concerted efforts were undertaken to develop a comprehensive estimation of the historical catches of west coast groundfish, with the species composition of historical rockfish catches in California representing a major focus of those efforts. At that time, the SWFSC was in the process of several efforts that have and will continue to aid in this effort, including a major effort to digitize spatially explicit (monthly summaries of catches by 10-minute CDFG geographic blocks) catch records extending from 1931 through the CalCOM (1969) period. Additionally, efforts are underway to digitize vessel-specific historical fish ticket information; both of these projects are currently funded by the NESDIS Climate Database Modernization Program (CDMP). These efforts were folded into the historical catch reconstruction efforts described below for commercial and recreational species, respectively. For both commercial and recreational catch histories, it should be recognized that reconstruction efforts are ongoing and the exercise is likely to be an iterative and multistage process. Consequently, catch estimates may change again in the future, although we expect that the magnitude of such changes should be minimal.

The methodology for reconstructing historical commercial catches for bocaccio and other groundfish is reported in detail in Ralston et al. (in prep; will be in supplementary materials). The recovered block summary data were decomposed into "trawl" and "non-trawl" landings based on the observed differences between trawl summary block data and total catch by block data, after accounting for irregularities, missing years and assuming a constant ratio for years for which no trawl summary data exist. Next, market category catches (by area and gear) were converted into species-specific catches by applying stratum-specific species compositions of the highly mixed market categories from port samples collected during the 1978-1984 time period. This assumes that the proportional representation of a given species in a given market category was static over time, an unavoidable consequence given the paucity of more detailed information, but validated to a considerable extent by comparing these reconstructed species-specific catches to the species composition of trawl-caught rockfish reported by Nitsos (1965) (see Figure 6 in Ralston et al., in prep).

Figures 14 a-c show the historical commercial catches(1916-2000) for all rockfish throughout the entire state as well as north and south of Point Conception, based on the catch reconstruction of the three most important (by volume) rockfish species over the last century: bocaccio, chilipepper, and widow rockfish (with all other species lumped together). The percentage of the total rockfish catch estimated to be bocaccio rockfish is also shown. Total rockfish landings were reported to be approximately 2,000 to 3,500 mt statewide from the early part of the 20th century, dipping slightly in the late 1930s and into the beginning of the war years in the 1940s. During this period, slightly more than half of the total California catch was taken south of Point Conception, with the majority of the remainder coming from central California ports (particularly San Francisco and Monterey). Although paranzella trawling (and later otter-board trawling) have been an important source of marine fisheries landings in central California since 1876, most of the trawl catch in early years was composed of flatfish (petrale and English sole) fished over soft bottom (Clark 1935), and rockfish catches were primarily from hook-and-line fisheries (Wolford 1930; Phillips 1949).

Based on the catch reconstruction efforts, bocaccio represented approximately 20% of the total catch (by volume) in both regions (19% in southern California and 22% in central/northern California) during this period (1916- early 1940s), although in both regions this percentage fluctuates somewhat. Phillips (1939) reported on the species composition of rockfish from the Monterey wholesale fish markets between April 1937 and March 1938, in which 39.4% of the fish in the market were bocaccio, compared to 30.8% chilipepper rockfish and 7.9% yellowtail rockfish. Catch reconstruction estimates are consistent with Phillip's observation, as they estimate that bocaccio represented 35.9% and 32.8% of the rockfish catch (by weight) in the Monterey region for 1937 and 1938, respectively. Phillips also noted that catches (and presumably local abundance and/or availability) of bocaccio and chilipepper seemed to be negatively correlated and, when both of these species were uncommon, catches were bolstered by yellowtail, vermilion, and canary rockfish. The 1937-38 catches examined by Phillips may have been during a peak in the relative abundance of bocaccio, as the reconstruction estimates that the percentage of bocaccio estimated in Southern California catches increased to peak (pre-1950) values in the 1936-1938 period, to 27-29% in southern California and 24-26% in central/northern California (above the 1916-1940 averages of 19% and 22%, respectively), presumably as more fish were landed in the bocaccio market categories that are the foundation of the reconstruction.

As stated earlier, total California rockfish catches declined through the 1930s and into the early war years, although most of this decline was observed in southern California, while central California landings were relatively constant. Although paranzella trawling was an important fishery during this period, ranging up and down the coast, over 70% of trawl catches during the mid-1930s were English, rex, or petrale sole, while only about 5% of the catch was rockfish (Clark 1935). Consequently, most rockfish catches were from hook-and-line gear throughout the state. However, in 1943 the balloon trawl was introduced to northern California waters from Oregon, in association with a strong market for frozen rockfish by the military to support the war effort. Trawl gear rapidly surpassed hook-and-line gear in accounting for the majority of California rockfish landings, particularly in the northern ports of Eureka and Fort Bragg (Scofield 1948; Phillips 1949). Although the initial pulse of landings was north of Cape Mendocino, where bocaccio represented a fairly modest fraction of the catch, the fishing gear and methods found their way to central California fisheries rapidly and resulted in a rapid increase in rockfish landings from the late 1940s through the early 1950s. The percentage of the total catch estimated to be bocaccio in the catch reconstruction increased as well throughout this period; in the early 1950s bocaccio represented 45% of the total rockfish catch in the San Francisco and Monterey regions, 38% of the southern California rockfish catch, and 34% of the total statewide catch (for which northern California continued to represent a significant fraction of total landings).

This is consistent with reports from CDFG biologists at the time; Phillips (1955) had described bocaccio as the dominant species "at present" in the statewide commercial catch, followed by chilipepper, canary, vermilion, yellowtail, and black rockfish. Heimann and Miller (1960) described the species composition of trawl fisheries in the Morro Bay region, based on 64 drags observed over a one year period from 1957-1958. Bocaccio were the most frequently encountered species, caught in every haul and representing 65.6% of the total catch (followed by 31.8% chilipepper and less than 1% stripetail, widow, shortbelly, vermilion, and several other species). The authors reported that most bocaccio (and other desirable species) were retained, with discards representing 0.43% of the total catch (by contrast nearly all stripetail, shortbelly, and greenstriped rockfish were discarded). Their samples suggested an average total length of 48.3 cm for bocaccio (based on over 1,200 measurements; would be nice to know whether those still exist!), with the discarded bocaccio averaging 30.7 cm (14 measurements). Heimann (1963) also reported the species composition of trawl catches in the Monterey Bay area from a 1960 study, in which bocaccio were the most important rockfish species in the shallow water (targeting largely flatfish; less than 10% of the catches in this sector were rockfish) fishery; accounting for 53.3% of the rockfish landed in that sector, and were the second most important rockfish species in the intermediate depth fishery (which targeted rockfish, which were nearly 90% of the catch) at 34.9% of the rockfish caught, following chilipepper at 49.5%. Retention of both species was high for both sectors; only 0.7% of bocaccio were discarded in the shallow (flatfish-oriented) fishery, and only 0.1% of bocaccio were discarded in the intermediate depth (rockfish-oriented) fishery. Consequently, we have assumed discards to be negligible in the historical era of the fishery.

Bocaccio remained the most significant species in California rockfish fisheries throughout the 1960s and 1970s, representing approximately 33% to 35% of the statewide catch throughout that era. As with earlier eras, bocaccio represented a modest (generally 5-10%) fraction of the rockfish catch in northern California, and a greater (often greater than 50%) fraction of the catch in central California. Again, catch reconstruction estimates of the species composition of the catch are consistent with other reports throughout that period (e.g., Nitsos 1965 and Gunderson et al. 1974). Landings in both the hook-and-line and the trawl fisheries throughout this period are reported for the regions north and south of both 38 N latitude (used as a break point for the trawl fishery as described later) and Point Conception from 1916 through 1968 in Table 4. Landings for the 1969-2008 period are presented in Table 5 for the three major gear types, with the same latitudinal break points, and including estimates of catches in the Eureka INPFC area of Oregon (all are assumed to be trawl). Oregon landings from 1969-1980 were taken from Douglas (1998), landings from 1981-2002 were taken from PacFIN (query March 2009). Landings of bocaccio are assumed to be negligible in Oregon waters prior to 1969.

Rockfish, including bocaccio, were observed in California fish markets as early as the 1850s, and even David Starr Jordan (Jordan 1884) described bocaccio as “rather more abundant southward than about San Francisco. It is, however, a common market fish, and its flesh is considered excellent.” Eigenmann (1894) also described bocaccio as abundant from San Diego to British Columbia. To estimate catches of bocaccio prior to 1916, we used rockfish landings reported by Sette and Fiedler (1928), who report landings irregularly from 1892 through 1926 (1892, 1895, 1899, 1904, 1908, and 1915). Landings are interpolated between unreported years, and an equilibrium catch was implemented prior to 1892 based on the average of the first two estimates of catches (for 1892 and 1895). To estimate the fraction of these catches that were bocaccio, we applied the proportion of catches north and south of the major Points (Point Conception and Cape Mendocino) as estimated in the historical catch reconstruction (average of 1916-1920 values, although the ratios were nearly constant through this period), in which 52.4% of landings were from south of Conception, and 47.6% were north of Conception (the percentage of landings north of Mendocino were minimal, less than 0.1%). Next we applied the fraction of the catch by region assumed to be bocaccio (again averaging 1916-1920 values), which was 18.9% south of Conception and 21.5% from Conception to Cape Mendocino. Table 6 provides the total California rockfish catch estimates based on Sette and Fiedler from 1892 to 1915, and the estimated catches of bocaccio by region based on these ratios. We assumed that all catches prior to 1916 were hook-and-line caught, based on the observation by Clark (1935) that the use of gasoline powered paranzella trawlers (the predecessors of diesel powered trawlers) peaked in the 1917-1922 period, at which time they began to replace earlier steam trawlers that fished shallow fishing grounds just outside of the entrance to San Francisco Bay, targeting primarily small flatfish.

Landings from north of the assessment area (Cape Blanco, Oregon) are reported for the remaining Oregon catches, Washington catches, and British Columbia catches, in Table 7. For Oregon and Washington these numbers represent PacFIN estimates (query March 2009) for 1981-present, and Douglas (1998) for 1969-1980 (the latter are likely an underestimate, as the species composition of the catch was not sampled in earlier landings). In general, bocaccio represent a modest proportion of the rockfish caught north of Cape Mendocino, where widow, canary, yellowtail and Pacific ocean perch dominate the catches. From 1981-2000, bocaccio represented less than 3% of the annual *Sebastes* catch. However, given that the total catch was considerably greater in this region, this still represents a significant fraction of the total coastwide catch of bocaccio. From 1969-2008, the total landings of bocaccio are estimated to be just over 85,700 mt, with 15,400 mt (18%) coming from the region north of Mendocino (by contrast, total commercial landings south of Point Conception were 12,300 mt in the same period, although total recreational landings were an additional 14,600 mt). As this assessment maintains the spatial structure of past assessments, and does not extend north of Cape Blanco, these landings are reported for informational purposes only.

From 1965 through 1976, foreign fishing fleets, primarily Russian and Japanese, fished for Pacific hake, rockfish and other species along the U.S. west coast. In recognition of the inconsistent manner in which estimated catches in these fisheries were (or were not) included in stock assessments, Rogers (2003) developed a method of allocating these catches to all *Sebastes* and *Sebastolobus* species by year and INPFC area. The estimated catches for bocaccio for this period are reported in Table 8, and catches from the Monterey INPFC are pooled with the "southern" trawl fishery, while those from the Eureka INPFC are pooled with the "northern" trawl fishery.

As described in the section on management measures, since 2002 both commercial and recreational fisheries have been subject to very restrictive management measures. Regulatory discards consequently represent a significant fraction of the catch, thus recent catches and discards, for the 2002-2007 period, are based on the total mortality reports produced by the Pacific States Marine Fisheries Commission and the Northwest Fisheries Science Center, based on a combination of landings data and observer reported discarding (Bellman et al. 2008; provided by E. Heery). The 2008 estimates are based on the PFMC's Groundfish Management Team scorecard (J. DeVore, PFMC) and recreational estimates from California Department of Fish and Game (J. Budrick, CDFG). For the purposes of the model, catches by the various open access fleets and research catches (the latter of which are principally trawl-caught) are pooled with the southern trawl fishery (note that due to reporting constraints the northern trawl landings in this period only reflect those north of 40 10' N latitude). Discards represented approximately 75% of total trawl landings during this period, and for commercial fisheries have been centered around the central California (Monterey Bay to San Francisco) region (Figures 15a-b). Table 9 reports these data by the fisheries used in the model. The length frequency data for these discards is consistent with being regulatory discards, as discarded fish tended to be larger on average than those in the retained catch in earlier years. This is likely a consequence of a shift in most fishing effort that encounters bocaccio to waters seaward of the Rockfish Conservation Areas (RCAs). It is likely that an offset or blocked selectivity pattern for the post 2002 period would be a more appropriate way to model recent catches; however, as these landings were modest overall, and as incidental landings for other fisheries as well as research surveys are included in trawl catches (and indeed are comparable or exceed total trawl catches in magnitude for many recent years), this was not determined to be a high priority for this model. Similarly, we did not attempt to estimate a discard rate for the period following substantial management restrictions, but prior to the implementation of the RCAs and the bycatch monitoring program, although this may well be an unrealistic assumption. Greater consideration of these factors is recommended for future efforts.

Figure 16 summarizes the total catches in the assessment area (Cape Blanco through the U.S./Mexico border), from 1892-2008, by the fleet definitions used in the model, while Figure 17 shows the total estimated catches of bocaccio by INPFC area in the region north of Cape Blanco from 1969 through the present.

Commercial Length Frequency Compositions

The length composition of commercial landings (here broken out into trawl, hook-and-line, and set net fisheries) were obtained from the CalCOM database, and cover the years 1978-2008. Figure 18 shows the length compositions for bocaccio by year caught in the trawl fisheries; Figure 19 shows the length information for the hook-and-line fishery, and Figure 20 shows this information for the set net fishery. Figures 21a-c show the length frequency distributions for the three major gear types for both sexes and all years combined, in order to evaluate possible differences in the vulnerability (or fishing methods) of fish of different sizes in different regions. Although there appeared to be some differences in the size composition of fish landed in all gear types along the coast, with a general trend towards catching fewer smaller fish and more larger fish in more northern regions. The apparent shift to the right in trawl fishery length frequencies between the Monterey/San Francisco region and the Bodega Bay/Fort Bragg region was the primary rationale in separating the trawl fishery north and south of 38° N.

After careful evaluation of the raw (individual fish) versus expanded (based on fish ticket and port information) length frequency data, we compiled length frequencies using raw length observations. This is consistent with past assessments (MacCall 2003, MacCall 2007) for which length frequency data were "sharpened," essentially adjusted using the Von Bertalanffy growth curve to grow (or shrink) observed length data to reflect the length at the middle of the year (the time at which the predicted length frequencies are estimated by the model). As length composition data is based on expansion methods that typically borrow over time (months, seasons) and space (ports), sharpening was not possible with the expanded length data.

Although we did not continue with the sharpening approach, based on what we considered to be reasonable model performance with the unadjusted length frequency data, concerns over borrowing across both seasons and ports led us to evaluate more closely the differences among raw versus expanded length composition data. This evaluation suggested that while the differences between raw and expanded length frequencies were typically negligible, where there were differences they tended to result in an apparent coarsening of the length frequency data, which would presumably add noise to the model. The initial effective sample sizes (input N) for commercial, recreational and fishery independent length frequency data were calculated using the approach developed by Stewart (2008) in which:

$$N_{eff} = N_{trips} + 0.138N_{fish} \qquad \text{if } N_{fish}/N_{trips} < 44$$
$$N_{eff} = 7.06N_{trips} \qquad \text{if } N_{fish}/N_{trips} \geq 44$$

In this method, trips are considered equivalent to sampling clusters in CalCOM or hauls in the triennial or NWFSC combined survey, and the maximum input N_{eff} is capped at 400. This approach tended to result in N_{eff} values for most fisheries and surveys that were more precise than the model-estimated effective sample sizes, but not to the magnitude at which trips (for CPFV trips) or clusters (which are subsamples of trips for sampling commercial landings) alone tended to result in lower effective sample sizes than those estimated by the model. The number of subsamples taken, fish measured, and the initial effective multinomial sample sizes for the commercial fisheries are provided in Tables 10-11.

Recreational catches

Until this assessment, estimates of recreational catches for the pre-RecFIN (pre-1980) era had changed little since the 1996 assessment, when they were estimated as a constant fraction of CPFV-reported rockfish catches for southern and central/northern California as reported in CDFG Fish Bulletins (e.g., Young 1969; Best 1963). As with the commercial catch reconstruction, the methodology for reconstructing historical (pre-1980) recreational catches for bocaccio (and other rockfish) are reported in Ralston et al. (in prep) and summarized only briefly here. The reconstruction was based primarily on linking historical CPFV logbook-reported catches of rockfish (where CDFG blocks are reported with the catch) with the species composition of rockfish catches for those blocks from more recent CPFV observer data and other sources. Skiff and private vessel estimates are considerably more uncertain, and the approach developed used estimates of private boat catch from studies in the 1960s and interpolated catches to the RecFIN era. The interpolation was developed to match early 1980s RecFIN catches, although we excluded 1980, which was only a partially sampled year and has been considered highly uncertain in retrospect due to anomalously high catch estimates of several species. Species composition information for skiff and shore modes is very limited, despite the apparently great significance of this component of the recreational fishery even in the pre-1980 era, and consequently estimations are much more uncertain. These early catch estimates are presented in Table 12.

A combination of RecFIN and California Recreational Fisheries Survey (CRFS) data provides ready access to catch and discard estimates to the species level for the recent period (1980-present). RecFIN data are based on Marine Recreational Fisheries Statistics Survey (MRFSS) catch estimates, which are based on a combination of angler field surveys and randomized telephone surveys from 1980 through 2008 (with a hiatus from 1990 through 1992), with four primary fishing modes: CPFV, private vessel, pier, and shore (only the first two catch notable quantities of bocaccio in most years, although, as discussed earlier, catches are high during years of exceptional recruitment). For 1980 through 2003, catches in both numbers of fish and weight of fish were obtained from the RecFIN database. Spatial resolution of these catch estimates is generally limited to north and south of Point Conception, although some data can be retrieved at the county level. As RecFIN records include a significant fraction of “unknown” rockfish catches, the proportion of bocaccio observed in the “known” catches was applied to the reported catches of “unknown” rockfish and the total bocaccio catch was adjusted accordingly (Table 13). This is recognized to be a problem that, similar to the historical catch reconstruction, will require a more sophisticated evaluation and analysis for future assessment cycles.

Recreational Length Frequency Data

Recreational length frequency data were collected in CPFV fisheries during onboard observer programs for different periods in northern and southern California fisheries. In southern California, observers monitored CPFV catches during 1975-1978 and 1986-1989; collecting a total of nearly 78,000 fish in over 1000 trips during the 70s program, and another 14,000 fish in over 400 trips in the 1980s program. The central/northern California CPFV observer program collected nearly 12,000 length frequency observations from a total of just over 1300 trips (that encountered bocaccio). As all of these observer program measured fish in total length and other data series are in fork length, lengths were converted by the equation: Fork_length = a+b*total_length; where a=0.93 and b= 0.956. Table 14 and Figure 22-23 show the length frequencies and associated sample sizes, including the initial effective N estimated in the same manner as the commercial effective sample sizes.

The central/northern California observer program was also the source of the recreational CPUE index developed in prior assessments to which these length frequencies are linked. In past assessments, the length frequencies were pooled directly with the RecFIN length frequencies. We differ from the past in linking the length frequency information from the observer program directly to the index itself (which is treated as a survey), rather than pooling the length frequencies together. In past assessments the independence of these observations has been questioned and evaluated, although it does appear that there is some contamination of RecFIN length information with data from these observer programs for years in which the two overlapped. This overlap is generally minimal and the southern California length frequency information was not used in the model as a result of these concerns (the data have little influence when included, this decision could be revisited).

Two other sources of length information were considered as well; one is length frequency information for the years 1959-1961 and 1966 from the Miller and Gotshall (1965) and Miller and Odemar (1968; and additional unpublished CDFG data). These data were collected as part of an exhaustive effort to evaluate recreational fisheries in the central and northern California region by CDFG, from which the recreational catch reconstruction effort in Ralston et al. (in prep) drew from considerably. Beyond the summaries reported in the publications, the raw length frequency and species composition data for Monterey Bay area recreational skiff and CPFV fisheries were recovered from paper forms by Jan Mason (ERD, SWFSC; pers. com.) with some of the results reported in Mason (1995) and Mason (1998).

Although the currently available data are limited to this region, this region was responsible for slightly more than 1/3rd of the recreational rockfish catch in central/northern California fisheries during this period. Additional paper records exist for Half Moon Bay, San Francisco, and Bodega Bay recreational fisheries, and efforts to digitize and utilize these data are also being implemented. While the early 1960s data suggest a consistent size mode without particular evidence of extremely strong recent year classes, the 1966 length frequency data is consistent with both a strong year class several years earlier (approximately 1962-63) as well as a strong year class that year (1966) based on the high frequency of 20-30 cm fish (Figure 24). Moreover, the percentage of the total rockfish catch represented by bocaccio also shifts during this period, from a range of 2-5% of the total recreational catch in from 1959-1964, to a range of 5-9% of the total rockfish catch from 1966 through 1972. This is consistent with the perceived increase in the relative abundance of bocaccio in the mid-1960s as evidenced from the CalCOFI data and recent assessments. However, as it seems likely that the recreational fishery had a more limited spatial distribution (across both latitude and depth) and it is not clear how compatible these data are with later length data, this information is not currently included in the model. Further evaluation of these data, as well as the spatial patterns of development of the recreational fisheries more generally, would be beneficial to future assessment efforts.

Most of the recreational length frequency data are from the 1980-2008 period (exclusive of the MRFSS hiatus of 1990-1992) and, as in past assessments, the length frequencies and catches are divided into southern and northern components (Figures 25-26). Oregon and Washington length frequency data (outside of the modeled area) are also presented (Figure 27), but as pooled 5 year intervals due to the paucity of data. Sexes are pooled in all RecFIN rockfish data. As in prior assessments, strong year classes tend to show up earlier in southern California fisheries than in northern California fisheries, with northern California fisheries tending to catch larger individuals. The 1999 and 2003 year classes are particularly prominent in these data in the southern fisheries, with a suggestion of a strong 2005 year class as well. Sampling is generally comprehensive in southern and northern California, where bocaccio represent a significant fraction of the total recreational rockfish catch. The total number of clusters, fish sampled, and initial effective sample sizes are presented as Table 15.

Ageing Uncertainties and Age Data

The 1996 bocaccio assessment (Ralston et al. 1996; Ralston and Ianelli 1998) attempted to utilize age-frequency information from otoliths aged using break-and-burn methods from trawl fishery samples collected in 1988, 1991, and 1994. Just over 1,300 otoliths were aged, and approximately one of every four was subsequently reexamined by a second age reader to determine the precision of the break-and-burn age data. They found that the percent agreement between readers declined from ~90% for age 1 fish to ~10% agreement at age 20. The pattern of decline appeared to reflect an exponential decay in the precision of age estimates with increasing age. In their evaluation of the diverse sources of data, the assessment authors concluded that the age composition data were in fundamental disagreement with all of the other data sources. This was primarily due to the bias and imprecision in the ageing results, which resulted in an uninformative age composition data that were wholly inconsistent with the highly variable recruitment patterns clearly informed by the length frequency data. Since that assessment, age data have not been utilized in any of the subsequent southern bocaccio stock assessments, although STAR Panels have frequently recommended re-examination of age information and the potential for developing ageing criteria that could be used to guide production ageing efforts.

Ralston and Ianelli (1998) also noted that the rapid growth of young bocaccio and the relatively brief seasonality of spawning likely exacerbated the interpretation of bocaccio otoliths, as they resulted in a proliferation of false annuli and accessory check marks that were difficult to interpret, resolve, and validate through the application of marginal increment analysis. These results are consistent with the later age validation efforts of Andrews et al. (2005) and Piner et al. (2006), both of whom validated the longevity ranges described in earlier break-and-burn estimates of age structure, and both of whom found a high degree of ageing imprecision. Piner et al. (2006) used otoliths from twenty four adult fish captured near the U.S./Canada border (~47 -49 N latitude), for which initial age estimates were available from the collecting agency. Second and third independent age determinations were made from experienced readers in two separate laboratories to provide an estimate of ageing precision and possible age bias. Their results indicated that ageing precision was low for most samples, although they found no evidence of bias in this imprecision. The number of samples in this effort was inadequate to evaluate whether and how ageing error changed as a function of age. In contrast to their results, Andrews et al. (2005), using otoliths collected from central California, did report a bias towards under-ageing of bocaccio, which they also found to be very difficult to age using break-and-burn methods. However, the otoliths that they evaluated had not been aged based on established ageing criteria.

The inconsistencies with respect to possible bias in ageing are to some extent consistent with expectations; although bocaccio have long been known to be among the most difficult fish to age by experienced readers, age readers in northern regions have tended to report less difficulty and smaller inter-reader errors than those in southern regions. To evaluate this issue more rigorously, the one experienced reader contributing to this assessment (Pearson) aged a number of similarly sized fish from the same or similar years, from three regions of the coast; southern California (south of Point Conception), central California (Monterey Bay) and the west coast of Washington. To facilitate the evaluation, otoliths were cut using a Isomet low speed precision saw with a diamond encrusted blade, and then burnt, rather than the break-and-burn method typically used in production ageing.

In general, we found a trend towards easier readability with more northerly latitudes, which would be consistent with the more rapid growth and smaller age at maturity in southern animals, as well as the more variable ocean conditions in southern waters. Moreover, Parrish (1981) noted that upwelling winds, which drive much of coastal ocean productivity, were strongly seasonal in northern waters (north of Cape Mendocino), with upwelling favorable winds in spring and summer seasons, and downwelling during fall and winter. Upwelling winds demonstrate a somewhat more extended and slightly weaker seasonality in northern and central

California, where onshore transport during winter tends to have more frequent interruptions. Seasonal patterns become weaker still south of Point Conception and into Baja California, where a more continuous but less intense level of offshore transport occurs year round.

Figure 28 shows examples of cut and aged otoliths from fish that were approximately 600 cm long and taken from similar time periods from each of the three regions of coast. For future research efforts it may be possible to develop more rigorous ageing criteria for the ageing of southern bocaccio based on the more resolved patterns observed in fish from the north; an effort that might merit collaboration among age readers from California, the Pacific Northwest and British Columbia. In the foreseeable future, it is unlikely that production ages will play a meaningful role in future assessment efforts, and we have maintained the approach of previous assessments of excluding the sparse, and highly uncertain, age data from this assessment.

D.1.b Fishery-Dependent Indices

Trawl Catch per Unit Effort

Ralston (1999) developed a CPUE index of bocaccio abundance based on California trawl logbooks that was initially used in the assessment (Figure 29). Because the logbooks do not identify most individual species such as bocaccio, Ralston applied species compositions from local port sampling to the overall catch rates of rockfish from the trawl logbooks. This assessment uses Ralston's "area-weighted" index of bocaccio CPUE, and the associated standard errors (average CV is 32%).

Recreational CPUE Indices

Recreational CPUE indices were developed for the 2003 assessment (MacCall 2003) using catch and effort data were from two sources, the RecFIN database (Wade Van Buskirk, Pers. Comm.) and the Northern California partyboat monitoring conducted by CDFG (Deb Wilson-Vandenberg, Pers. Comm.). These two sources contain different kind of information and were treated differently in the 2003 assessment, although for the RecFIN data only the partyboat catch and effort data were used, as bocaccio catch rates from private boats appeared to be less consistent than those from partyboats.

MacCall (2003) developed indices based on the RecFIN data using a multispecies discriminant function analysis (Stephens and MacCall 2004) to identify which fishing trips are appropriate to include in calculation of a CPUE index of abundance. The concept behind the method is that the species mix in the catch of a fisherman or a fishing trip is indicative of the habitat where fishing occurred, allowing discrimination between those trips where the target species (bocaccio in this case) could have been caught and trips where bocaccio were unlikely to have been caught. Essentially, given the various fishing strategies of CPFV operators across many different habitats, seasons, and target species, the latter trips are not informative, and should be excluded from the CPUE analysis. The approach involves identifying the general list of species commonly caught on fishing trips in the region under consideration, and then converting trip records to a vector of presences (1) and absences (0) of those species.

For each trip record, the probability of the target species (bocaccio) being present was fit by maximum likelihood using a logit function based on an indicator function consisting of the sum of estimated species-specific coefficients, such that these coefficients include large positive values for species that consistently co-occur with bocaccio (e.g., chilipepper and bank rockfish), and large negative values for species that occur in habitats where bocaccio are unlikely to be encountered (e.g., oceanic species such as albacore, and nearshore species such as barracuda). Figure 30 shows an example of these coefficients for the southern California recreational index (for additional details, see past assessments, including responses to past STAR Panels). Next, each trip record is assigned an estimated probability that bocaccio could have been encountered. The trip records are sorted by descending probability, and a threshold probability is chosen for exclusion of trips from the CPUE calculation. After additional refinements to account for discards and other factors (See MacCall 2003, or Stephens and MacCall 2004 for a greater detailed description of the analysis), a delta-GLM model is applied to the retention-corrected records to arrive at a relative abundance index, with year and wave effects estimated as factors.

The resulting indices were also corrected to account for the expected impact of bag limits and for intentional avoidance of bocaccio in the post-2000 period, although the behavioral changes associated with increased regulatory activity from 2000 onward are difficult to fully understand. Consequently, the post-2000 data points should be interpreted as being more uncertain than previous points, and following the 2003 assessment the index was not updated due to the expectation of even greater bias as a result of management activities. Consequently, the indices included in this assessment are unchanged from those developed in the 2003 assessment (and subsequent updates), and additional details (including additional analyses conducted for past STAR Panels) should be referred to from those documents or from the publication that originated from this analysis by Stephens and MacCall (2004). It is also worth noting that the approach has subsequently been applied in many other west coast groundfish stock assessments for which recreational catches and effort represent a significant fraction of the fishery, including those for gopher rockfish (Key et al. 2006), yelloweye rockfish (Wallace et al. 2006), blue rockfish (Key et al. 2008), and black rockfish (Sampson et al. 2008).

In addition to the indices derived from the MRFSS data, the California Department of Fish and Game conducted on-board monitoring of partyboat catches in central and northern California from 1988 to 1998. Presence of location and depth information associated with catch and effort at individual fishing sites (Deb Wilson-Vandenberg, Pers. Comm.) allowed a more direct identification of appropriate records for use in a CPUE calculation. The analysis used only those fishing sites with at least seven occupations and at least five positive occurrences of bocaccio catch in the data set. Initial exploration allowed collapse of monthly effects into a seasonal winter (January, February and March) and nonwinter effect; and the few records from depths greater than 80 fm were combined to form an 80+ fm depth effect. The final delta-lognormal GLM included year (12), season (2), site (100) and depth (8) effects. As with the other recreational CPUE indices, this index was not revisited for this assessment. However, the index was treated as an independent survey in this assessment, with the length frequency information (which was pooled with the RecFIN length frequency information in the 2003 assessment and subsequent updates) treated as independent observations from the RecFIN data. The independence was somewhat artificial, in that the selectivity curves for the RecFIN length frequency data and this survey were linked (mirrored selectivity), consistent with the notion that the two data sources are related. Sensitivity analysis suggests that the two curves were highly similar when estimated independently, however, this allowed for these data to be evaluated and weighted (tuned) independently. All three of these recreational CPUE indices developed for the 2003 assessment are shown in Figures 31a-b.

D.1.c. Fishery-Independent Data

CalCOFI larval abundance data

The historical ichthyoplankton abundance data from the California Cooperative Oceanic and Fisheries Investigations (CalCOFI) surveys was first used in the bocaccio stock assessment in 1996, although it was not included in the 1999 assessment due to the re-analysis of the CalCOFI dataset during that period (it was used again beginning in the 2002 and subsequent assessments). Egg or larval abundance data from these surveys have also been used in stock assessments for other important west coast species, including northern anchovy (Jacobson and Lo 1994), Pacific sardine (Hill et al. 2007), shortbelly rockfish (Field et al. 2007) and California sheephead (Alonzo et al. 2004). Although a larval abundance index was developed in the first stock assessment for cowcod (*S. levis*, Butler et al. 1999), this index was not included in the most recent assessment (Piner et al. 2006) out of concerns for the rarity of cowcod in sampled tows. Similarly, these data were explored for an a recent assessment of the closely related and often co-occurring chilipepper rockfish (*Sebastes goodei*), the index was ultimately not included in the final model as most of the data were from the southern periphery of that stock's range, and the near total absence of larvae in the southern region between the early 70s and 2000 (Field 2008).

Bocaccio rockfish are one of only several *Sebastes* species for which larvae are readily identifiable using morphometric methods (Moser et al. 1977). Most of these larvae were not identified to the species level in initial plankton sorting efforts; rather the core area dataset was reanalyzed following the development of morphological criteria that allowed for conclusive identification to the species level. Consequently, data for the northern regions are only available for a subset of years, although historical samples are currently being enumerated from 1968 back to 1951 (W. Watson, SWFSC, pers. comm.). Table 16 shows the number of total tows, positive tows, and the mean CPUE of positive tows for the southern and northern stations, for years in which adequate sampling took place during the winter (November-May) spawning period (sampling was generally triennial from 1969-1984). The mean catch rates by station and decade are also shown as Figures 32a-f, note that for the central Californian stations, sampling effort is typically far lower than the south (as shown in Table 16). Although contemporary sampling effort in the central California region is not as intensive as that in the southern region, the time series for central California will continue to grow both forwards and backwards in time.

We developed the CalCOFI index consistent with the approach from past assessments, in which we used tow specific information and a delta-GLM approach to derive an index of spawning output. Fixed effects in the model included year (fixed to spawning season, such that data from November and December are used to estimate the year effect for the following year, along with the January-April data from that year), month and line-station effects. We also explored alternatives to the line.station factor approach, including combinations of line, distance from shore, and depth. Although these approaches used a lesser number of parameters, they also resulted in models that had significant interactions among the different factors, and when such factors were accounted for using interaction terms the effective number of parameters varied little from the line.station model. As the resulting indices were all comparable, and AIC additionally indicated that the line.station model explained more of the variance in the model, we continued with the use of line.station effects for this index. However, we did evaluate alternative link terms in the binomial component of the model, and found that a complementary log log (cloglog) link function performed better (AIC of 20 likelihood units) than the logit link term used in the past. This link term was consequently used to develop the relative abundance index.

These estimates and the associated standard errors estimated from a jackknife routine were used in the model as a relative index of population spawning output (Figures 33a-b). The trends suggested by both the raw data (percent positive tows and catch rates of positive tows) suggest that relative abundance was declining through the 1950s, but increased sharply in the 1960s through the early 70s, after which the index declines similar to the decline observed in other indices. Throughout the time series, there is considerable high frequency year-to-year variability in larval distribution and abundance that may be related to variability in climate, oceanographic features and circulation patterns, or variable reproductive output (MacGregor 1986, Moser et al. 2000; Lenarz et al. 1995).

Larval production estimates

In addition to the relative abundance estimates based on the delta-GLM model, we consider estimates of absolute biomass developed by Ralston and MacFarlane (in review), for the Southern California Bight (U.S. waters south of Point Conception). These estimates are developed from an estimation of the spawning output necessary to produce observed daily rates of larval production, using a methodology developed first by Ralston et al. (2003) for shortbelly rockfish (*Sebastes jordani*) and subsequently used in an assessment of that unfished population (Field et al. 2007). Ralston and MacFarlane used expanded the daily rates of larval production observed in the CalCOFI Ichthyoplankton surveys during 2002-2003, a year in which sampling in the Southern California Bight was enhanced within the region currently encompassed by the Cowcod Conservation Areas (CCA's) as part of an effort to improve the assessment of that stock. Their results indicate that in 2002 and 2003 there were approximately 3470 and 5921 mt, respectively, of female spawning biomass in the Southern California Bight, corresponding to 6953 and 10,656 mt of total biomass. Interestingly, their results also indicate that the concentration of bocaccio in the years of their survey was strongly centered around the Cowcod Conservation Areas (CCA's), which have been closed to fishing since 2001, and which was not typical of the long-term average distribution of larval abundance through the duration of the time-series (Figures 34a-b). While the causes of this shift in distribution are unclear (certainly it is not reasonable to think that it was the result of a 1-2 year closure), the consequence does have implications for the interpretation of data from those indices that sample in the Conception area, but avoid sampling within the Cowcod Conservation Areas themselves. Additional details can be found in the manuscript included in the assessment background materials.

Additional visual and acoustic methods of abundance estimation currently under development

Several additional non-lethal methodologies for the assessment and monitoring of rockfish stocks off Southern California are currently under development and may provide useful data for future assessments. For example, data from multifrequency echosounders and underwater cameras have been used jointly by the Advanced Survey Technology (AST) and In-Situ Survey groups at the Fisheries Resources Division (SWFSC) in La Jolla to map the dispersions and estimate the abundances of rockfish at a suite of historical fishing sites within this region. The techniques were developed in 2003/04 from the Commercial Passenger Fishing Vessel (CPFV) Outer Limits; applied throughout the SCB in 2004/05 and 2007 (COAST07), largely from NOAA Ship David Starr Jordan. The frequency dependence of sound-scatter intensity is commonly exploited to classify fish, zooplankton and seabed observed in acoustic surveys. Although less utilized, techniques based on scattering statistics of echo amplitudes can also be used to extract information, and workers have developed a hybrid, statistical-spectral method for target identification (SSID), which incorporates information contained in both the signal amplitudes and phases (Demer et al. 2009). This approach should ultimately provide the means to separate scatter from demersal fish and the seabed, as well as estimate seabed depth, within-beam slope, hardness and roughness, and the height of the dynamic acoustic dead zone. Additionally, preliminary success has been made in investigating sound production in rockfishes, including the identification of sounds made by bocaccio and several other species (Širović and Demer 2009). From August to October 2007, the acoustic and visual surveys described above were augmented with two passive-acoustic seabed recorders, which were subsequently analyzed for the presence of rockfish sounds. A repetitive pulsing from bocaccio was the most commonly recorded sound and it occurred predominately at night. The daily calling rates at each site were quantitatively compared with the rockfish abundance estimates obtained from the active-acoustic survey, and they were positively correlated (Širović et al. 2009). These results suggest it may be feasible to use passive acoustic tools to efficiently monitor changes in rockfish populations, possibly in conjunction with acoustic and/or visual survey methodologies. However, as all of these approaches show some promise for potentially useful survey methodologies, none was sufficiently developed to be used as an index in this assessment.

Triennial Trawl Survey

A primary source of fishery independent information for most managed and assessed groundfish species in the California Current is the West Coast triennial trawl survey conducted between 1977 and 2004 (e.g., Weinberg et al. 2002). As the general consensus from recent data workshops has been to exclude 1977 data, we have not used these data in either the area-swept or GLMM indices, but continue to report the data here. We obtained both stratum-specific area swept biomass estimates and haul-specific survey data from 1980 to 2004 (M. Wilkins, AFSC; B. Horness, NWFSC), both of which were generated after excluding bad performance tows and "water hauls," in which few benthic organisms were noted (Zimmermann et al. 2001). Catch rates pooled over all years are shown relative to the latitude and longitude in Figure 35, while the log of tow specific CPUEs from this survey by year, relative to both latitude and depth (but excluding depth contours to better capture the depth distribution) are shown in Figures 36a-j, which also illustrate the variation in the latitudinal range of this survey over time. The number of hauls, number of positive hauls, number of hauls in which lengths were measured, and total number of lengths measured by year are presented as Table 17. Biomass estimates, and their associated coefficients of variation based on area-swept indices are presented by depth and INPFC strata in Table 18.

The area-swept index of abundance has been criticized in the past due to the infrequent occurrence of very large hauls, which leads to noisy abundance estimates in the time series. This is a consequence primarily of the aggregating behavior and habitat associations of many semi-pelagic rockfish species, which tend to be characterized by patchy distributions and often highly specific habitat associations. Consequently, survey workshop recommendations and trends in stock assessment applications have been to developed survey indices an index of abundance using the Generalized Linear Mixed Model (GLMM) approach described in Helser et al. (2007); this method is also used for the Northwest Fisheries Science Center combined survey data described later. The model uses depth strata and latitude (or INPFC latitude proxies) as fixed effects, and vessel as a random effect, to develop stratum-specific estimates of catch rates (kg/ha), which are then expanded to the total area of a given stratum to arrive at an abundance estimate. The model assumes a log-normal error variance assumption for the positive observations, which is consistent with observations of observed catch rates (Figure 37a). Models with gamma or inverse Gaussian error distributions generally failed to converge, likely due to low sample sizes in many strata. Point estimates of biomass and the associated CVs are based on the median of the marginal posterior density from MCMC (although standard errors and CVs are reported in the tables, the starting value for the indices in the assessments were based on the square root of the CV+1).

The STAT considered the standard depth and area stratification structure used for the GLMM to be potentially problematic for bocaccio. The traditional stratification is based on the INPFC areas (essentially, proxies for latitude effects) and depth bins from 55-183 meters, 183-300 meters, and 300-550 meters (deeper strata are not used for rockfish). However, the northern region of the Conception INPFC area was sampled only occasionally (and was never sampled south of Point Conception), such that there are essentially no Conception area data for the 1980-1986 period. Consequently, we evaluated an alternative stratification in which the northern Conception area (34.5-36° N) was grouped with the southern Monterey area (36-38° N), and the remaining Monterey INPFC area (38- 40.5° N) was considered a distinct region. We also had concerns regarding the design of the depth strata, which essentially bisect the depths of greatest abundance for bocaccio. Figures 38a-c show depth effects (as factors) with the standard depth strata, and with alternative 50 and 25 meter depth bins, illustrating that the greatest catch rates of bocaccio tend to occur between 150 and 250 meters, with low catches in both shallower and deeper depths. Consequently, we also explored alternative depth stratification, in which strata were redesigned into 100 meter depth bins (55-150, 150-250, 250-350). Revised estimates of the total areas of these new strata were provided by Beth Horness (NWFSC, pers. com.).

As seen in Figures 39a-c, there is a significant difference between the design-based estimate and the GLMM estimates. This is a consequence of the down-weighted significance a small number of tows with very large positive catches. The influence of these tows is reduced in the GLMM under the assumption of a log-normal error distribution, and consequently the index has a smoother (temporally autocorrelated) trend, as opposed to the relatively noisy trend of the area-swept index. However, the difference among the indices with the standard versus the alternative area stratifications was relatively modest (note that the standard stratification in this example excludes the Conception area data entirely due to the lack of data in many years). Similarly, a coastwide GLMM that incorporates the (relatively modest volume) data from the Columbia and Vancouver INPFC areas (using the standard, rather than alternative stratification, and thus excluding the Conception area data) was nearly identical to the index based on the assessment area alone, not surprising due to the paucity of positive tows in the northern INPFC areas (Table 19). Similarly, there was little difference when the alternative depth strata were used, suggesting that the model does not require informative depth factors to arrive at consistent results. Due to the apparent habitat preferences of bocaccio, which tend to prefer untrawlable habitat, as well as the fact that the triennial survey did not survey the Conception INPFC area in many years (and never extended to the core of that area, south of Point Conception), this index is treated as an index of relative, rather than absolute biomass, such that q is treated as a nuisance parameter.

Length frequencies for the triennial survey were calculated based on standard estimation methods (Dark and Wilkins 1994). However, it was noted that in the early years of the trawl survey, length measurements were not taken from every haul, and in fact most hauls with only a small number of bocaccio (less than 10 fish) in the catch did not report length frequency information (Figures 37b-c). This may have led to a bias in which larger fish were disproportionately excluded from the length frequency data, as the mean weight of fish in the hauls with no length frequency data tended to be greater than the mean weight of fish in hauls that did include length frequency data. Length frequency data are shown in Figure 40.

Northwest Center Trawl Survey

The Northwest Fishery Science Center has conducted combined shelf and slope trawl surveys since 2003, based on a random-grid design from depths 0of 55 to 1280 meters. Additional details on this survey and design are available in the abundance and distribution reports by Keller et al. (2008). Geographic locations of catches and negative tows pooled over all years are shown as Figure 41, while tow-specific Log CPUE estimates from this survey by latitude, depth and year are shown as Figures 42a-f. Additional data on the number of tows, number of positive tows, number of length measurements and mean CPUE rates by depth and INPFC area are provided in Tables 20. The design-based area-swept biomass estimates for the West Coast are provided by INPFC area in Table 21, which range from 1235 mt in 2003 to 9184 mt in 2004, with a (very general) declining trend suggested from 2005 through 2008 (3644 to 1784 mt). The vast majority of the estimated biomass is found in the assessment area (Conception, Monterey and Eureka INPFC areas), and in the shallower depth strata.

As with the triennial survey, an alternative index GLMM methods described above for the triennial survey index (the error distribution was assumed to be lognormal). We explored both the standard stratification (INPFC area and 55-183, 183-300, 300-549 meter depth bins) and the revised depth stratification used for the triennial survey as described in the previous section (Figure 38a-b); we maintained the standard INPFC area stratification due to the consistency in sampling the entire Conception INPFC area throughout the survey. However, it should be noted that sampling density in the Conception area is relatively modest, and does not include the habitat in the Cowcod Conservation Areas (CCAs). As with the triennial survey, the results varied little among the two models, similarly there was little difference between the assessment area estimate and the coastwide model estimate (Figure 43). For consistency with the area-swept biomass estimates and the expanded length-frequency estimates, which were derived using the standard depth stratification, we used the index from the model with the standard depth stratification. As the indices vary little among the alternative stratifications, we do not consider this to be a major concern.

Length frequency data were based on the expanded length frequencies provided by Beth Horness (NWFSC), shown in Figure 44. The length frequency data in most of these years are dominated by the 1999 year class, with signs of the incoming 2003 and 2005 year classes in later survey years.

NWFSC Southern California Bight hook-and-line survey

Since 2004 the NWFSC has conducted a hook-and-line survey for rockfish in the region south of Point Conception, using essentially recreational gear types, surveying locations that are either likely or known sites where recreational fishing occurs, and chartering recreational (CPFV) vessels to conduct the survey (Harms et al. 2008; Harms et al. in prep). Importantly, this survey does not include fishing sites within the Cowcod Conservation Areas, a large region closed to commercial and recreational fishing in order to rebuild the cowcod rockfish (*S. levis*). Consequently, the trends inferred from this index should be interpreted with some caution.

Bocaccio rockfish are among the most frequently encountered species in the survey, representing approximately 25% of all fishes encountered. Harms et al. (in prep; included in supplementary materials) standardized catch rates of bocaccio rockfish from 2004 – 2007 using a Bayesian Generalized Linear Model to account for site, fishing time, survey vessel, angler, and other statistically significant effects. Their results are moderately indicative of a slight downward trend in the biomass vulnerable to this survey (Figure 45a), which like the southern California recreational fishery, is likely to show dome-shaped selectivity. As with the NWFSC combined survey and the southern recreational fishery length frequency data, the length-frequency distributions are dominated by the 1999 year class from 2004-2006, with signs of the incoming 2003 year class, which together with an apparent strong 2005 year class tends to dominate the length frequencies of the later years of survey data (Figure 45b).

Recruitment Indices

Two recruitment indices were used in the 2002 bocaccio assessment: the Midwater Trawl Survey of juvenile rockfish in Central California, and an index based on impingement rates at Southern California electrical generating stations (Power Plant Index). The 2003 assessment added a third recruitment index, the Pier CPUE Index based on recreational catches of young-of-the-year bocaccio from piers. However, the 2003 STAR Panel recommended that all three recruitment indexes be removed from the model, so the 2003 assessment, as well as the 2005 and 2007 update assessments did not include any recruitment indexes. All three recruitment indexes are reconsidered in the 2009 assessment. The Power Plant Index data end in 2000 and have not been updated due to changes in plant ownership, but the index has been re-estimated here. The Midwater Trawl Survey and Pier CPUE Index have been substantially revised and extended. Although all of these indexes are imprecise, they potentially provide improved stability to the pre-1970 abundance and recruitment estimates when length composition information is otherwise lacking.

Power Plant Index (Southern California)

Annual impingement rates (number of bocaccio per volume of intake water) at five Southern California electrical generating stations from 1972 to 2000 form the basis of a recruitment index (data supplied by Kevin Herbinson, Southern California Edison). The five power plants (sites) are El Segundo (ES), Huntington Beach (HB), Ormond Beach (OB), Redondo Beach (RB), and San Onofre (SO). San Onofre consists of three time series for three separate intakes; the first extends from 1972 to 1993, and the other two extend from ca. 1982 to 2000. A preliminary delta-GLM produced overlapping jackknife confidence intervals for the three San Onofre "effects" which supported using a combined average value for San Onofre (this avoids need for complicated weighting to preserve equal weighting among power plant sites). A gamma model of the positives was marginally better than a lognormal model, deltaAIC = 2.48, and was used in this analysis. The shape parameter of the gamma distribution was 0.87, indicating an approximately exponential distribution of the positive values.

Jackknife estimates of standard error were possible for most years. The three years 1982, 1993 and 1994 contained only one positive site; index values were estimable and approximate standard errors were based on an assumed CV of 1.5, derived from the trend of CV vs. index value. El Nino years 1983 and 1998 contained no positive sites, but an index value of zero cannot be used by Synthesis. These two years were represented by an index value somewhat smaller than the minimum observed positive values, and with an assumed CV of 2. The time series of log(index) values is shown in Figure 46a, and shows a general trend of declining recruitment over the duration of the observations.

Pier CPUE Index

Young-of-the-year bocaccio have long been known to be occasional targets of recreational fishermen from fishing piers, where high catch rates appear to be associated with strong year classes. MacCall (2003) developed an index of bocaccio recruitment along the California coast based on bocaccio catches and associated effort from piers during the May-October period. Based on these data, San Luis Obispo County was described as the apparent center of historical bocaccio recruitment, with Santa Barbara (34° 24' N) to Santa Cruz (36° 58' N) being the typical geographic range of large recruitment events. Juveniles were rarely observed at piers in or south of Ventura and Los Angeles Counties, and MacCall concluded that there was no evidence of separate southern California recruitment events from this analysis. This analysis demonstrated that 1980, 1984, 1988 and 1993 were years of strong bocaccio recruitment; most other years in the time series showed weak or no catches of bocaccio.

Miller and Gotschall (1965) reported on one such event in 1956 and 1957, during which large numbers of young bocaccio occurred at all piers from Avila Beach, CA (35° 11" N) to Princeton, CA (39° 24' N; four coastal counties). They reported that the greatest concentrations appeared in mid-1956; by 1957 larger fish had moved to deeper waters and by 1958 they were not observed from piers or near shore. This event was also observed by Dr. Milton Love (USCB, pers. Com), who as a young fisherman witnessed very high catch rates of bocaccio at the Cayucos Pier (just north of Morro Bay) during a family vacation in August of 1956. Sadly, Love lost half of his fishing pole through the slats in the Cayucos Pier during this experience, and did not manage to land any of these fish himself. Large numbers of bocaccio were also observed in pier fisheries in the Central California region during the fall of 1966, accounting for 26.4% of the 1.3 million fish estimated to have been caught in pier fisheries in three different central California counties during that year (Miller and Odemar 1968).

The bulk of the pier data were obtained from the RecFIN database covering most of the years from 1980 to 2008. RecFIN records of bocaccio catch per angler hour were summarized by years (26), 2-month waves (3), and counties (6), each combination constituting a single record. Records with bocaccio mean length larger than 175mm FL were dropped (9 positive records). Also, the seasonal frame was restricted to May-October, which removed two more positive records, leaving 42 positive records out of a total of 438. No pier-caught bocaccio were seen in 13 of the years, and bocaccio were very rare in some locations such as Los Angeles and Ventura Counties.

Analysis of an initial GLM including year, wave and county effects indicated that the three wave effects were indistinguishable, allowing the model to be simplified to just year and county effects. Individual wave records were treated as replicates. AIC values showed no significant difference between gamma and lognormal models (deltaAIC = 0.06) , and the estimated gamma shape parameter of 86.7 indicated a non-zero mode for the positive observations. Consequently the lognormal model was chosen for the pier CPUE data. Values for the 13 zero-index years were replaced by minimum values of 0.01, which is about one-half the smallest non-zero estimate, and associated CVs were set at 1.5. All of the CVs were subsequently converted to standard errors in log space (sigma) by the transformation, sigma = sqrt(ln(CV^2+1)). These data were merged with the RecFIN data to produce the final index values. Miller and Gotshall (1965) anecdotally observed that bocaccio catch rates had been much higher in 1954 and 1956, so nominal index values for those years were set at 0.1 (1955 and 1957 were set at the default minimum of 0.01), and all were assigned large CVs. The final time series is shown in Figure 46b. The value for 1966 is quite high, but is strongly supported by observed data.

Midwater juvenile rockfish survey

The Fishery Ecology Division of the Southwest Fishery Science Center has conducted a standardized midwater trawl survey during May-June aboard the NOAA R/V David Starr Jordan every year since 1983. The primary purpose of the survey is to estimate the abundance of pelagic juvenile rockfishes (*Sebastes spp*.) and to develop indices of year-class strength for use in groundfish stock assessments on the U. S. west coast. This is possible because the survey samples young-of-the-year rockfish when they are ~100 days old, an ontogenetic stage that occurs after year-class strength is established, but well before cohorts recruit to commercial and recreational fisheries. This survey has encountered tremendous interannual variability in the abundance of the ten species that are routinely indexed, as well as high apparent synchrony in abundance among the ten most frequently encountered species. Past assessments have used this survey as an index of year-class strength, including assessments for widow rockfish (He et al. 2005), Pacific hake (Helser et al. 2006), shortbelly rockfish (Field et al. 2007) and chilipepper rockfish (Field 2008).

Historically, the survey was conducted between 36°30' to 38°20' N latitude (approximately Carmel to just north of Point Reyes, CA), but starting in 2004 the spatial coverage expanded to effectively cover the entire range of shortbelly rockfish indexed in this model, from Cape Mendocino in the north to the U.S./Mexico border (Sakuma et al. 2006). Additionally, since 2001 juvenile rockfish data are available from a comparable survey conducted by the Pacific Whiting Conservation Cooperative and the Northwest Fisheries Science Center (spanning from just south of Monterey Bay to Westport, WA; see Sakuma et al. 2007). Comparison of the coastwide data have revealed two types of shifts in the distribution of most pelagic species, in which species characterized by a more southerly geographic range (e.g., bocaccio, shortbelly, and squarespot rockfish) were caught in relatively large numbers south of Point Conception, while species with more northerly distributions (widow, canary, and yellowtail rockfish) were caught in moderate numbers north of Cape Mendocino. Thus the near absence of fish in the core survey area during the 2005-2007 period, which saw two of the lowest abundance levels of juvenile rockfish ever observed in the core area time series, was associated with an apparent redistribution of fish, both to the north and the south.

The survey index is calculated after the raw catch data are adjusted to a common age of 100 days to account for interannual differences in age structure. For this assessment cycle, a number of survey indices were developed by S. Ralston (SWFSC) as a combined index that uses both SWFSC and NWFSC/PWCC survey data (report in supporting materials). As the core area index seems to have failed to capture the magnitude of the 1999 year class for most stocks, the recommendations from the juvenile rockfish survey workshop held in 2005 were to exclude the core juvenile indices unless a convincing case could be made otherwise. The coastwide juvenile bocaccio index (Figure 47) was developed by integrating the results of both surveys in an ANOVA model with year, latitude, vessel, period, and depth effects, was used to inform the relative year class strength for the years 2001-2006. Past assessments have used a power coefficient to transform the index (He et al. 2006), based on the assumption of a compensatory relationship between pelagic juvenile abundance and subsequent recruitment to the adult population following settlement (Adams and Howard 1996). However, due to the short duration of the time series, a power transformation was not estimated for the coastwide index in this assessment.

D.2 History of modeling approaches and transition to new modeling platform

D.2.a Pre-STAR Panel Consultations

Due to time and budget constraints, a pre-assessment data workshop was not held for the bocaccio stock assessment. Email communications were exchanged between the STAT team and the GAP, GMT and PFMC representatives regarding major changes to the model and the new data sources being considered. In particular, a draft of the historical catch reconstruction was circulated to these members, as this was among the more significant changes with an effect on the ultimate model outcome.

D.2.b Responses to previous STAR Panel recommendations

The 2003 STAR Panel report and subsequent STAR Panel reports from the 2005 and 2007 updates highlighted a number of recommendations for future research activities. All of these recommendations were addressed to the greatest extent practicable in this assessment. The primary research recommendations from the 2003 STAR Panel report, and a narrative on how these recommendations were addressed, follows. Most of the 2005 and 2007 STAR Panel recommendations were similar in nature, those that are not addressed in the discussion below are summarized and responded to in the paragraph that follows the response to the 2003 recommendations.

> *Due to the extensive fishery closures and regulations prohibiting retention of catch in excess of the legal limits, fishery CPUE indices in the future will be biased indices of abundance. The Council and NMFS need to consider to how to monitor bocaccio status in the future. The CPFV data set consisting of reef-specific indices of abundance from partyboats is extremely valuable for evaluating of local fishing effects and as an index of overall abundance. Reef-specific CPUE is not as subject to the typical limitations of fishery CPUE data. A program of exempted fishing permits for partyboats with observers to monitor stock status should be considered.*

The Southern California Bight hook-and-line survey discussed earlier was developed in part as a result of that recommendation (Harms et al. 2007; Harms et al. in prep), and is incorporated into this assessment. The performance of this index is discussed in the model evaluation section. The STAT Team also points out that the CalCOFI larval abundance index, which represents the longest (largely) continuous time series of relative abundance for any west coast groundfish, seems to be working well for bocaccio over long time periods, and it is doubtful that exempted CPFV fishing would provide information of greater utility. This is particularly true given the uncertain effects of the area closures (CCAs and RCAs), particularly in southern California, which are likely to be biased with respect to relative abundance trends which are currently limited to those regions open to fishing and do not sample in regions where fishing has been excluded (now for nearly 8 years). The diagnostics of the relative shift in the spatial distribution of spawning output inferred from the larval production paper (Ralston and MacFarlane, in review) provide substantive evidence of this problem.

> *More attention needs to be given to how growth is modeled in the assessment. A model with time varying growth or cohort-specific growth may improve the fit to the length frequency data. Alternative ways to model variation in length with age should also be considered. Also, the Panel recommends that ageing of bocaccio be re-visited. A modest ageing sample could be used to evaluate whether the linear trend in the coefficient of variation (CV) of length with age in Stock Synthesis is a reasonable assumption, as well as confirming the model estimates of growth.*

In this assessment, growth is revisited and continues to be estimated internally. Although improvements in the fits to the length composition seem to reduce the necessity of exploring time-varying growth, there are still patterns in the residuals that suggest either time- or cohort-specific growth patterns that contribute to poor fits to some data. Initial efforts to incorporate time-varying growth did result in an improvement in the fit to the data and indicate that this process is important to incorporate into the modeling framework. However, the initial results also suggest that the results of the base model change only marginally with incorporation of time varying growth, thus for the purposes of this assessment, time-varying growth is not adopted. The CV of length at age was explored to the extent it could be with available data as well as through the relative change in fit with varying values, and profiles of the CV of length at age were used to inform the final values. Although several age validation manuscripts have been published since the 2003 assessment, all recognize the difficulty in ageing bocaccio; we have initiated an effort to better understand if, and why, bocaccio from the southern region of the California Current appear to be more difficult to age than those from the north, which likely is a combination of factors relating to the differences in the seasonality of secondary production among these regions, acting in concert with the very rapid and likely variable growth typical of bocaccio in the southern region.

> *The Stock Synthesis model apparently does not perform well with the diverse data sets used to assess bocaccio. Consideration should be given to moving the bocaccio assessment to a new modeling environment, ideally one with optimization routines using automatic differentiation rather than numerical differentiation as in Stock Synthesis.*

Movement of the model to the SS3 modeling platform addressed this need in a highly satisfactory way, with an apparent improvement in model performance, improvements in fit related to more plausible model parameters (e.g., steepness), and greatly improved run times (draft base model run time is approximately seven minutes without inverting the Hessian matrix, versus over two hours for the 2003 SS1 model).

> *Early catch history of bocaccio is a significant source of assessment uncertainty. Focused research on historical catch is needed. A comprehensive approach should be taken where historical catches of all West Coast groundfish species are investigated at the same time. Assessing historical effort in West Coast groundfish fisheries may be more successful as a collaborative undertaking between an expert in historical research and a stock assessment scientist.*

As discussed in the comparison to the most recent assessments, this assessment uses a greatly revised catch history based on a major effort to reconstruct historical landings for groundfish throughout California waters. The authors of this assessment were deeply involved in this effort.

> *Work needs to be done to figure how to the start the model with appropriate initial conditions and with sensible initial depletion which is consistent with the data.*

The revised catch history and time period of the model (which now starts in 1892 rather than 1950) addresses these concerns.

> *The relationship between the CalCOFI index and climate should be evaluated. Two analyses are suggested. The first is to compare the residual patterns in model fits to an environmental index such as the Scripps Pier water temperatures. Adding an environmental covariate to the CalCOFI index catchability coefficient may improve the model fit to the index if annual egg production is influenced by environment conditions. A second analysis would be to compare biomass trends to indices associated with regime-*

scale environmental variability to see if significant correlations exist that would help explain long-term abundance trends.

We have not had sufficient time to evaluate this in great detail. However, initial evaluation of the residuals of the CalCOFI index to environmental indices (such as the multivariate ENSO index or the Pacific Decadal Oscillation index) do not show great promise for explaining much of the variability; interestingly the fit to climate indices tends to be better with the raw data than with the residuals to the fitted index (although neither would be considered a good fit in any meaningful sense). This suggests that climate conditions relate to fecundity (larval production) patterns as well as growth, and these interactions will be investigated in greater detail in the interim period between this assessment and the next assessment cycle, in concert with the research efforts related to time varying growth (discussed above).

The recommendations of the 2005 and 2007 STAR Panels (for the two assessment updates) varied little from those in the 2003 STAR Panel report, and the vast majority are consequently addressed in the above discussions. Among the topics not explicitly addressed in the above responses from the 2005 STAR Panel were the observation that an exploratory delta-GLM analysis of the triennial survey appeared to offer a more promising approach to evaluating the information from that time series (implemented in this assessment for both the triennial and the NWFSC combined survey); that the multiple spawning of bocaccio should be investigated with respect to the significance of this on larval counts or juvenile indices (addressed to some extent in the Ralston and MacFarlane, in review, manuscript described in this document); and that consideration should be given to the development of a more spatially-disaggregated model for bocaccio, similar to the approach developed but rejected in the 2002 model. Among the topics not explicitly addressed in the above responses from the 2007 STAR Panel report were to evaluate assumptions about stock structure and boundaries in light of information on catches of bocaccio rockfish taken off Mexico, Oregon, and Washington (addressed to the extent practicable in the discussion on genetics, stock structure and differences in growth and maturity patterns between the southern region modeled here and the northern/Canadian regional center of bocaccio abundance); and that length data be modeled seasonally (not addressed in this model).

D.2.c Transition to SS3 modeling platform and comparison to most recent assessment

In the last full assessment (MacCall 2003), contrasting information from a low 2001 triennial trawl survey data point with high recreational CPUE indices was difficult to reconcile, and the STAR Panel consequently adopted two "equally likely" but separate models. The first omitted the triennial trawl survey data (STARb1) and the second omitted the recreational CPUE data (STARb2). The STAT Team preferred a single, intermediate model (STATc) which included all of the data despite their inconsistencies, and the PFMC's SSC subsequently agreed that all three models could be considered by the Council as bracketing the full range of uncertainty. The STATc model was subsequently the focus of the two updates to the 2003 model (in 2005 and 2007), with updated data sources confirming the strength of the 1999 year class (which had been observed to be strong in the 2003 assessment) and a relatively high 2004 triennial survey data point reducing (albeit not eliminating) the tension between the triennial survey and the recreational CPUE indices. Consequently we focused our attention on developing an SS3 model comparable to the most recent update of the STATc model in 2007.

To replicate the 2007 STATc model (herein called the 2007 model), an SS3 model was developed with an identical time frame and fisheries (trawl, hook-and-line, set net, recreational south and recreational central) as well as three surveys (CalCOFI larval abundance, triennial trawl survey, and the CPFV observer survey referred to as the Wilson-Vandenberg survey in the 2007 model). The 2007 model, as with earlier models, was a length-based model, the 2007 model began in the year 1951 with equilibrium catches estimated at 2000 mt/year and significant initial depletion. Landings were unchanged, as were the years in which recruitment deviations were estimated. Survey and length frequency data from the SS1 model were imported into the SS3 file structure with the associated tuned CVs and effective sample sizes from the tuned 2007 model. As with the 2007 model, the lambda (emphasis) on the stock/recruitment relationship was downweighted to 0.1, all other likelihood components were set at 1.

As the selectivity curves in the 2007 model were double logistic, the curves were duplicated as closely as possible using the double logistic parameterization in SS3 and "fitting" the curves visually with the slider bars in the selex24 spreadsheet provided by Rick Methot. The parameters from these "fits" were used as fixed values in the SS3 model. While not absolutely identical, the selectivity curves were replicated with a high degree of accuracy and we expect that their performance was effectively identical to the 2007 model parameterization (spreadsheet and parameters to compare the selectivity curves available upon request). As in the 2007 model, the selectivity of the CPFV observer time series was set equal to that of the central recreational fishery. The growth parameters in the SS3 model were estimated with a T_{min} of 1.6 and a T_{max} of 25 with starting values taken from the 2007 assessment (noting that the growth parameters were freely estimated in the 2007 model as well). All other biological parameters (natural mortality, weight/length, maturity, fecundity) were set to the 2007 model, as was sigma-R (set to 1). As R0 was to some extent a nuisance parameter in the 2007 model (model estimated h was approximately 0.2), this parameter was freely estimated in the SS3 model, and a range of steepness values was explored.

The trends observed in the SS1 model could be simulated reasonably well in SS3, however could not be perfectly replicated. There have been tremendous changes between the SS1 and SS3 modeling framework, including the use of ADMB and changes in the parameterization of the spawner-recruit relationship and the recruitment deviation values. The current model (SS3) fits vector of recruitment deviation parameters, by contrast, SS1 would fit individual log recruitments and then estimated the spawner recruit relationship with a component of goodness of fit to that relationship. The high recruitment variability observed in all previous bocaccio models led to very poor estimates of productivity (steepness) in the spawner-recruit relationship, and the emphasis on this relationship was downweighted in the final model. The earlier (SS1) model did not have as sophisticated a translation between pre-dev and post-dev bias adjustments to the spawner-recruit relationship, which is also likely responsible for some of the discrepancies between the models run with identical data and similar parameterizations. Other changes in the model structure that may have led to discrepancies between SS1 and SS2 (and would therefore be equally true for transitioning to SS3) were reported in the 2004 modeling workshop. For example, the likelihood components associated with length-frequency data often differed among the two modeling approaches, likely due to a simpler structure implemented for the emphasis coefficients in SS2. Another modest change was that small constants (which can be user defined) are added to composition data in SS2 (an option not available in SS1), mean weight at age is calculated from weight at length internally (rather than input directly) and SS1 had no adjustment for growth of individuals in the accumulator age within the population (Summary Report from the Stock Assessment Modeling Workshop, October 25-29, 2004, Northwest Fisheries Science Center).

Despite these discrepancies, the SS3 model replicated general trends in biomass, spawning output and recruitment with a fairly high degree of similarity (Figures 48a-c). As early runs clearly indicated that the low steepness (h=0.21) scenario was not as comparable as runs with higher steepness values, we explored a range of steepness values, including the h=0.44 estimate (based on the posterior median estimated in the 2007 model), and scenarios in which h was fixed at the 2007 Dorn prior (based on updating the rockfish steepness meta-analysis of Dorn 2002) of 0.61, as well as the mean plus one standard deviation (h=0.79). Interestingly, the trends from the SS1 model were best replicated with a considerably higher (0.79) steepness value; the SS3 model with steepness set to the SS1 estimated value of 0.21 diverged notably in the early part of the model (particularly the 1960s through the early 1970s, during which CalCOFI larval abundance was essentially the only source of information). Additionally, the Hessian does not converge when steepness is fixed at 0.21, suggesting that the low steepness configuration was inconsistent with the data and results. In general, the model run with steepness set at 0.44 and 0.61 resulted in trends and reference points similar to the h=0.75 run, and a likelihood profile demonstrated that this version was close to the best-fitting estimate of steepness for this SS3 model configuration. Likelihood values were quite different between the SS1 model results and the SS3 models, further evidence that the substantial changes in the modeling framework have made exact replication of the results nearly impossible.

All of the SS3 models estimate a slightly lower total biomass and spawning output (relative to the SS1 model) during the period from the mid-1970s through the early 1990s, the cause of this discrepancy is unclear. There are some interesting differences in the distribution of recruitment pulse in the early 1960s that is driven by the fits to CalCOFI data, with the "high steepness" SS3 model "smearing" the unusually strong 1962 year across several years, while the low steepness models reflect a single year pulse of strong recruitment. As these recruitments are driven by trends in the (somewhat noisy) CalCOFI data rather than informed by length information on recruitment, this presumed artifact of the manner by which recruitment deviations are estimated is of little concern, particularly as later recruitments (which are informed by very strong signals in length frequency data) are nearly identical during most of the modeled period. Similarly, all three models produce nearly identical estimates of the total and spawning output from the late 1990s to the end of the modeled period (2006), such that the range of difference in ending (2006) spawning output among these three models is less than 27 mt. However, the resulting depletion levels in 2006 differ more significantly, from 12.7% of SSB_0 in the SS1 model to 16.9% of SSB_0 in the SS3 model with low steepness (h=0.21) model and 20.7% of SSB_0 in the h= 0.79 model, due to the substantial differences in the estimated unfished spawning output levels among the models. Table 22 provides the estimated mean unfished recruitment, SPR, SSB_0 and relative (2006) depletion for the 2007 SS1 model relative to the 2009 SS3 model that is most similar to the SS1 biomass and spawning output trajectories (the h=0.79 version). Although the percent change was not trivial for all of these metrics, it was relatively modest (within 10%) for all.

To compare the influence of the new catch data, which together with the transition to the SS3 modeling platform are the most significant and influential changes in this assessment, we next compared the SS3 version most compatible with the 2007 SS1 model (the h=0.75 version) with the same model after the revised catch history and start year were revised from the 2007 model. As with the comparison between SS1 and SS3, the two models track each other closely in the recent historical period (~1970-present), however the revised catch history leads to a major change in the perception of starting (unfished) biomass and the relative abundance of bocaccio immediately prior to the 1950s when the 2007 model was initiated. The greatly revised catch history is largely responsible for this shift; whereas the SS3 best fit to the 2007 model had a initial (1950) equilibrium depletion level estimated to be at 43% of the equilibrium unfished level, the same model with the revised catch history and start year of 1892 had a 1950 depletion level of 87% of the unfished spawning output (Figures 49a-c).

This is due to the fact that the model beginning in 1951 had an estimated equilibrium catch of 2000 mt, comparable to the total estimated catch of bocaccio in the 1950s in the catch reconstruction developed for earlier assessments (Ralston 1996). In contrast, while the results of the catch reconstruction effort (Ralston et al., in prep) are consistent with that level of landings in the 1950s, catches of bocaccio in the 1940s appeared to be at relatively low levels, despite the fact that total catches of rockfish in California waters increased rapidly during this period. However, much of this increase was in northern California waters, particularly north of Cape Mendocino, where bocaccio appear to have historically represented a much smaller fraction of total rockfish catches. As described in the catch reconstruction document, as well as the abridged discussion of the catch reconstruction in this document, bocaccio trawl catches rose rapidly from several hundred to nearly 3000 mt per year during the 1950s as the balloon trawl fleet expanded from Oregon and northern California waters to central California waters (declining again in the late 1950s and early 1960s). Bocaccio catches in central California until that period had rarely been greater than 500 to 600 mt, caught primarily with hook-and-line gear. Overall, this revision is the primary cause of one of the most significant changes in our perception of the relative stock status of bocaccio in California waters. Remaining revisions are numerous, and are discussed in the description of the base model, the intent here was to capture the history of modeling approaches used in the last several assessments (including updates) and provide documentation of the major aspects of the transition from the last assessment.

D.3 Model Description

Modeling software

This assessment used the Stock Synthesis 3 modeling framework developed by Dr. Richard Methot (Methot 2009a; Methot 2009b). For the comparison to the SS1 assessment, we used the most recent (at the time) version, (SS-V3.02B). The final model used the most recent version at the time (May 2009), SS-V3.03A.

Model Priors

This model used uninformative priors on many of the selectivity parameters in early modeling efforts, which contribute trivially to the total likelihood function. The Dorn (2002 and updated, pers. comm..) beta prior distribution for steepness was used to steepness in both the early modeling to compare the SS1 bocaccio model to the SS3 model, and in the final base model. The final base model steepness was estimated with the updated Dorn prior following the reanalysis of past stock assessments, which for bocaccio was 0.736 with a standard deviation of 0.186, considerably higher than the 2007 bocaccio point estimate of 0.612 with a standard deviation of 0.18. The resulting model posterior was 0.573 (nearly one standard deviation below the point estimate), which was consistent with the results of a likelihood profile across the fixed values of steepness.

D.3.a Base model selection, evaluation and description

From the SS3 model developed to evaluate the transition from SS1 and the impact of the revised catch history (describe in detail in the previous section), a number of alternative models were explored, for which comparable sensitivity analysis similar to that provided to document the transition to SS3 and the revised catch reconstruction would be overwhelming. New or revised survey indices, length frequency information, growth and maturity parameters, and other explorations were done based in part on the availability of new information and time, through over 100 versions of the control and data files (including a transition from the earlier version of SS3 and the May 2009 release of SS3.03). For example, in evaluating the utility of modeling northern and southern trawl fisheries independently, we implemented an incremental approach in which we visually evaluated the length frequency data by port group, compared the results of pooling all length frequencies, of pooling length frequencies north and south of Cape Mendocino, and of pooling length frequencies north and south of 38° N. In all cases the two fleet models had selectivity curves estimated independently and jointly ("mirrored"), and the relative improvement in fit with independently estimated curves, as well as visual analysis of the residual patterns, was used to divide the data from this fleet north and south of 38° N. Additionally, while the F estimation method in the early comparison models was based on estimating fishing mortalities as year and fleet specific parameters (comparable to the SS1 model), the new model uses the "hybrid" method (Methot 2009b), which reduced the run time from ~40 minutes to ~7. While the data, control and many of the output files are archived from this transition, including an annotated log of the significant change in each model version, the number of model versions and minor changes (many of which were reversed or later superseded by other changes) is too lengthy and convoluted to present in a clear and concise manner. Consequently, the impacts of the most significant of those changes are evaluated in the model sensitivity section.

As mentioned earlier, these changes include an expansion of the modeled assessment area, such that the northern boundary is now Cape Blanco, OR rather than Cape Mendocino, WA. In part due to this change, and in part due to patterns observed in the trawl length frequency data by port group, the trawl fishery was subsequently split into a northern and southern trawl fishery. The remaining fleets (hook-and-line, set net, southern recreational and northern recreational) are consistent with earlier modeling approaches. In the base model we include most of the survey indices, which include the trawl CPUE time series (linked here to the southern trawl fishery), the three recreational CPUE time series, the triennial trawl survey index (based on the GLMM index), the new NWFSC combined survey index, the new NWFSC Southern California Bight hook-and-line survey, the revised pier index and the revised (coastwide) pelagic juvenile index.

The power plant impingement data is not included, as it has not been updated to reflect recent years, and recruitment for the years for which the data do exist are well informed by length frequency data. The larval abundance biomass estimates were not included in the base model due to the mismatch in the spatial distribution of the estimates. Many of the selectivity and other parameters are estimated with diffuse, normal priors that are close to their final estimated value, which seemed to be helpful in stabilizing the model early in the development (particularly for growth parameters).

Although the base model is not spatially disaggregated, most of the data sources have some regional bias within the assessment area, thus the spatial nature of the various fisheries and indices is captured to the extent practicable by the separation of fisheries and indices. As described earlier, the trawl fishery was broken up into southern (south of 38° N) and northern fleets, as described above, the geographic pattern of other fisheries was held constant relative to earlier model configurations. In other words, both hook and line and setnet catches and length frequency data were pooled across all areas (although catches are very low north of Cape Mendocino, and there were no data for the small amount of the assessment area north of the California/Oregon border for these fisheries), and the recreational fisheries were treated independently north and south of Point Conception, CA (34.5° N). The three recreational fisheries indices are in turn based on data exclusively from southern or central/northern California respectively, similarly the trawl fishery CPUE index is derived from data derived from central California logbooks (this time series is linked to the trawl fishery south of 38° N), and the triennial trawl survey reflects data N of 34.5° N (with inconsistent coverage between 34.5° N and 36.5° N). The NWFSC combined trawl survey covers the entire assessment area, although trawl density is relatively sparse south of Point Conception, and the survey does not sample within the Cowcod Conservation Area (CCA) closures. The NWFSC hook-and-line survey is exclusive of the southern California Bight (south of Point Conception), although this too excludes the CCAs. The CalCOFI indices, while inclusive of data from the central California for many years, primarily reflect the "core" CalCOFI survey area (south of 35° N), the pier index reflect primary central (south of 37° N) and southern California, as juveniles are rarely caught in pier fisheries north of Half Moon Bay, while the coastwide juvenile survey includes data from the entire assessment area, although most data is from north of Point Conception (34.5° N).

In the base model, the size at age 1.5 is fixed at 26 cm for both males and females (as discussed in the growth section), although values for sex-specific Lmax and K are freely estimated for each sex (estimation is as independent parameters, rather than the option in which male growth parameters are estimated as exponential offsets from females). Growth is time-invariant in the base model. Other growth and maturity parameters are fixed as discussed in the section on growth and maturity. Length bins start at 16 cm (versus 26 in the 2007 model) and are incremented at 2 cm intervals to the largest sizes (68, 72 and 76 cm), at which point bins are in 4 cm increments due to the relative rarity of larger fish (as in the 2007 model). Ages 0-20 are individually tracked, with 21 representing the accumulator age. R_0 (mean unfished recruitment) is freely estimated, steepness is estimated with an informative prior as described above, and sigma-R is fixed at 1. Recruitment deviations are freely estimated from 1954 through 2008; early deviation parameters are influenced only by the CalCOFI and pier index data, while year class strengths from about 1970 through 2006 are well informed by length data. The most recent years (2007-2008) are influenced primarily from the juvenile trawl index. All catchability coefficients (q parameters) in the base model were freely estimated as nuisance parameters. Recruitment deviations were estimated from 1954 through 2008, a slight shift from the 2007 model which began estimating recruitment deviations in 1960. This shift was done to allow the incorporation of some information from the pier survey index, but the difference between a start of 1954 and 1960 was negligible.

As with earlier models, and as noted in earlier STAR panels, the parameterization of the selectivity pattern for the triennial survey is notoriously unstable. In both early and quasi-final versions of this assessment, it was noted that when the model was "jittered" or when some starting (initial) values were altered, the selectivity pattern for this survey would vacillate between a strongly dome-shaped pattern (in which selectivity was greatest for age 1-2 fish, and declined sharply for larger, older fish) and a nearly asymptotic pattern (in which selectivity rose sharply for young, small fish but stayed high into larger, older fish, declining very modestly at sizes greater than approximately 70 cm). This seemed to be the result of two local minima in the negative log likelihood. Although the dome-shaped selectivity pattern resulted in an improved fit to the data, the model seemed to be unable to achieve that minimum in many model runs in which initial values were "jittered." This same phenomenon took place with both the NWFSC combined survey selectivity pattern, and the selectivity pattern for the southern trawl fishery; in the case of the latter, an approximately 100 likelihood point difference took place when the jittered run found the local minimum associated with the "asymptotic" selectivity relative to the dome-shaped.

Consequently, the selectivity patterns for the triennial survey were fixed at values arrived at from the best fitting "jittered" run, the selectivity pattern for the NWFSC combined survey was fitted as asymptotic, and the latter five (of six) selectivity parameters for the southern trawl fishery were fixed at the values that resulted in the best fit to the data upon multiple "jittered" runs (parameter 1, the peak of the ascending inflection, remained freely estimated). The selectivity pattern for the southern fishery is best fitted as a double-normal selectivity option, while the northern fishery is best fitted as an asymptotic selectivity option. Selectivity patterns for the hook-and-line, set net, and southern recreational fishery are also modeled as double-normal, while the selectivity for the central/northern recreational fishery is modeled as asymptotic. Selectivity patterns for the triennial survey and the NWFSC Southern California Bight hook-and-line survey are modeled as double-normal, while the selectivity for the NWFSC combined trawl survey is modeled as asymptotic (see below). Selectivity for the CalCOFI larval abundance time series is set to mirror population fecundity, while selectivity for the age 0 recruitment indices is strictly age-based, such that age-0 fish are fully vulnerable and all other ages are fully invulnerable. Upon fixing these parameters, model results were generally stable when jittered, although slight excursions (of 0.5 to 1.5 likelihood units) did take place in a small fraction (approximately 30%) of the jittered runs. This likely reflects an irregular likelihood surface, and similar results have been seen in many other relatively "data rich" models in which there are conflicting signals from various data sources. Although a cause for some concern, the effects of this did not seem to be severe with respect to the model results.

As so many of the survey variances were derived from different approaches (jackknife routines, MCMC routines, ANOVA routines), iterative re-weighting was applied to these indices by adding a constant to the variance adjustment in the control file such that the model estimated

RMSE was approximately equivalent to the mean input RMSE plus the adjustment (within ~5%). Table 23 reports the model observed RMSE values, along with the mean input values and the input variance adjustments. Similarly, effective sample sizes for the length frequency data were iteratively reweighted using the multiplicative scalar to adjust the input sample sizes for each fleet. Table 24 reports the mean input sample sizes, the mean effective sample sizes, and the corresponding multiplicative scalars used to reweight the length frequency data in the base model.

Table 25 shows values for the key fixed parameters, and all estimated parameters, along with the model estimated standard deviations for estimated parameters (although steepness was fixed, the standard deviation from the run where steepness was estimated with the Dorn prior is also reported, in parentheses). The model estimated growth curve is also shown as Figure 50, all of the estimated selectivity curves are shown as Figures 51a-j. The southern trawl fishery, hook-and-line, set net, and southern recreational fisheries all had greatly improved fits to length data with dome-shaped (double logistic) selectivity, while the central/northern recreational fishery and the northern (north of 38˚) trawl fishery fits to length data did not improve with double-logistic selectivity, and were fit using logistic selectivity curves. As discussed above, the triennial survey selectivity was fixed to avoid local minima in the negative log likelihood surface, as were all but the peak selectivity parameter for the southern trawl fishery. Although it seems illogical that the NWFSC combined survey would have a selectivity pattern dramatically different from the triennial trawl survey, the fit to the length frequency data degraded substantially when dome-shaped selectivity was either "fixed" for this survey, or when selectivity was explicitly linked ("mirrored") to triennial selectivity. The best fitting selectivity curve using the double-logistic parameterization was "virtually logistic," thus a logistic curve was used for this survey. The CPFV observer index and associated length frequency data from the central/northern California recreational fishery were explicitly linked to the central/northern CPUE time series based on the RecFIN dataset (and associated length frequency data) by mirroring those selectivity curves. and Figures 52a-b show the estimated recruitment deviation parameter values and the associated asymptotic standard error.

STAR Panel Requests and Response by the STAT Team

1. Eliminate the central CA rec. CPUE (MRFSS) index. Rationale: These data could be misleading because they may be more indicative of changes in the spatial pattern of the fishery than in the fish stock.

Elimination of the central recreational cpue index resulted in a drop in 2009 depletion from 25 to 22%. The index was ultimately included in the final model (see request #11).

2. Iteratively up-weight each informative index to determine the major conflicts in the model and to bracket more of the model uncertainty (adjust lambdas) and determine the estimates of current biomass and depletion under each scenario. Rationale: To identify major conflicts amongst the biomass indices and determine which indices were optimistic and which were pessimistic.

Due to growing run times, this request was not fully completed, and results that were completed were merged with request number 3.

3. Iteratively re-weight "optimistic" indices and "pessimistic" indices Rationale: To provide a useful pair of runs to bracket uncertainty.

Response: Based on both past assessments and various sensitivity analyses in the draft assessment, the STAT and STAR had identified the fundamental tensions in this model as being primarily between two pessimistic indices, the triennial trawl survey index and trawl fishery CPUE and two optimistic indices, the southern recreational CPUE index and the CalCOFI larval abundance index. The two pessimistic indices both indicate a steep decline in the 1980s, a decline also observed in the optimistic indices (albeit of lesser severity), while the two optimistic indices both suggest stronger rebuilding in the early 2000s. Upweighting the pessimistic indices resulted in a better fit to the 1980s decline and changed depletion to 16% (from the then "base" level of 22%). Upweighting the optimistic indices produced a better fit to the 2000s rebuild and indicated considerably less depletion (39% when recSO was upweighted; 36% when CalCOFI was upweighted).

4. Evaluate the effect of the relative weighting of the biomass indices and the compositional data by down-weighting the compositional data. Rationale: To determine whether there are any conflicts between the biomass and compositional data.

Response: All length frequency lambdas were scaled by 0.5 and 0.25 in two separate runs, and by fishery-specific scalars provided by the STAR Panel based on a methodology developed by Dr. Chris Francis (see STAR Panel report). The overall effect relative to the base model was fairly modest, the fit to survey indices improved by less than 2 likelihood points with lambdas of 0.5, another 3 with lambdas of 0.25. Fits to the trawl CPUE and triennial index improved more, resulting in a slightly more pessimistic perception of stock status (depletion in 2009 changed from 0.22 to 0.21 with lambda of 0.5, and to 0.20 with lambdas of 0.25). The result was similar when the lambdas were scaled by the values provided by the STAR Panel, with a consequent dip in depletion from 0.22 to 0.19.

5. Do a model run as a sensitivity analysis that incorporates all coastwide catches and mirrors selectivity of the northern trawl fishery. Rationale: To evaluate the effect of uncertainty about the northern boundary of the stock.

Response: The primary consequence of including OR and WA catches (when the compositional data were not included) was simply to scale up the biomass trajectory. In this scenario, the catches were simply combined with the "northern trawl" fishery catches, and the estimated current status was slightly more pessimistic (23% depletion, from 22%).

6. Do an additional model run as a sensitivity analysis that incorporates all coastwide catches and compositional data. Rationale: To evaluate the effect of uncertainty about the northern boundary of the stock.

Inclusion of the compositional data required the creation of a 7th "fishery" for Oregon and Washington landings and length frequency information. As length comps, which were based on relatively sparse data, were comprised almost exclusively of very large fish, an asymptotic selectivity curve was used, adding two parameters to the model. No relative abundance indices were available for this region. In this scenario, the assessment became more optimistic (28% depletion), although the exact reason was unclear. Growth parameters changed slightly in this scenario, with L_{max} increasing by several cm for both males and females, and the growth coefficient (K) decreasing, resulting in a degraded fit to many of the length compositional data. One problem noted with this approach is that the size bin structure developed for the base model is not optimal for the large sizes of the fish observed in northern catches.

7. Fix M for older fish at 0.1 and allow M to be estimated for younger fish. Rationale: Based on the Hoenig method, an M of 0.1 is more consistent with the longevity data than the current value of 0.15. There are also indications that mortality of younger fish (before settlement to demersal habitat) may be higher that that of older fish.

Response: The result is highly sensitive to the (assumed) fixed ages of "young" and "old" mortality rates (rates are interpolated between the two). If "young"=3 and "old"=5, M_{young} is estimated ~0.06, a counterintuitive result. However, if "old" age is 8 or 10, M_{young} estimated at 0.17 and 0.21 respectively. Depletion changes from 0.22 in base, to 0.20 and 0.19 in the latter two cases. Overall fit degrades 25 and 20 units respectively, with improvement to the pessimistic indices and degradation to the optimistic indices (CalCOFI, Southern RecCPUE). Although the STAT and STAR were in agreement that the assumed value for natural mortality is not entirely consistent with estimates of longevity for this species, it was agreed not to change the value of M used in the base model, given the sensitivity to the definition of "old" fish age and inadequate data for estimation of M for "young" fish.

8. Include in the assessment report reference to the proposed listing of bocaccio in Georgia basin as endangered (under the terms of the Endangered Species Act). Rationale: A proposed listing of a distinct population segment of bocaccio rockfish is important background information that managers may want to consider when developing management measures for rebuilding the southern bocaccio stock.

Response: A new section has been drafted for the assessment report.

9. Assess the effect of the maturity curve by doing alternative runs using the maturity curves of Love et al. (1990) and Wyllie Echeverria (1987). Rationale: To evaluate the sensitivity of the assessment to previously published maturity curves.

Response: Although trajectories of biomass, spawning output and recruitment changed slightly, the effect on 2009 depletion was negligible (all 3 runs estimated 2009 depletion at 25%; note that this request was filled after implementing request 11). The Wyllie Echeverria (1987) curve resulted in a slightly poorer fit, the Love et al. (1990) maturity curve resulted in a modestly improved fit.

10. Specify the area covered by the assessment in the title of the assessment report. Rationale: To improved clarity since the entire US west coast was not assessed.

Response: The report title was amended to include the area assessed.

11. Include recCEN index back in the base model. Rationale: It seemed more reasonable that this index be downweighted, rather than removed, and the tuning procedure already does this downeighting.

Response: Reintroducing the recCEN index changed the depletion from 22% to 25%.

12. Conduct two runs to bracket the uncertainty in the assessment: one upweighting the triennial and trawlsou indices, and the other upweighting the recSO and CalCOFI indices. Rationale: To bracket the uncertainty.

Response: Upweighting an index was done by setting the associated $\lambda = 10$. The depletion changed from 25% to 14% when the triennial & trawlsou indices were upweighted, and to 38% when recSO and CalCOFI were upweighted. The standard deviation for 2009 depletion (based on the estimation of the hessian) was 0.033 (range 22-28%) but this only accounts for variance in estimated parameters.

13. Provide confidence intervals for model outputs, with and without delta method (McCall, in prep.) contributions for uncertainty in steepness, h, and natural mortality, M. Rationale: For models in which h and M are fixed, the usual confidence intervals (based on the inverse Hessian) may substantially underestimate uncertainty.

Response: When uncertainty in both M and h was included in the calculation of standard errors, this made the changes caused by the two bracketing runs (see request 12) approximately equivalent to ± 1 s.e. in depletion as estimated by the base model.

14. For the base model use the revised CalCOFI index (presented to the Panel) that utilizes a complementary log log link in the binomial part of the GLM (instead of the usual logit link). Rationale: An alternative GLM, using a complementary log log link in the binomial model, rather than the previously used logit link, fitted the CALCOFI data better (AIC decreased by 20 in the index GLM).

Response: This change had only a slight effect on the biomass trajectory, changing the depletion from 25% to 26%.

15. Conduct run in which catches north of 40° 10´ N were removed. Rationale: To evaluate the consequences of using the assessment to manage bocaccio fisheries south of 40° 10´.

Response: This change had only a slight effect on the biomass trajectory, changing the depletion from 26% to 27%. The catch north of 40° 10´ throughout the assessment period was approximately 6.7% of the total catch. The 2009 spawning biomass for the model excluding the catch north of 40° 10´ is 5.4% lower, while the summary biomass is 5.0% lower.

D.3.b Base model results

The base model results for summary biomass, spawning output, depletion and age-0 recruitment are shown as Figures 53-54, and in Tables 26. The initial unfished summary (age 1+) biomass is estimated to be 44,070 mt, with a spawning output (SSB_0) of 7,861 x 10^9 larvae and mean age 0 recruitment (R_0) of 5,060,000 recruits. The estimated steepness (h) for the base model was 0.573, approximately one standard deviation lower than the prior point estimate of 0.73. The initial (fixed) value for sigma-R was 1, the effective (output) sigma-R is 1.10; when the early years of estimated recruitments (1954-1969) are excluded the effective sigma-R remains high (1.16) indicating that the recruitment estimates for the early (poorly informed) part of the time series are not having an undue influence on the effective sigma-R. Sensitivity tests suggested little change in model fit or results when slightly higher fixed values for sigma-R were used. As the error around early recruitments is essentially as great or greater as sigma-R for most early years, these recruitments should be considered relatively poorly estimated from the data, and do not necessarily represent the nature of episodic recruitment in this early period that likely existed. The spawner-recruit curve, and the observed recruitments are shown as Figure 55. The total catches, fishing mortality rates (by fishery), estimated SPR rates and a phase plot of the SPR rates against depletion, are shown as Figures 56-57. Table 27 and 28 provide the numbers at age (female and male, respectively) estimated by the base model.

The summary biomass, spawning output and recruitment in 1892 (when the catch history begins) are slightly below the estimated unfished levels (96.8, 96.4 and 99.3% of unfished estimates respectively), due to the assumed existence of a very moderate fishery beginning in the 1850s. The population trajectory exhibits a very moderate decline until about 1950, when summary biomass, spawning output and recruitment are estimated to be at 82.6 80.7 and 95.7% of the unfished levels respectively. From 1950 through the 1960s the biomass is estimated to have declined steeply, as catches rose from several hundred to several thousand mt, reaching a local minimum in 1963 of 28.4% of the unfished spawning output, associated with harvest rates significantly above the (current) target levels. The biomass increased sharply thereafter, as a result of one or several very strong recruitment events in the early 1960s (informed primarily by the CalCOFI time series, with some support by irregular years of pier fishery data), exceeding the mean unfished biomass level through the early 70s, when catches again began to climb rapidly to their peak levels, associated with high (SPR of less than 0.2) fishing mortality rates and a rapid drop in biomass. By the mid 1980s depletion was at approximately 20% of the unfished level, and by the early 1990s depletion was at about 15%. Fishing mortality remained high throughout this period, even as catches declined rapidly, and recruitment during the 1990s was at very low levels. Fishing mortality declined only at the very end of the 1990s, in response to severe management restrictions. By 2002 SPR was generally close to or above 0.9, and in concert with a strong 1999 year, and relatively strong year classes in 2003 and 2005, spawning output has been increasing steadily. The base model estimates a current (2009) depletion level of 28.1%, a 2008 SPR of 0.947, with the forecast under constant harvest rates indicating a continued increase in spawning output.

Fits to the relative abundance indices, in both arithmetic and log space, and including plots of the observed vs. predicted values, are shown as Figures 58-67 for all of the indices used in the model. Fits to the length frequency data are shown as Figures 68-78. Fits to the CPUE indices were generally reasonable, the model was able to replicate the trends of both the trawl fishery and southern recreational fishery fairly well, although the model fits to the central/northern recreational fishery were poor, particularly in the last several years of the index, and the fit to the CPFV CPUE index completely missed the rapid rise and fall in catch rates from 1989 through 1992 that appears to have resulted from a strong 1988 year class. It is possible that a disproportionate influence of larger fish in the catches in some later years, when the fishery may have explored fishing grounds not widely exploited by recreational fleets earlier in the fishery, resulted in a selectivity curve that failed to predict higher catches of smaller fish from strong cohorts. Alternatively, strong year classes may result in large numbers of fish available in atypical habitat types (e.g., soft bottom) prior to dispersal, or fisheries may target abundant year classes resulting in higher catch rates and relatively greater catches of smaller individuals. Some greater exploration of this would be worthwhile. Fits to survey indices were also reasonable.

Although the relative lack of conflicting information facilitates the fit to the early years of the CalCOFI index, this index also captures the rapid decline in the 1970s through the 1990s and the increase in abundance in the post 1999 era that are observed in other indices and consequently predicted by the model. The use of the GLMM for the triennial trawl survey index also results in a relative improvement to the model fit to the data, although there is some suggestion of autocorrelation in the residuals in that the model underestimates the index in early years and overestimates the index in several years towards the end of the time series. As described earlier, there is considerable evidence that both past and present trawl survey methods are ill-suited for sampling bocaccio. The NWFSC trawl survey index and the index developed from the NWFSC hook-and-line survey in the southern California Bight are neither consistent with nor influential to the model estimated trends in abundance in recent years; both predict relatively flat or slightly declining trends while the model is estimating a relative increase in abundance. Although the pier survey index has little conflicting information for the early years, the data do conflict with the model biomass and recruitment estimates as informed by the CalCOFI data. This index does capture many of the strong recruitments in the period informed by length composition data (e.g., 1984, 1988, 1999, 2005), although it often underestimates the magnitude of these events, and also indicated strong year classes for several years in which strong cohorts did not later appear from the length composition data. The juvenile index seems to have overestimated the relative strength of the 2001 and 2002 year classes while underestimating the magnitude of the 2003 year class; the index may have captured the 2005 year class to a reasonable extent. The effectiveness of this index has yet to be determined, although the relatively low values observed are consistent with the generally unusual and low productivity ocean conditions observed in recent years (e.g., Goericke et al. 2007).

For the most part, the length composition data fit reasonably well in most fleets, particularly the southern recreational fishery and south/central trawl fishery, both of which clearly demonstrating the modal progression of strong year classes. There are some patterns of autocorrelation in the residuals to the length composition data that suggest an inability to perfectly fit the strong year class modes. This could be a consequence of slight differences in the timing of landings for some fisheries (as growth during the first several years is sufficiently rapid that data early or late in the year may not match expected length frequencies in the middle of the year), the geographic areas of given fleets (which may tend to capture slightly smaller or larger fish depending on the region), or variability in growth rates with differences in oceanographic conditions. The likelihood values associated with the base model are presented with values in the sensitivity analysis (below).

D.3.c Uncertainty and sensitivity analysis

Several diagnostics were developed to assess the sensitivity of the model to different values for key parameters, particularly steepness (h) and natural mortality (M). Profiles for those two values are shown in Figures 79a-b and differences in key reference points and relative likelihood values (by survey and/or fleet) are presented as Tables 29 and 30. The profile of steepness shows that the best fit occurs within a range of 0.4 to 0.6, consistent with the model estimated value of 0.573 when steepness was estimated with the Dorn prior. Although the fit is still reasonable at most higher levels of steepness, low levels of steepness appear less plausible based on the likelihood profile. However, as seen in Table 29, different data components have different responses in fit to the range of steepness values. In general, the trawl CPUE index (and trawl fishery length frequency data) and the triennial survey have better fits with lower values of h, while the recreational CPUE indices and associated length frequencies, as well as the CalCOFI time series, have a better fit with high values of h.

Similarly, a profile of natural mortality (M) suggests that the model has a better fit with higher values of M, with the best likelihood values in the range of 0.16 to 0.22. The trawl fishery CPUE and length frequency data, and triennial trawl survey, had better fits with lower M, while recreational fishery CPUE and CalCOFI indices fit had the best fit with higher M. Given the lack of age data in the model, improvements in fit alone were not deemed adequately informative to alter the estimated natural mortality rate, which remains one of the most significant unknowns in the model. The potential effect of migration of strong cohorts from the south to the north is an added complication. The relative influence of alternative values for steepness and natural mortality are shown as Figures 80-81, the results of which are generally intuitive. With higher assumed steepness values (and natural mortality rates), the estimated historical unfished biomass declines, leading to a more optimistic perception of stock productivity and relative abundance, the opposite is of course observed with lower assumptions of steepness and natural mortality.

In addition to the sensitivity to these life history parameters, we evaluated the sensitivity to changes in the data included in the model, to changes in model structure (developing essentially independent models north and south of Point Conception) and the influence of incorporating time-varying growth. These explorations were explored and discussed during the STAR Panel review, and the STAR Panel and STAT Team ultimately agreed that alternatively weighting a suite of indices for which the greatest source of model tension existed would capture the major axes of uncertainty in the model. Consequently, two models were developed to reflect the primary sources of uncertainty in the model, and thus bracket the plausible states of nature. State one is the scenario in which the two pessimistic indices (the triennial trawl survey and the trawl fishery CPUE index) were upweighted by setting the associated lambdas equal to ten. State two is the scenario in which the two optimistic indices (CalCOFI larval abundance and the southern California recreational fishery index) were upweighted, also with lambdas of ten. Figures 82a-c show the results of these two scenarios. The estimated depletion changed from 25% to 14% when the triennial and trawl fishery CPUE indices were upweighted, and to 38% when recSO and CalCOFI were upweighted. The corresponding point estimates of steepness in each of these scenarios was 0.539 for state one (the pessimistic scenario) and 0.724 for state two (the optimistic scenario), relative to 0.573 for the base model.

The retrospective analysis (Figures 83a-c) do not seem to demonstrate a major shift in perception of stock status when data from the last 2, 4 or 6 years are removed (only 2 and 6 are shown, as 4 is essentially no different). It is likely that a retrospective analysis that went back more years would reflect greater uncertainty with respect to stock status, trends and productivity, as it is clear that the 1999 year class was among the most defining events in altering the perception of the status and productivity of this stock. This is illustrated further in Figures 84a-b, which show the results of this base model relative to past assessments, from 1996 to the most recent (2007) update of the 2003 model (2005 varied little from 2007, so is excluded to improve readability). Again, prior to the clear recognition of the magnitude of the 1999 year class, assessments were highly pessimistic.

E. Reference Points

Reference points are presented in Table 31, which provides the unfished summary biomass, unfished spawning output, mean unfished recruitment and the proxy estimates for MSY based on the $SPR_{50\%}$ rate as well as the fishing mortality rate associated with a spawning stock output of 40% of the unfished level and with MSY estimated based on the spawner/recruit relationship and yield curve. The corresponding yields for these three estimates vary by a relatively minor amount, ranging from 1250 tons based on the spawning output proxy and 1270 tons based on the MSY estimate. However, the relative impact of the higher harvest rate on spawner abundance is results in a significantly lower equilibrium spawning output and summary biomass with both the SPR proxy and the estimated MSY rate, relative to the spawning output reference point.

Harvest projections and decision tables

The base model indicates that larval production, as a function of spawning output, has been increasing since the 1999 recruitment event and several subsequent year classes of moderate magnitude. The spawning output trajectory indicates that the stock is likely to continue to increase in coming years under current harvest rates, although the form of this trajectory is highly dependent on the magnitude of several year classes currently thought to be of moderate magnitude, as well as future recruitment events, which are highly uncertain. The results of the base model, coupled with a (largely unrealistic) assumption of mean recruitment into the future, would indicate that this stock should approach 40% of the unfished spawning output in approximately 2018, if current (2008) harvest rates are maintained. However, as bocaccio are a rebuilding species, tradeoffs among future harvest projections and population trajectories will be evaluated in greater detail in the rebuilding analysis.

The alternative states of nature used in the decision table (Table 32) were developed in conjunction with the STAR Panel. As both the STAT and the STAR Panel identified the major sources of uncertainty in the model as relating to the tension between two generally pessimistic indices (both derived primarily from north of Point Conception, California) and two optimistic indices (both derived primarily from south of Point Conception), the two alternative states of nature sequentially increased the emphasis on each of these groups to bracket uncertainty. The low abundance scenario was obtained by upweighting ($\lambda = 10$) the triennial and southern trawl CPUE indices, while the high biomass scenario was obtained by upweighting the southern recreational CPUE index and the CalCOFI indices. Thus, these scenarios also provided useful contrast between an apparent, but poorly understood, spatial dimension to relative abundance trends, as the data suggest that recovery may be taking place more rapidly in the south, and recovery in the central/northern California region may be dependent on an influx of fish from the southern area.

Catch trajectories for the three scenarios were developed in coordination with the Pacific Fishery Management Council (PFMC), Groundfish Management Team (GMT) and Groundfish Advisory Subpanel (GAP) representatives to the STAR Panel, and were based on three possibilities. The first catch stream was based on the fishing mortality rates associated with status quo (2008) catches projected into the future. In this scenario, catches then track changes in biomass, including a very slight dip in 2010 due to anticipated poor recruitment in 2007 and 2008. As recent catches have been less than half of the adopted OY values, this scenario is considered the low catch scenario; the 2009 catch in this scenario would be 65 tons. The second scenario projected catches that are associated with the SPR rate adopted in the Council's rebuilding plan of 0.77 in the base model, which results in a 2009 OY of 267 tons. Finally, the third catch stream was based on the Council-adopted SPR rate applied to the "optimistic" state of nature. Although the ABC (based on the 40:10 rule) would have been greater than this catch stream, the likelihood of management adopting an OY equal to the ABC for this rebuilding species was considered unlikely.

Regional management considerations

As described throughout the document, the stock structure for bocaccio is poorly understood. The decision to extend the boundaries of what we consider to be the southern subpopulation from Cape Mendocino to Cape Blanco was based on the observation that catches (both fishery and survey-derived) do not end abruptly at Cape Mendocino, but rather tend to taper off to the north. As such the fish in this region were more likely to originate from the southern subpopulation than the subpopulation distributed to the north. However, either boundary is imperfect. More significantly for management, it is worth noting that as the vast majority of the catches, and virtually all of the data used to inform the indices, are derived from the region south of Cape Mendocino, it may be reasonable to apply the results of this assessment to management measures applied to bocaccio solely in this region. Correspondingly, it would likely not be appropriate to set catch targets and limits for a small part of the northern range based on a downscaling of model results (for example, the small area of Oregon south of Cape Blanco ostensibly covered by this assessment). Practical considerations relating to the complexities associated with implementing catch monitoring or catch sharing agreements could preclude the application of these results in this region. There is clearly a need to devote additional effort into understanding population structure and connectivity, and to evaluating trends in abundance in the waters of the Pacific Northwest, as discussed in the research needs section below.

Future Research Needs

Stock structure for bocaccio rockfish on the West Coast remains an important issue to consider in future assessments as well as management. Although reanalysis of the genetic evidence suggests no genetic differentiation among the major oceanographic provinces in the California Current, both recent and historical data on the distribution of bocaccio rockfish, and the apparent differences in growth, maturity, and longevity, are indicative of moderate demographic isolation. This assessment does not address population abundance levels or trends in the Columbia or U.S. Vancouver INPFC areas, which might be considered more likely to be comparable to those observed in Canadian waters than waters south of Cape Blanco. However, this issue has yet to be resolved. It is possible that more refined genetic analysis, trace elements analysis of archived otoliths (Elsdon et al. 2008) or parasitology studies, could potentially shed some light on population structure, connectivity and/or movement patterns throughout their range. Ideally, such efforts would be conducted in coordination with Canadian and Mexican researchers. Similarly, several of the indices developed for this assessment could be improved by greater evaluation and consideration of the spatial distribution of fishing effort and fish size, particularly in the context of possible ontogenetic movement patterns.

Closely related to this issue is the question of whether a separate area model could be developed for bocaccio. There could be clear advantages with regard to the ability to more appropriately link the various indices to their appropriate spatial scale. However, possible diffusion or migration patterns and rates are completely unknown for this stock, and would likely prove to be a source of significant uncertainty.

Currently the CalCOFI index is the longest time series of relative abundance in the model, and may be the longest time series currently used for any west coast groundfish. However, for most of the time series the data are only available for the southern region of the range of bocaccio. Current CalCOFI surveys have surveyed the central California region for most of the past decade, additionally, ongoing efforts are retrospectively analyzing samples from the northern stations collected in the 1950s and 1960s. Both of these efforts will increase the data available for both monitoring trends and possibly for better understanding differences in relative abundance trends among these regions. As such these efforts are of high importance for future assessment.

The potential to develop defensible ageing criteria for bocaccio in the southern area should be evaluated further, and such criteria could possibly be developed in a coordinated effort among workers throughout the West Coast. Although production ageing is likely to remain a challenge given the expectation of high ageing error and uncertainty, as well as the high information content of the length frequency data in assessing growth and year class strength from animals of younger ages, future ageing efforts would likely improve the ability to adequately inform natural mortality rates, variability of size at age, and possibly contribute to an improved understanding of differences in life history parameters and rates in different regions of the West Coast.

With respect to both time varying growth and a more comprehensive evaluation of the interaction between climate and fecundity (as a potential source of error or bias in the CalCOFI data). Time varying growth has been shown to be an important factor in a number of stock assessments of west coast groundfish, and a more focused exploration of time-varying growth has also been strongly encouraged in past models and STAR Panel reviews of bocaccio. Although time constraints limited the extent of exploration that could be done in this assessment, some exploration of time-varying growth was developed in the draft assessment, by estimating offsets to the von Bertalanffy growth parameter (K) as free parameters in various types of time blocks. As these preliminary explorations did not have a tremendous influence on the outcome in the current assessment, the final model did not include a time-varying growth component. However, the STAT Team intends to expand on process studies relating environmental conditions to growth and fecundity, using those results to modify existing bioenergetics models, and further investigating mechanisms by which climate may drive changes in energy budgets. Our hope is that the results of that effort can improve upon the manner by which time-varying growth (and potentially fecundity) have can subsequently be incorporated into future stock assessments.

The trawl survey indices (triennial and NWFSC combined shelf-slope survey) are not well suited to species that largely associate with highly structured habitat. Research to develop or improve upon alternative survey methodologies would benefit this assessment.

Currently, most of the fishing mortality on bocaccio rockfish takes place in the southern California recreational fishery, where a broad area of habitat is closed to fishing in the cowcod conservation areas (CCAs) and rockfish conservation areas (RCAs). Although the entire coast has significant RCA closures, with consequent impacts on the distribution of fishing effort and likely consequences on selectivity, the Cowcod Conservation Areas have been treated as closed to most monitoring efforts as well (the NWFSC SCB hook-and-line survey, the NWFSC combined trawl survey), unlike the RCAs. Consequently, the time series derived from these indices in this region are likely to be biased, and the inability to develop time series of abundance, as well as to assess potential differences in demographic structure, could eventually compromise the ability to assess the status of this stocks. This is by no means a problem limited to bocaccio (Field et al. 2006), however the problem may be particularly acute in the Southern California Bight, as suggested by the difference in trends observed from the CalCOFI data relative to the hook-and-line survey, and the apparent concentration of spawning output in the area now protected by the CCAs.

Although the influence of alternative maturity curves was relatively modest in this assessment, there have been few historical, and no recent, histology studies to confirm macroscopic staging for confirming the maturity relationship. Additionally, there is very little data available in the southern area (south of Conception) for smaller fish, somewhat complicating efforts to detect differences in maturity across space.

Acknowledgements

We are grateful to a large number of individuals for their help with this assessment. Beth Horness provided data from the NOAA Northwest Fisheries Science Center's West Coast Groundfish Survey Database, John Harms provided data on bocaccio from his ongoing Southern California Bight hook-and-line survey, John Wallace provided assistance with the GLMM function for developing survey indices, Eliza Heery provided estimates of total mortality in commercial fisheries from 2002 through 2007, Allan Hicks shared his code for plotting survey catch data, Marlene Bellman provided figures of bycatch rates over space, and John Budrick provided estimates of recreational fisheries mortality in California waters from 2004 through 2008. Additionally, Rick Stanley kindly shared information and data from Canadian bocaccio research and ongoing assessment efforts, Devon Pearse re-analyzed the genetic data that in turn was very kindly provided by Andrew Matala and his coauthors, Milton Love, Linda Snook and Mary Yoklavich provided access to the bocaccio data from their ongoing submersible research efforts, David Demer and Kevin Stierhoff shared information from their ongoing acoustic and ROV survey efforts in the Southern California Bight, and William Watson and Richard Charter provided access and assistance with the CalCOFI data. Steve Ralston, Meisha Key and Xi He were helpful in provided comments and assistance with the development of early versions of the model, the assistance provided by Richard Methot was essential and invaluable in debugging and running SS3, and the R graphing packages provided by Ian Stewart and Ian Taylor were equally valuable in rapidly viewing and evaluating model results. The entire STAR Panel, Martin Dorn, Chris Francis, Vladlena Gertseva, J. J. Maguire, John DeVore, Gerry Richter, and John Budrick, was extremely helpful in improving both the model and the documentation during the assessment review. Finally, the multitude of personnel involved in years of fisheries surveys, port sampling and other monitoring efforts all deserve great thanks and recognition.

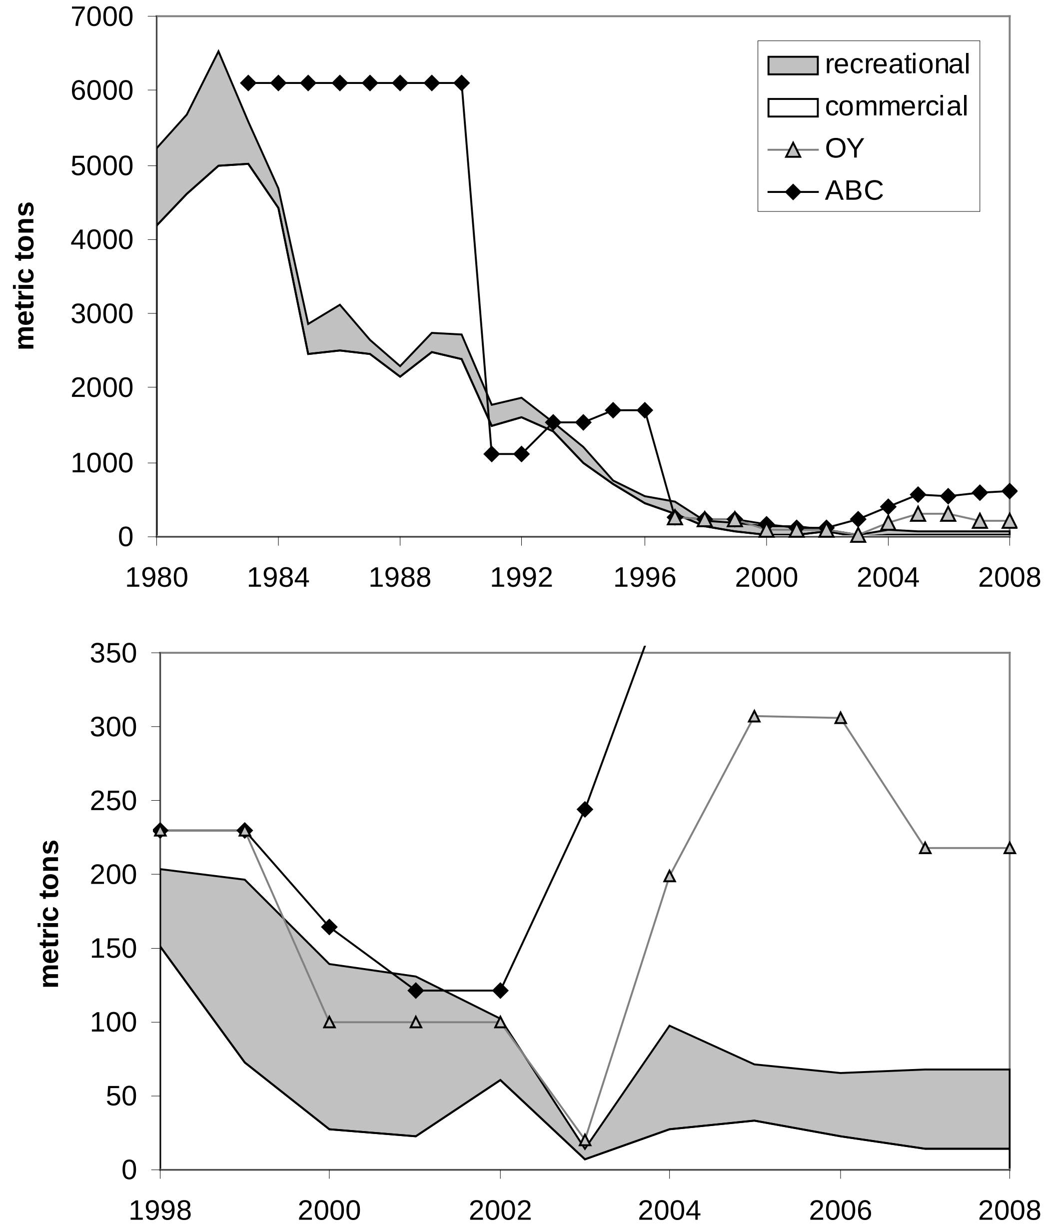

Figure 1: Management performance with PFMC adopted ABC and OY values relative to estimated landings (1980-2002) and landings + discards (2002-2007; 2008 is set to 2007 until final numbers provided). Lower graph provided for scale in recent years.

Figure 2: Map of the West Coast INPFC management areas. This assessment covers the bocaccio stock in the Eureka, Monterey and Conception management areas.

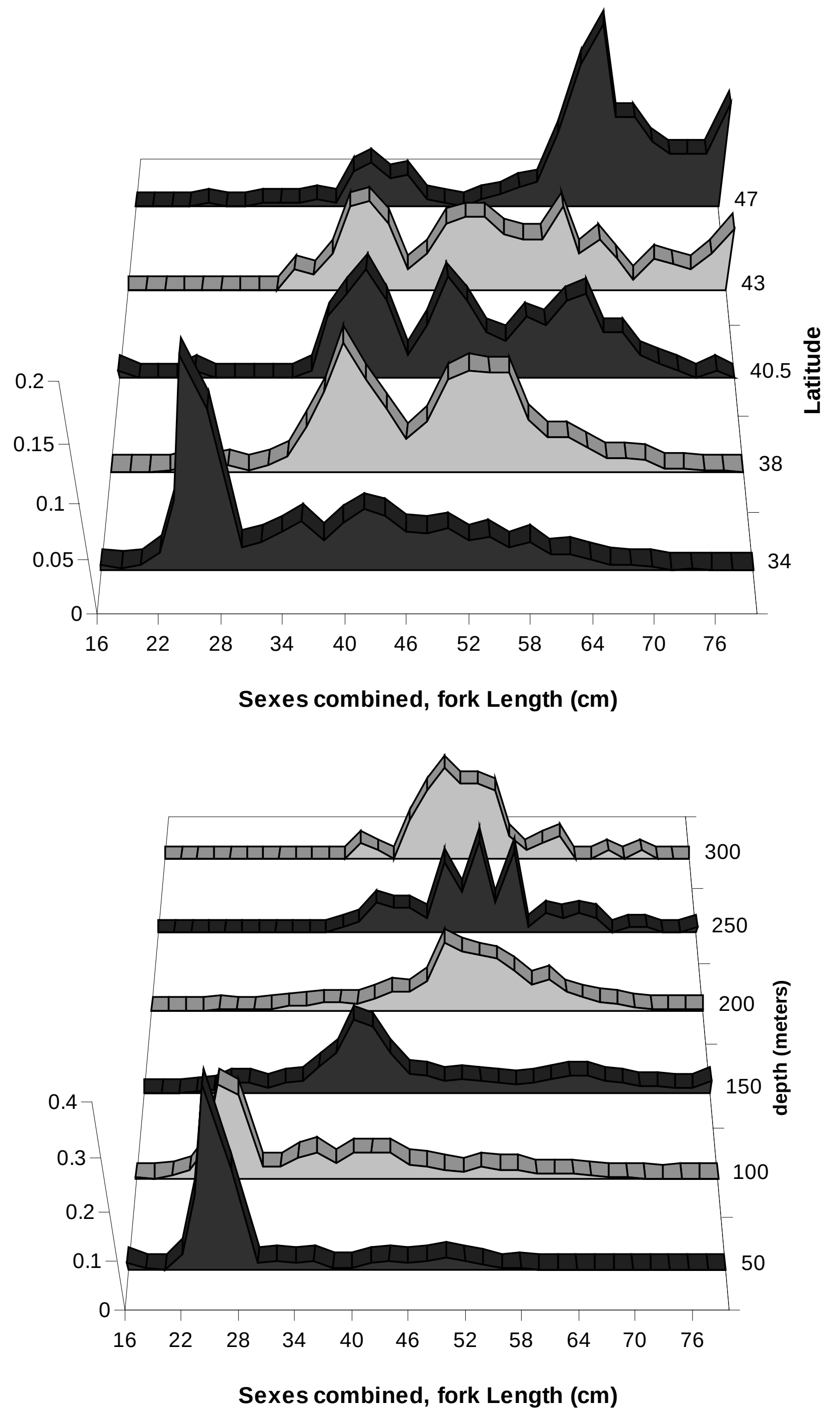

Figure 3a-b. 3a (top) Length frequency information from the triennial trawl survey by region; all years aggregated, demonstrating the shift in size distribution in the northern areas; 3b (bottom) length frequency information by depth bin, illustrating ontogenetic movement to deeper water with size.

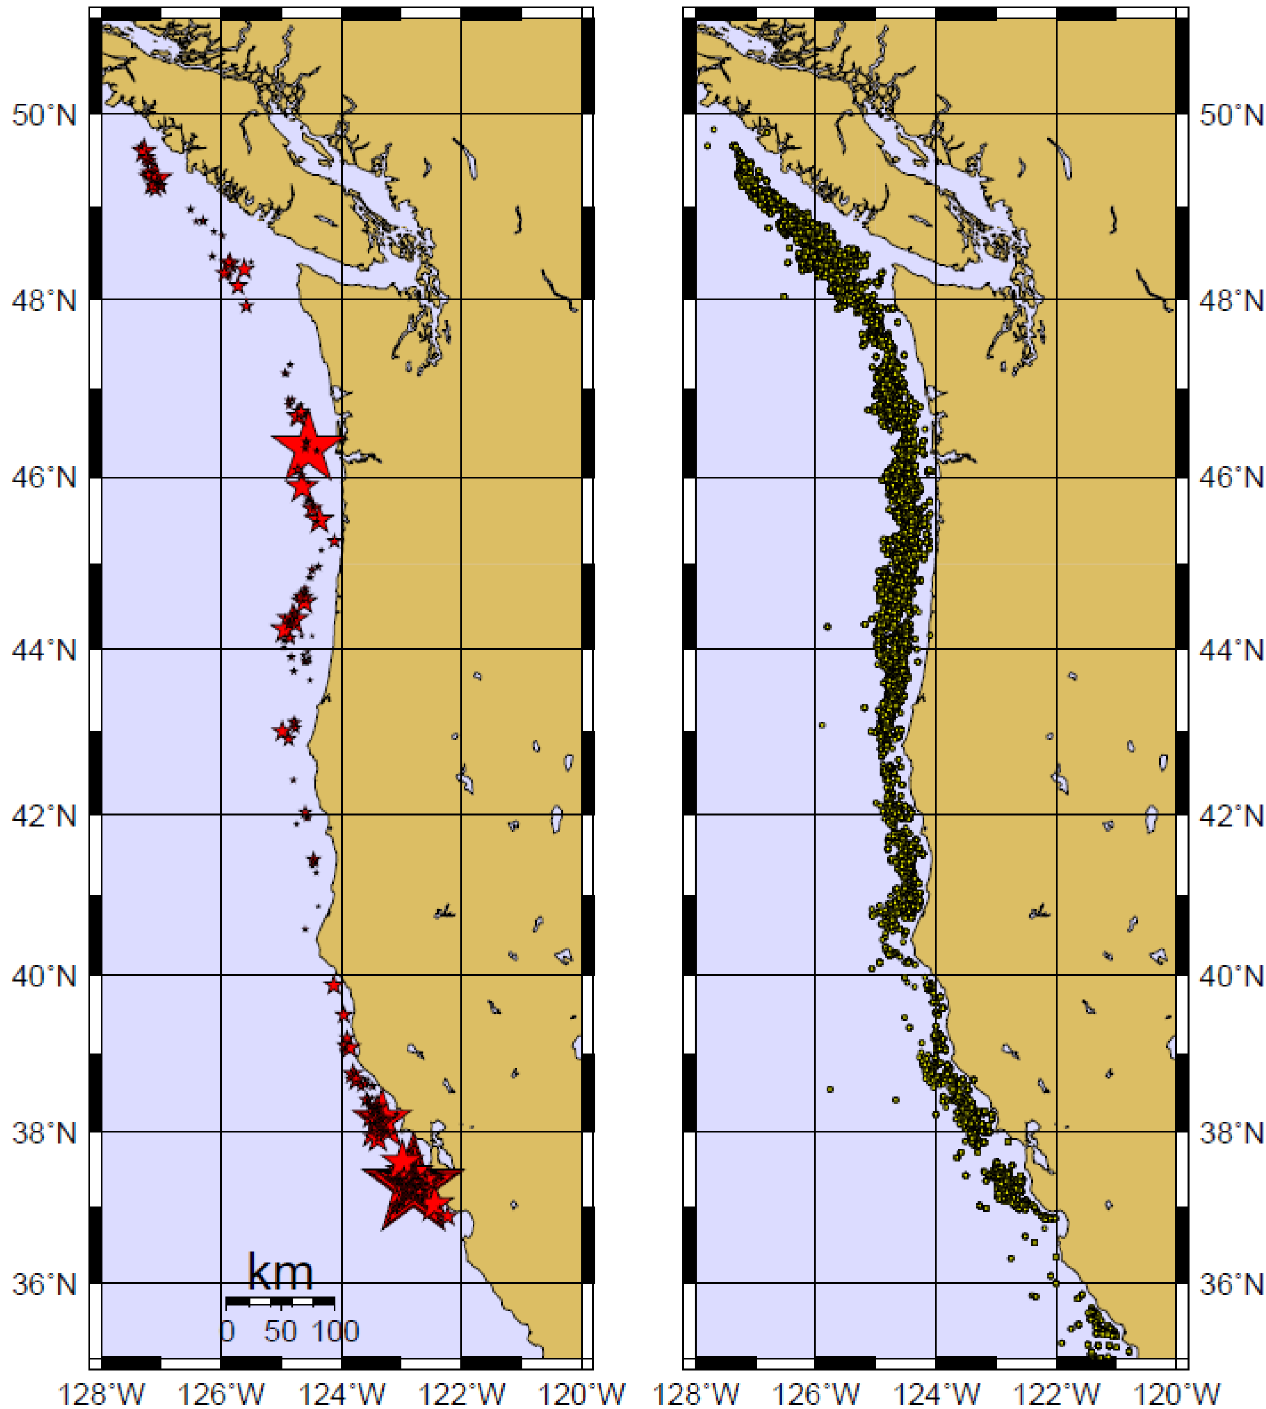

Figure 4. Locations of Russian trawls where bocaccio were caught (left panel) versus tow locations where no bocaccio were found (right panel) from trawls taken between 1963-1978. Stars are sized proportional to the square root of the total number caught per tow.

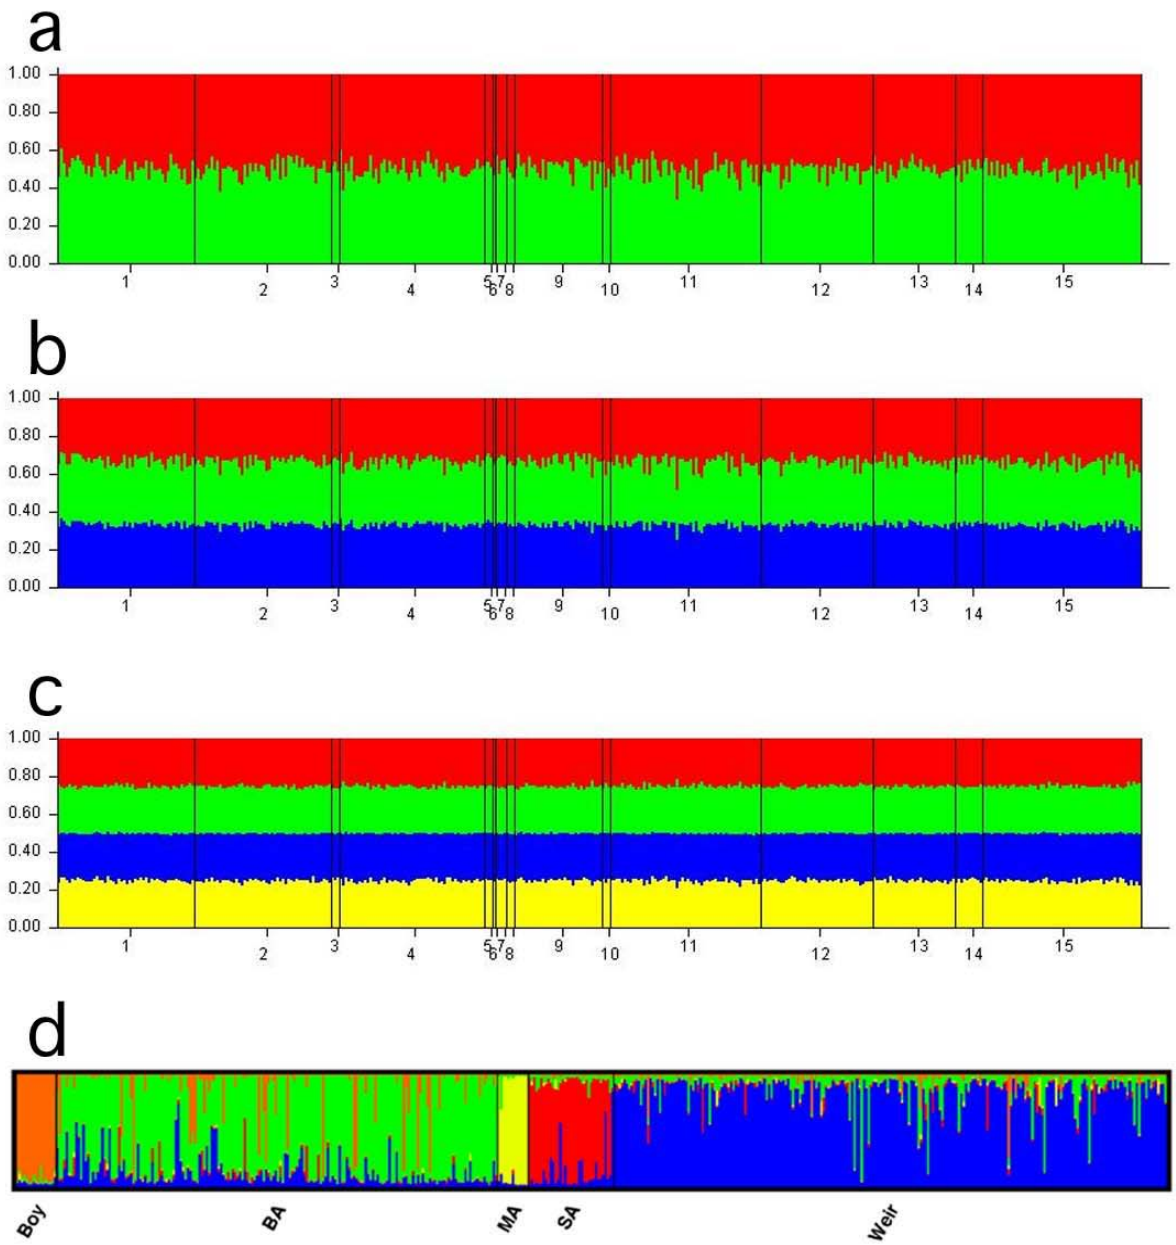

Figure 5a-d. Results of analysis of data from seven microsatellite loci in 386 *S. paucispinis* using the program STRUCTURE (Pritchard et al. 2000; data from Matala et al. 2004; analysis by D. E. Pearse, FED/SWFSC/NMFS). Each vertical line represents an individual, and color indicates membership in a specified number of distinct genetic groups. Panels a, b, and c show results for two, three, and four groups, respectively. For comparison, analysis of five genetically-differentiated populations of steelhead/rainbow trout is shown in 5d (*from* Pearse et al. *In Press*).

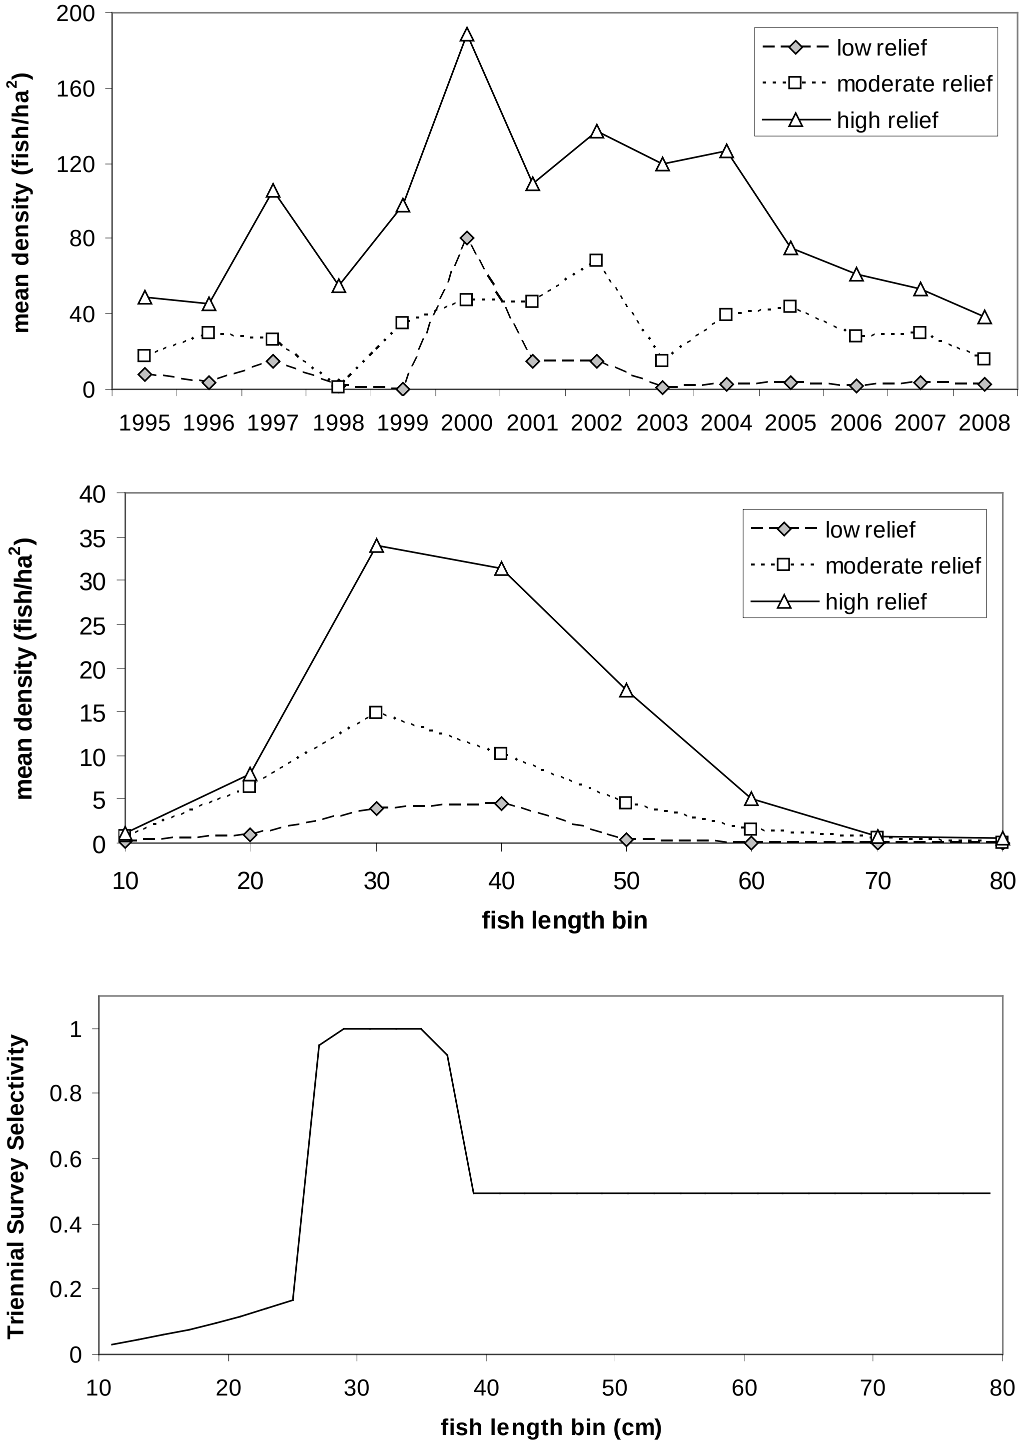

Figure 6. Habitat associations of bocaccio based on submersible observation data from Love (pers. com). Top panel shows the mean density (in numbers of fish observed per hectare) by year (pooled over all sizes), middle figure shows the mean density by habitat type and fish size, bottom figure shows the estimated selectivity of trawl survey from the 2007 model.

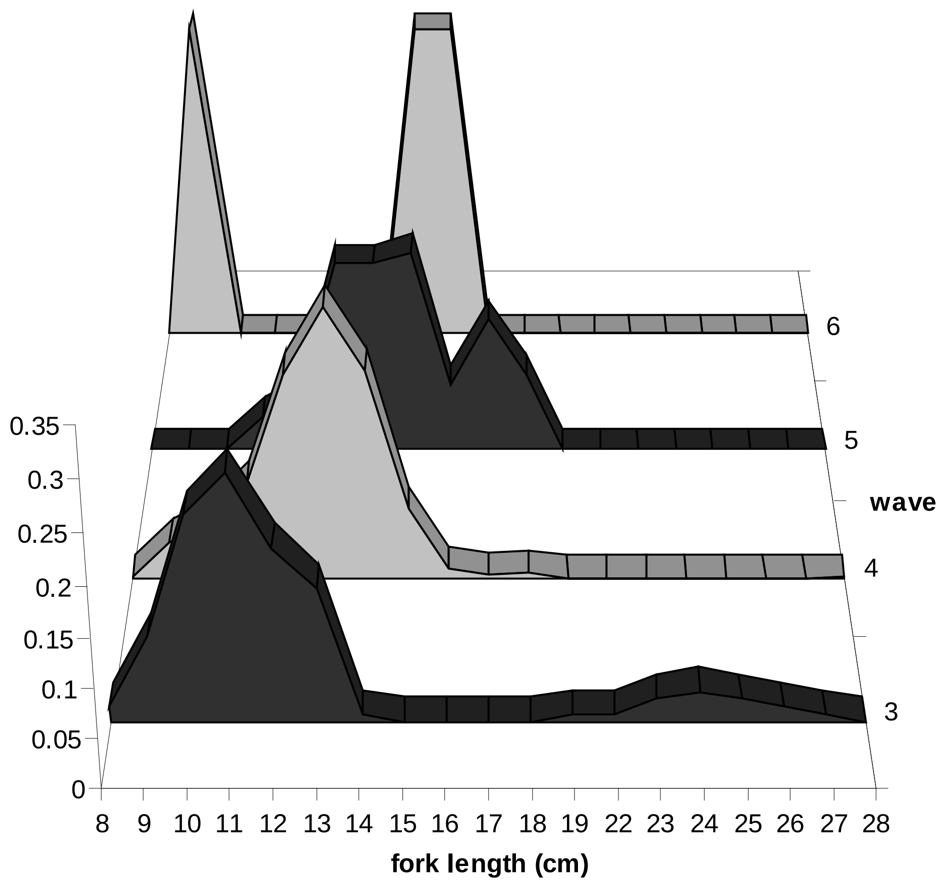

Figure 7. Length frequency data from recreational pier and shore fisheries in California (all years combined) showing the modal progression of age-0 size at age. Waves correspond to bimonthly sampling periods (such that wave 3 is May-June, wave 4 is July-August, etc).

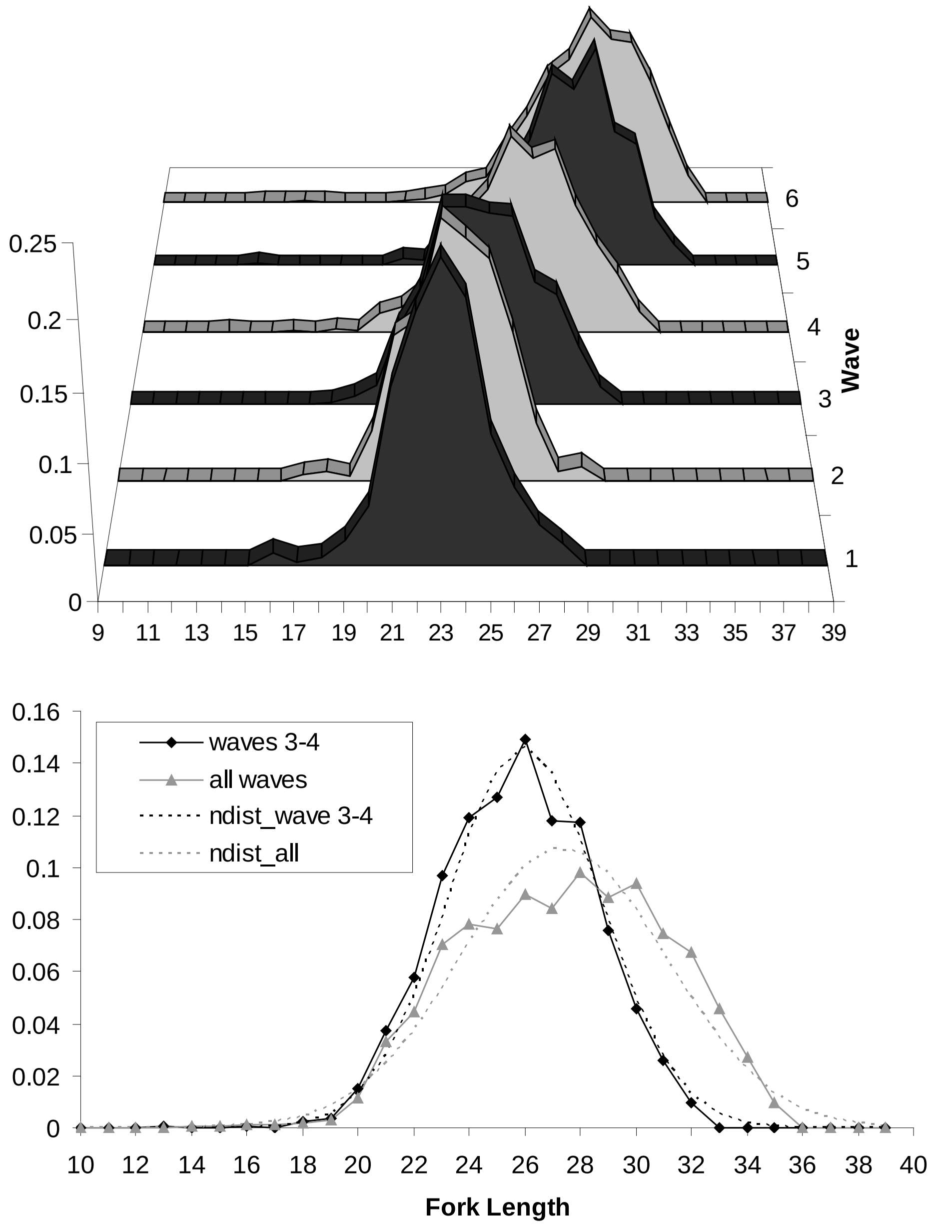

Figure 8a and 8b. Length frequency data from the Southern California CPFV fishery in 1978, with sizes data truncated above a wave-specific maximum to illustrate the modal progression of the 1977 year class by wave. Bottom figure shows the same data with a fitted normal distribution for all waves versus waves 3-4 (May-August).

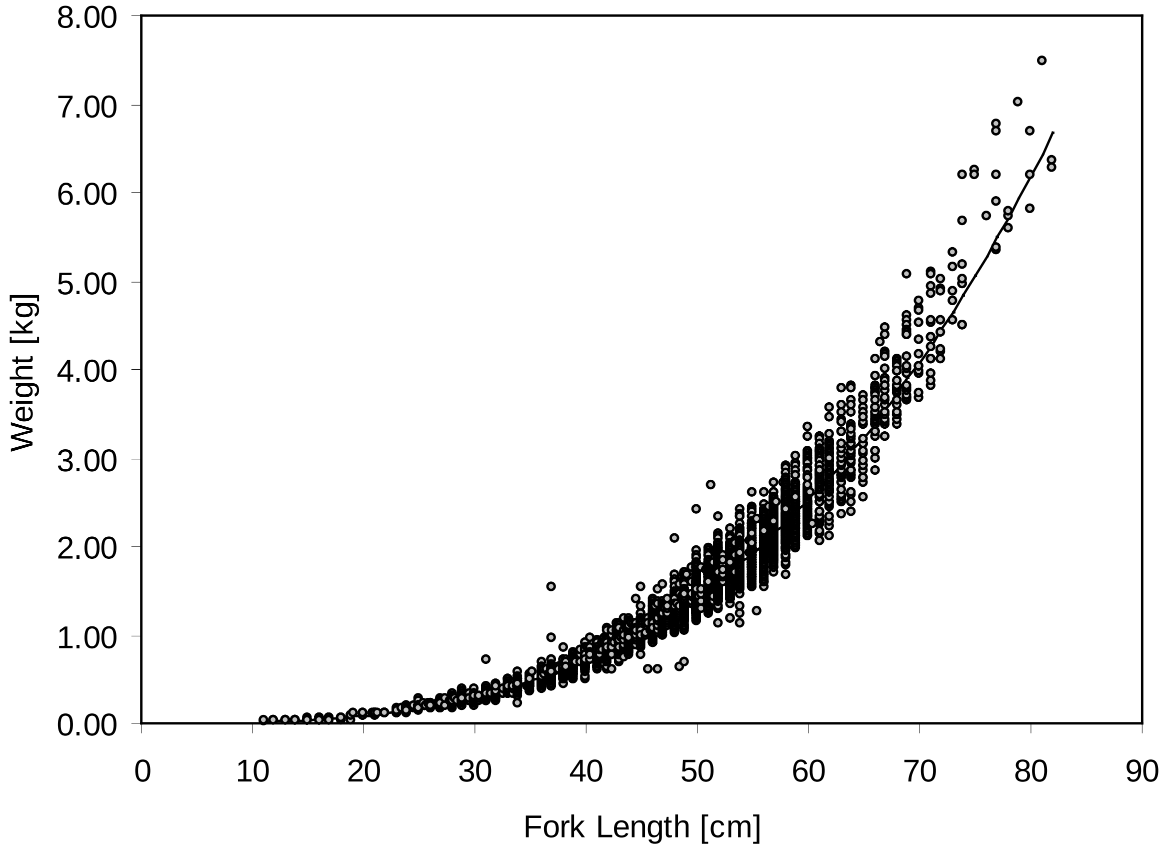

Figure 9. Weight-length relationship for bocaccio rockfish.

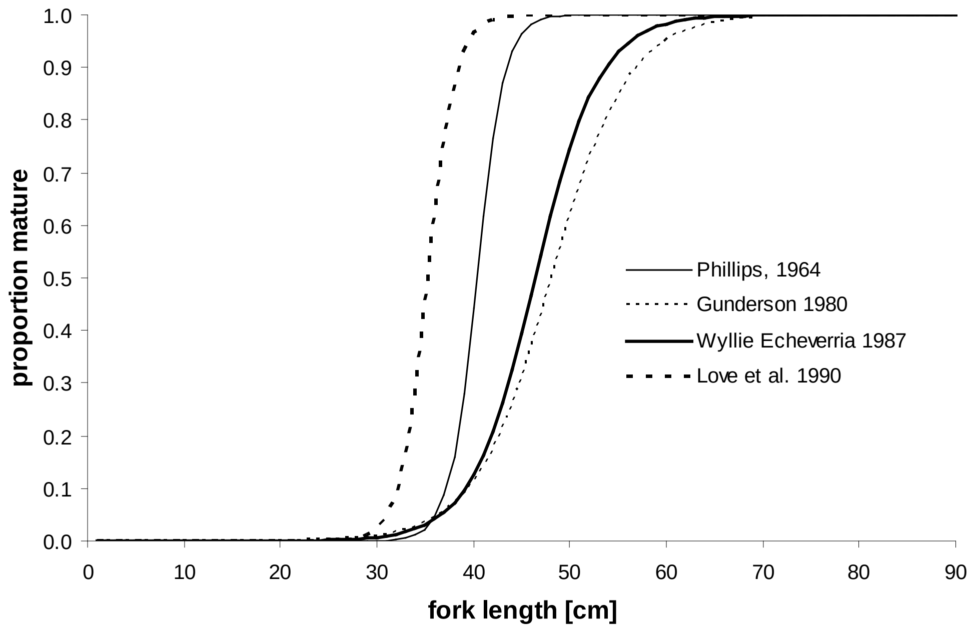

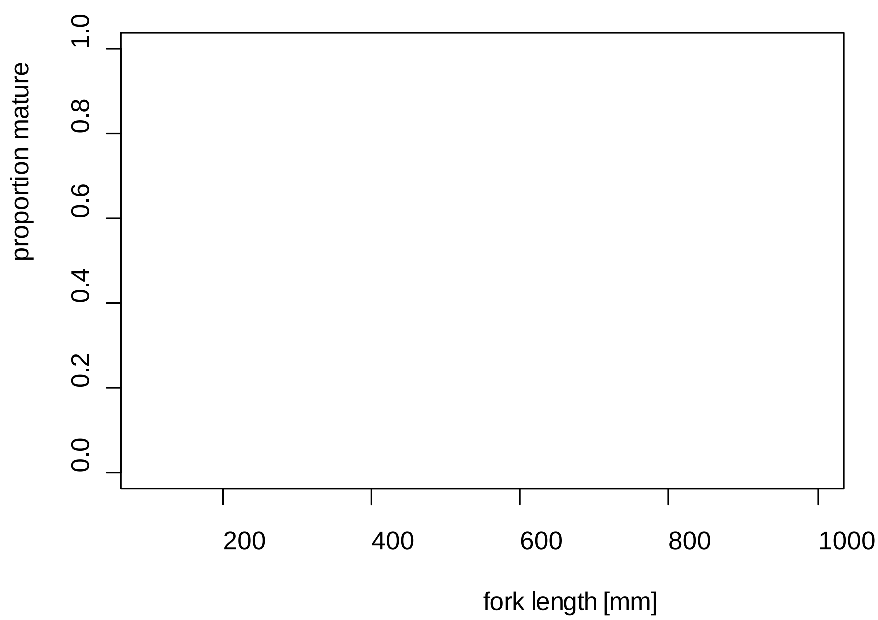

Figure 10a-b. 10a (top) Logistic curves representing the proportion of female bocaccio that are mature as a function of body length, as reported in four published studies. Figure 10b (bottom) observed proportion of mature female bocaccio at length (solid circles, 2-cm length bins) and binomial GLM predictions (solid line) for central and northern California, all years and regions combined.

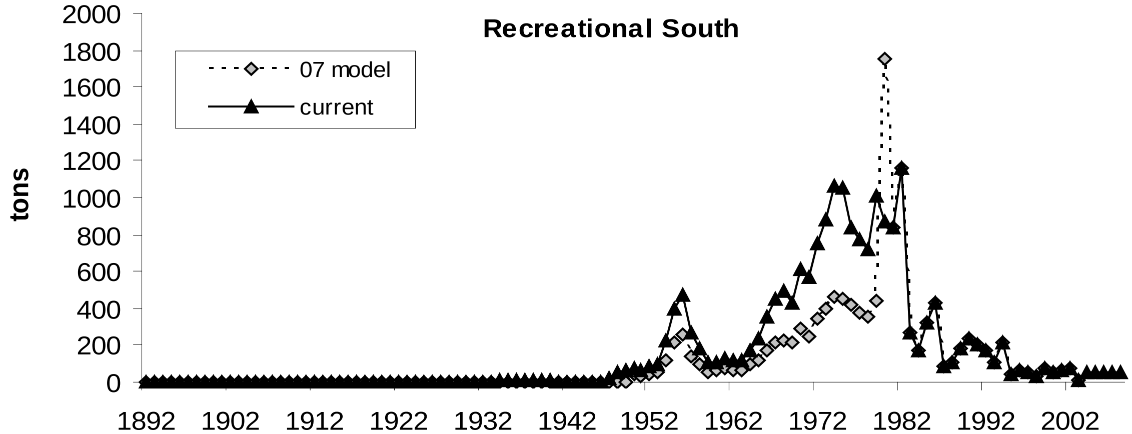
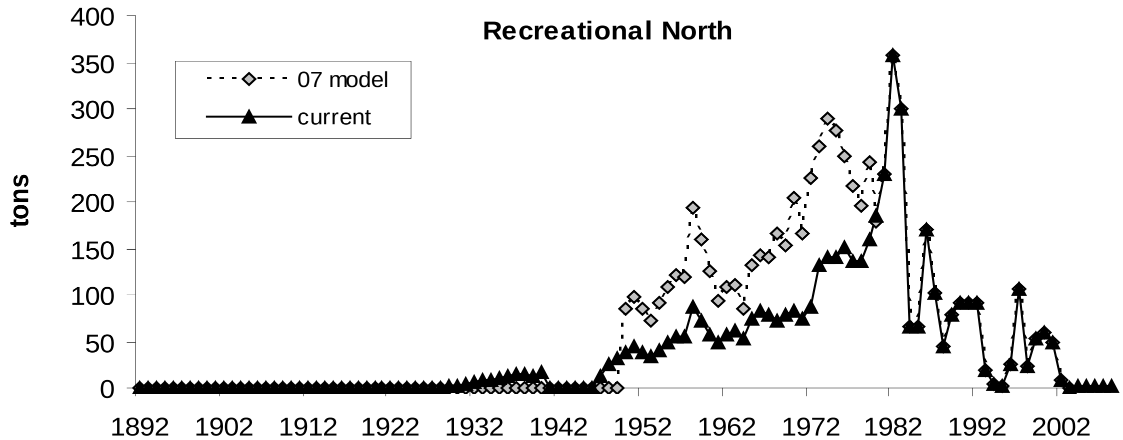
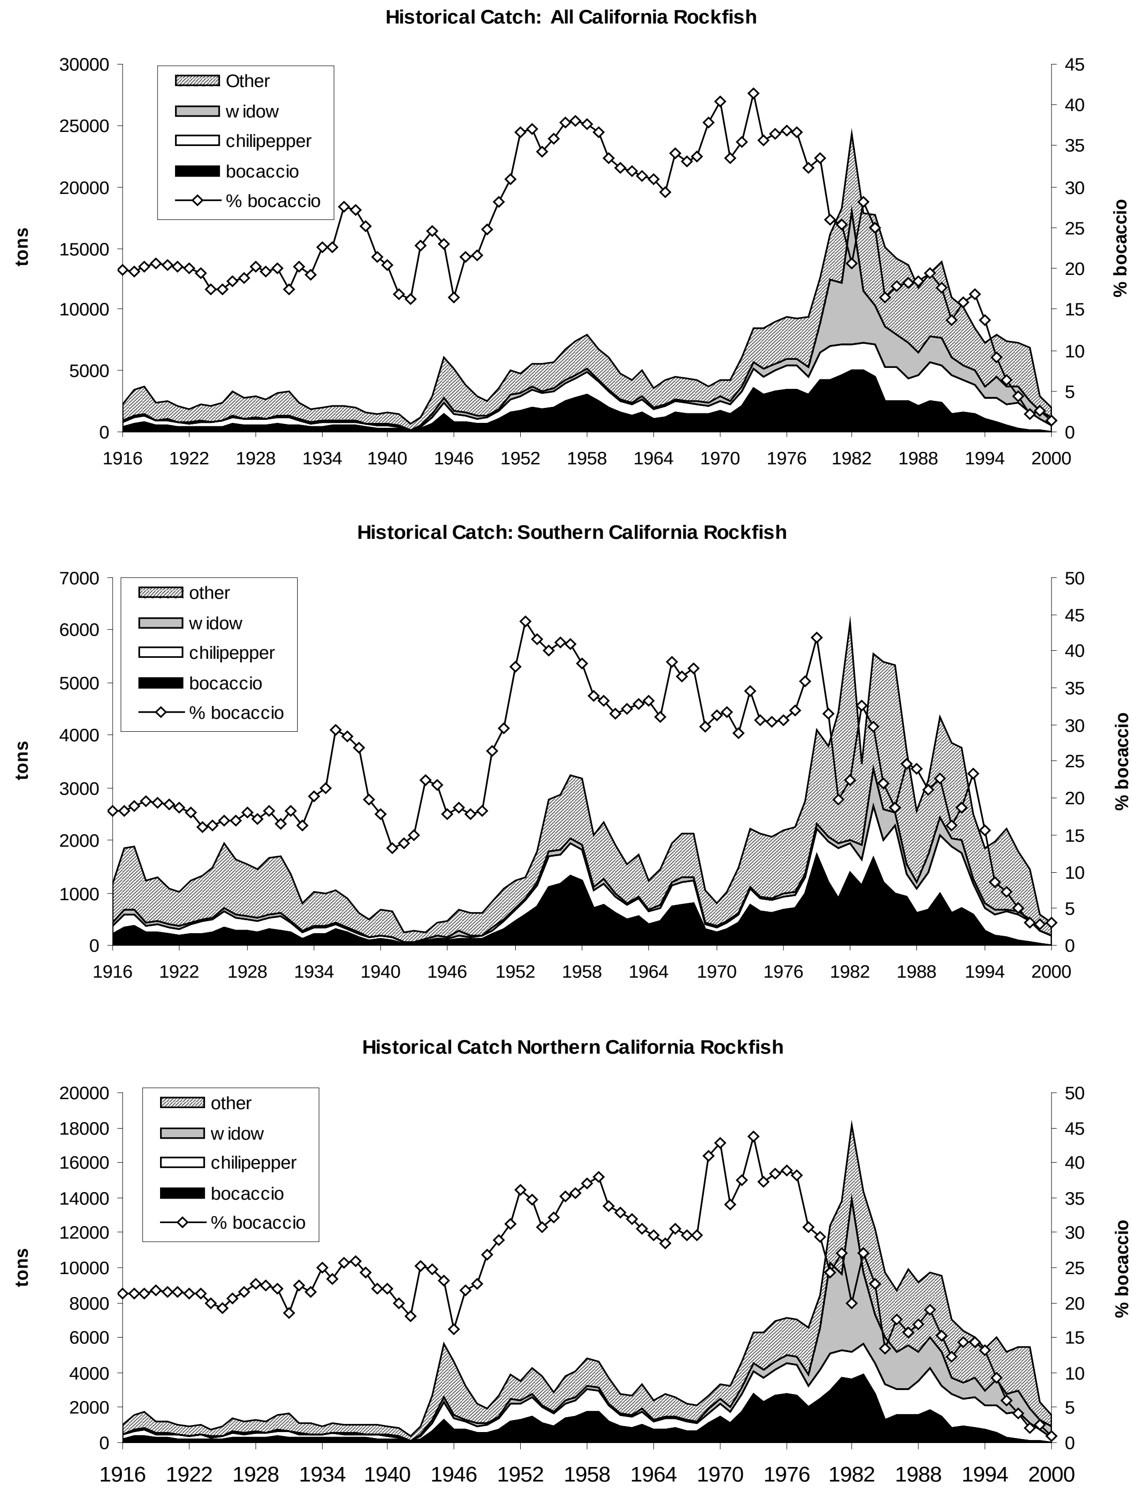




Figures 13d-e. Comparison of 2007 and current model catch estimates for the two recreational fisheries, south (top) and north (bottom) of Point Conception.



Figures 14a-c. Reconstructed commercial catches of California rockfish for bocaccio, chilipepper, widow and all other rockfish species, including the percentage of the total catch estimated to be comprised of bocaccio rockfish, for all of California (top), south of Point Conception (middle) and north of Point Conception (bottom).

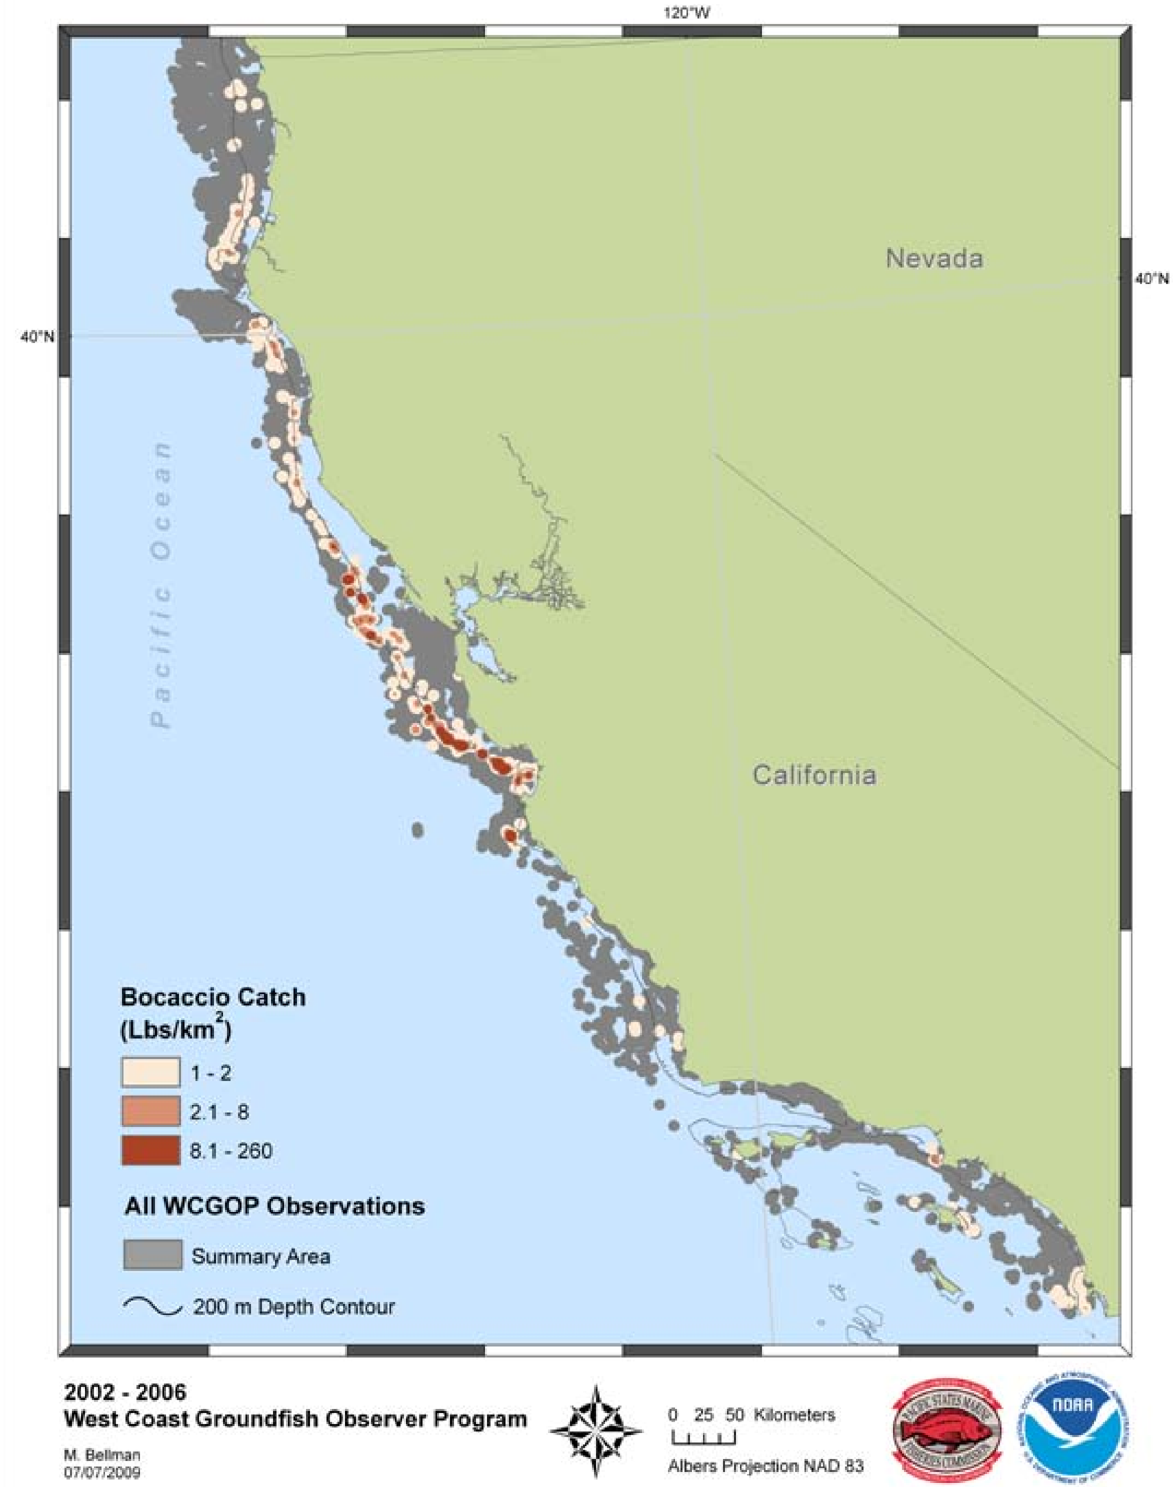


Figure 15: Bocaccio bycatch rates for California waters, from the West Coast Groundfish Observer Program (WCGOP).

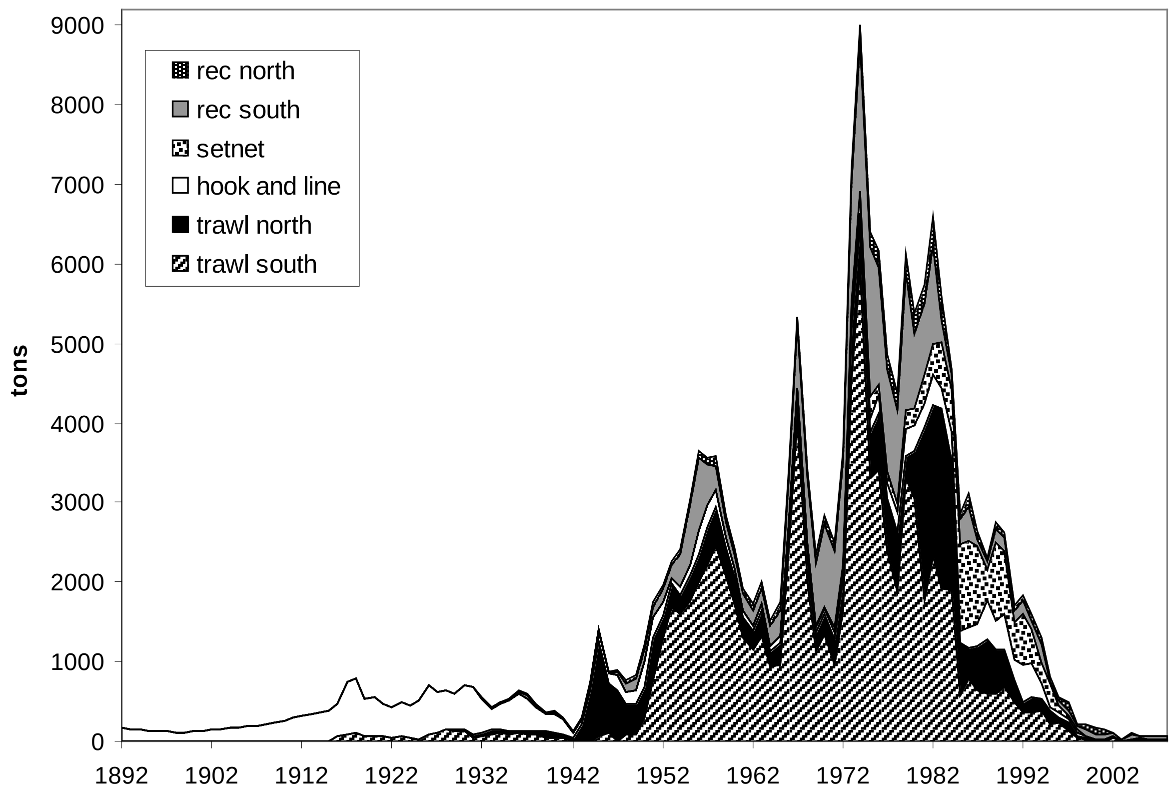

Figures 16. Assessment area (U.S. waters south of Cape Blanco) catch estimates for the six fisheries used in the model.

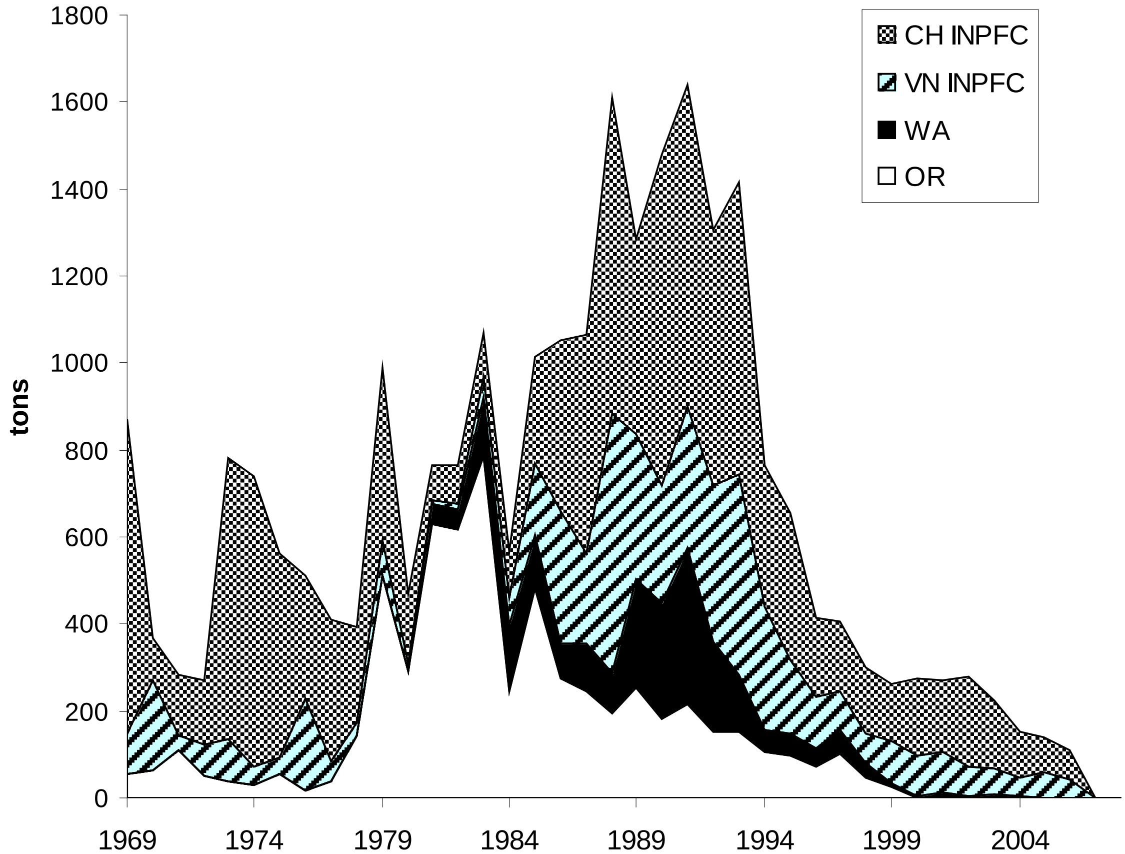

Figure 17. Catch estimates for the recent (1969-2006) period for areas north of Cape Blanco, Oregon, not included in the assessment model.

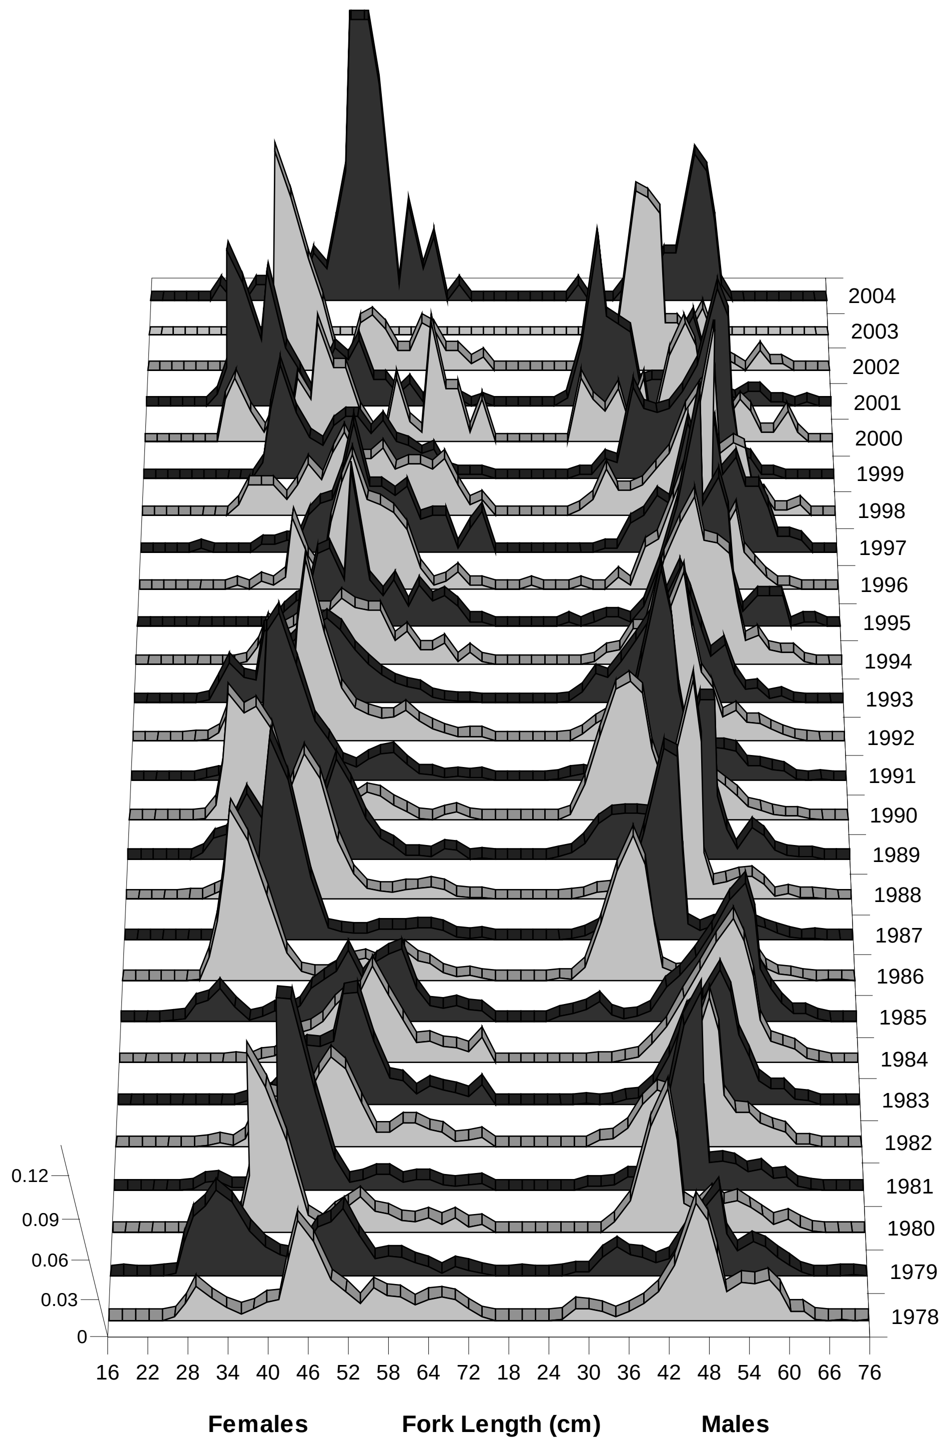

Figure 18. Length frequencies for all California trawl catches, 1978-2004.

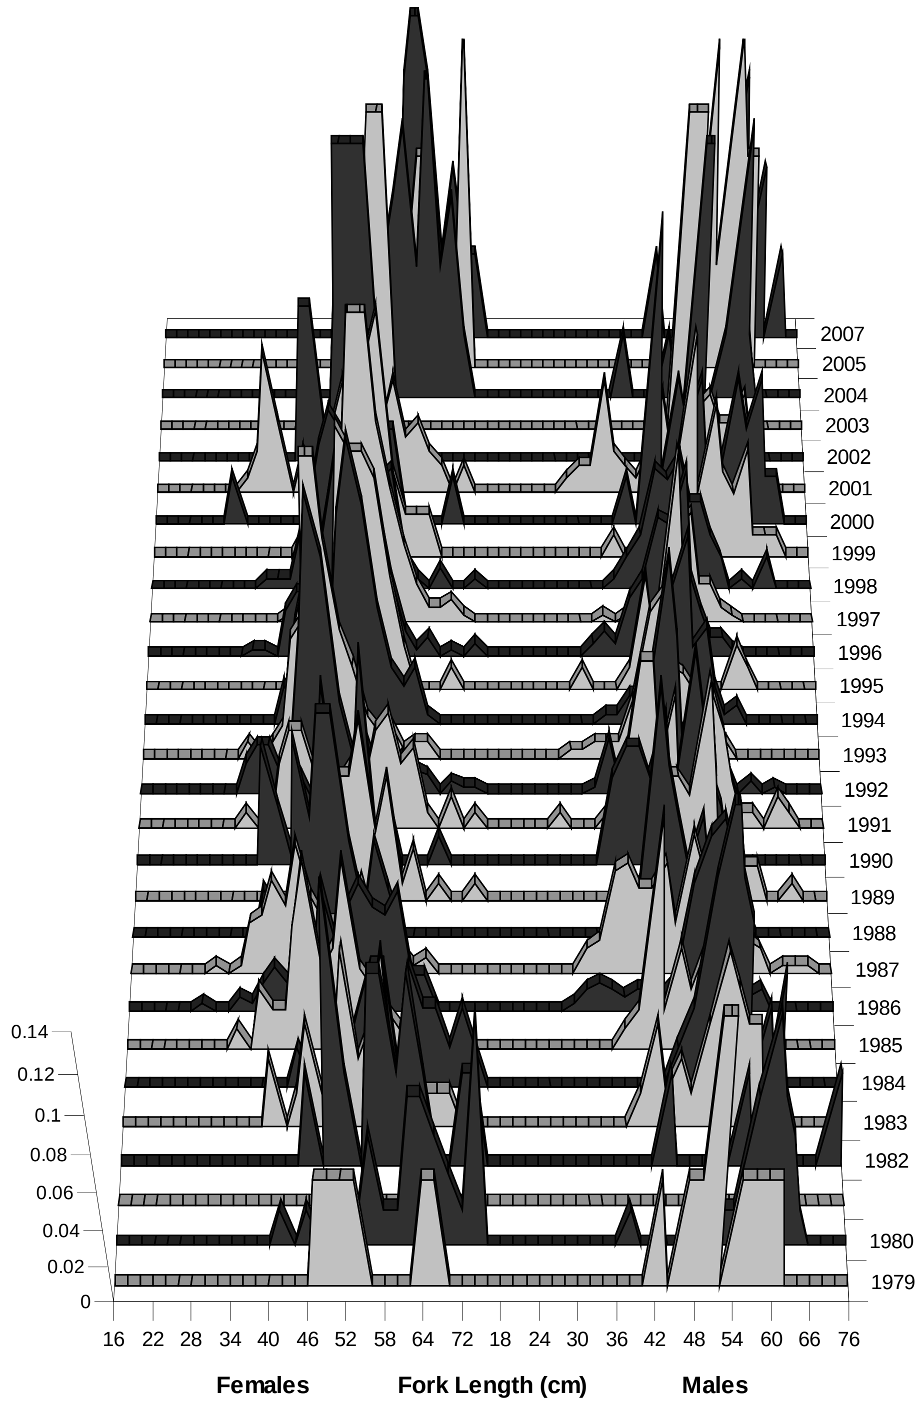

Figure 19. Length frequencies for all California hook-and-line catches, 1978-2004.

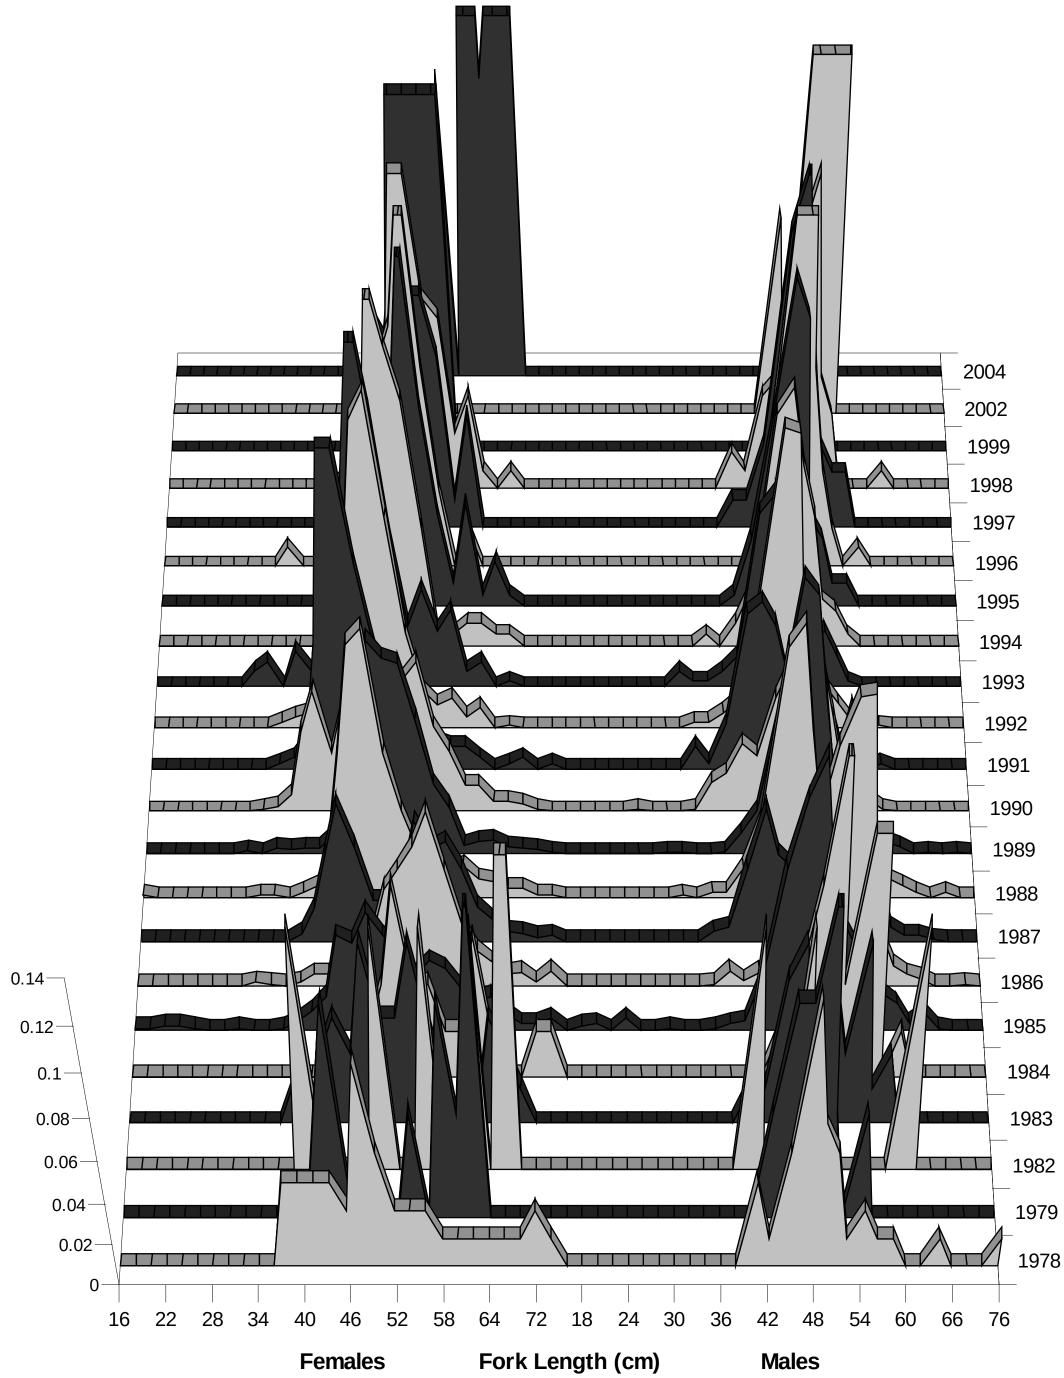

Figure 20. Length frequencies for all California set net catches, 1978-2004.

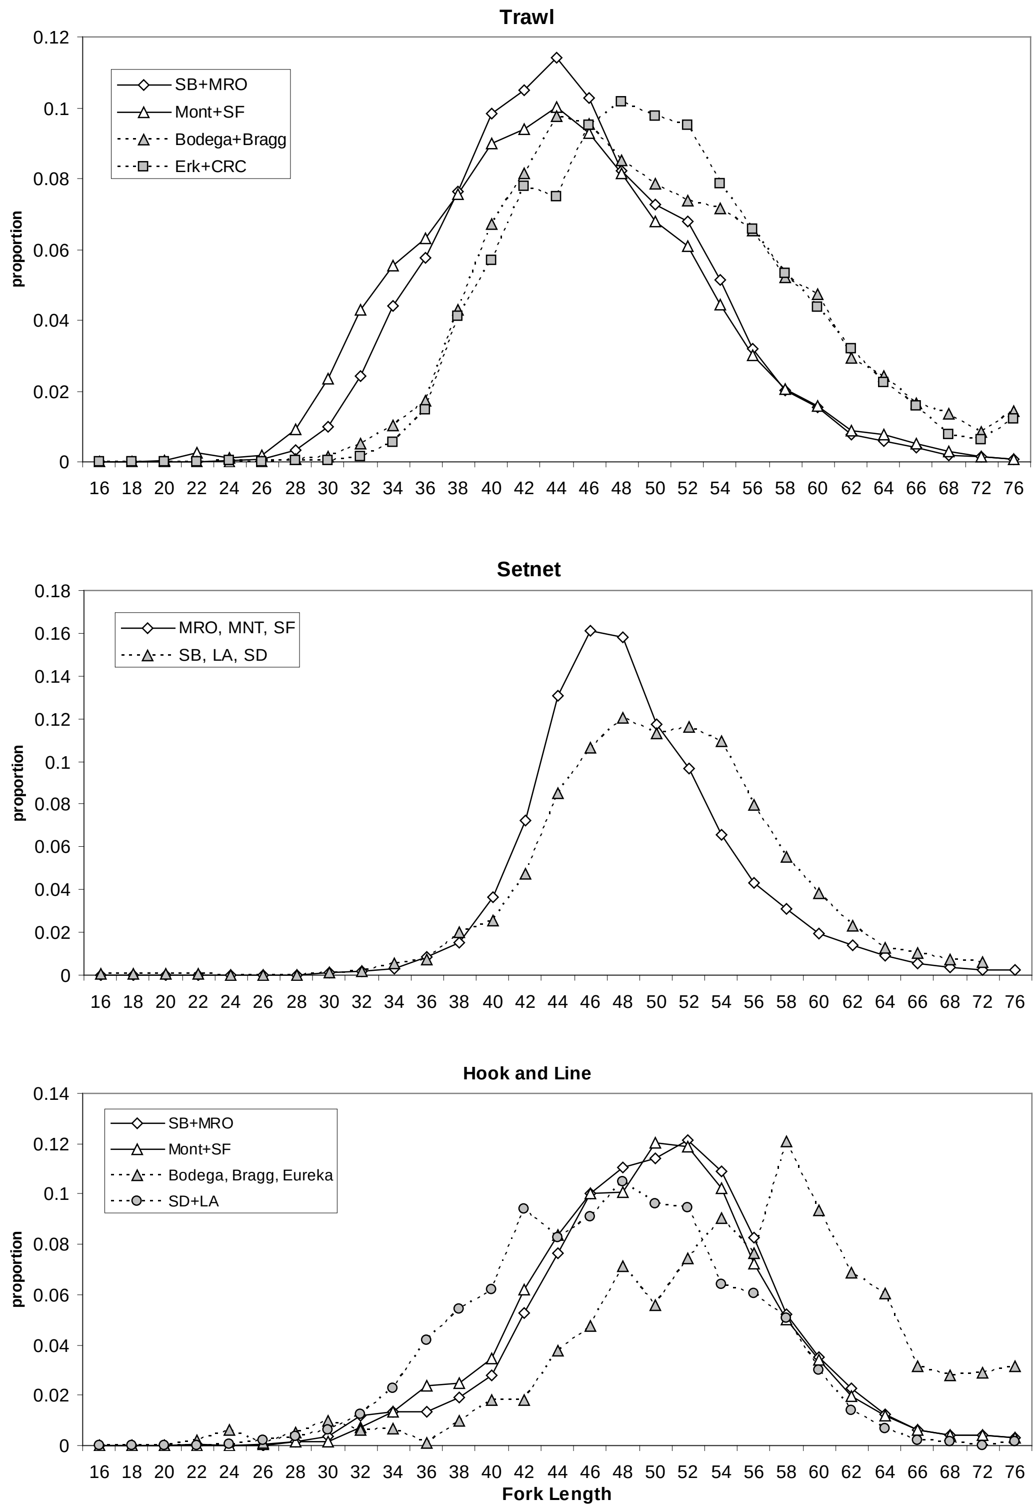

Figures 21a-c. Length frequency composition data for the trawl, hook-and-line and set net fisheries by port groups and regions. From south to north, port groups (essentially regions) are SD (San Diego), LA (Los Angeles), SB (Santa Barbara), MRO (Morro Bay), MNT (Monterey Bay), SF (San Francisco Bay), Bodega (Bodega Bay), Bragg (Fort Bragg), Erk (Eureka) and CRC (Crescent City).

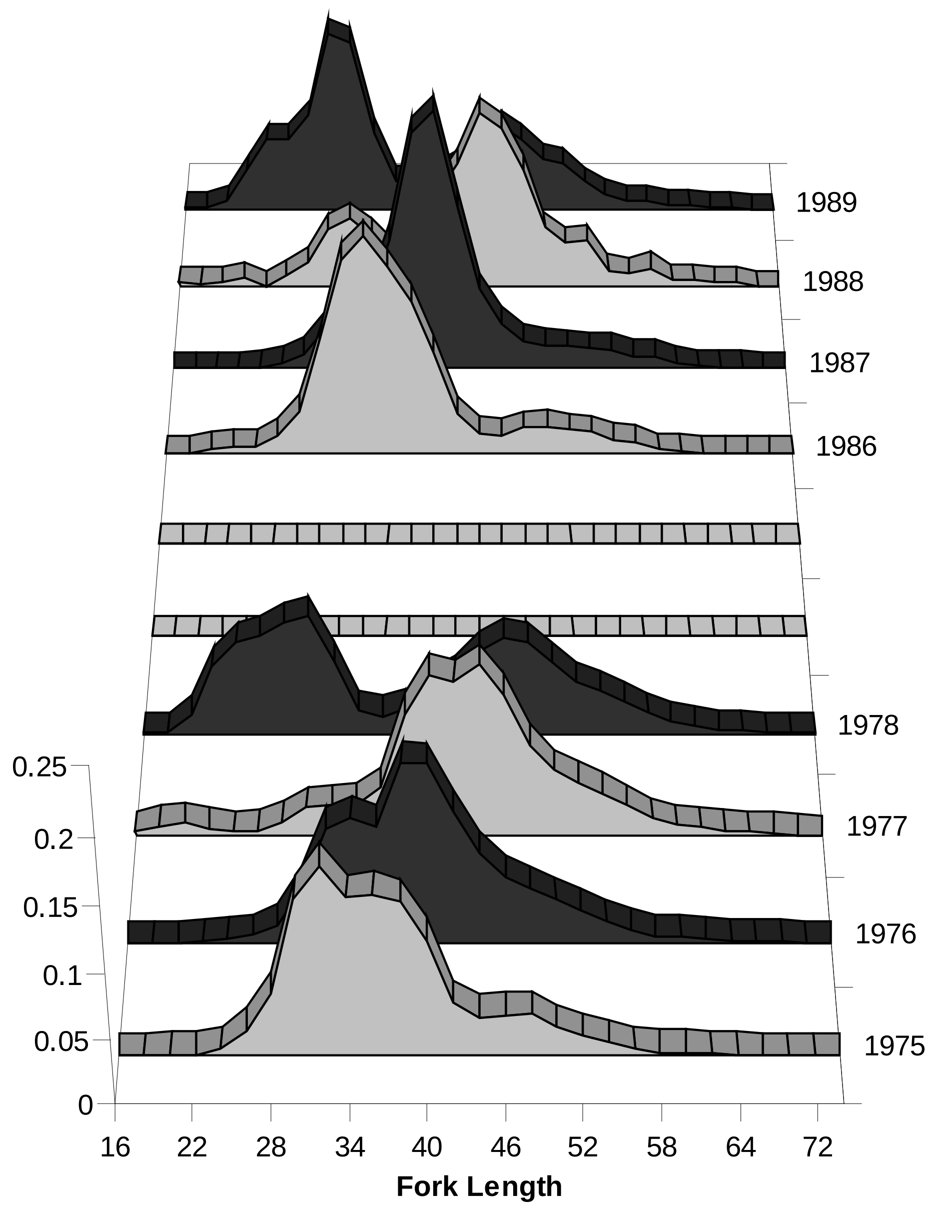

Figure 22. Length frequency distribution for Southern California CPFV observer program1975-1978 and 1986-1989.

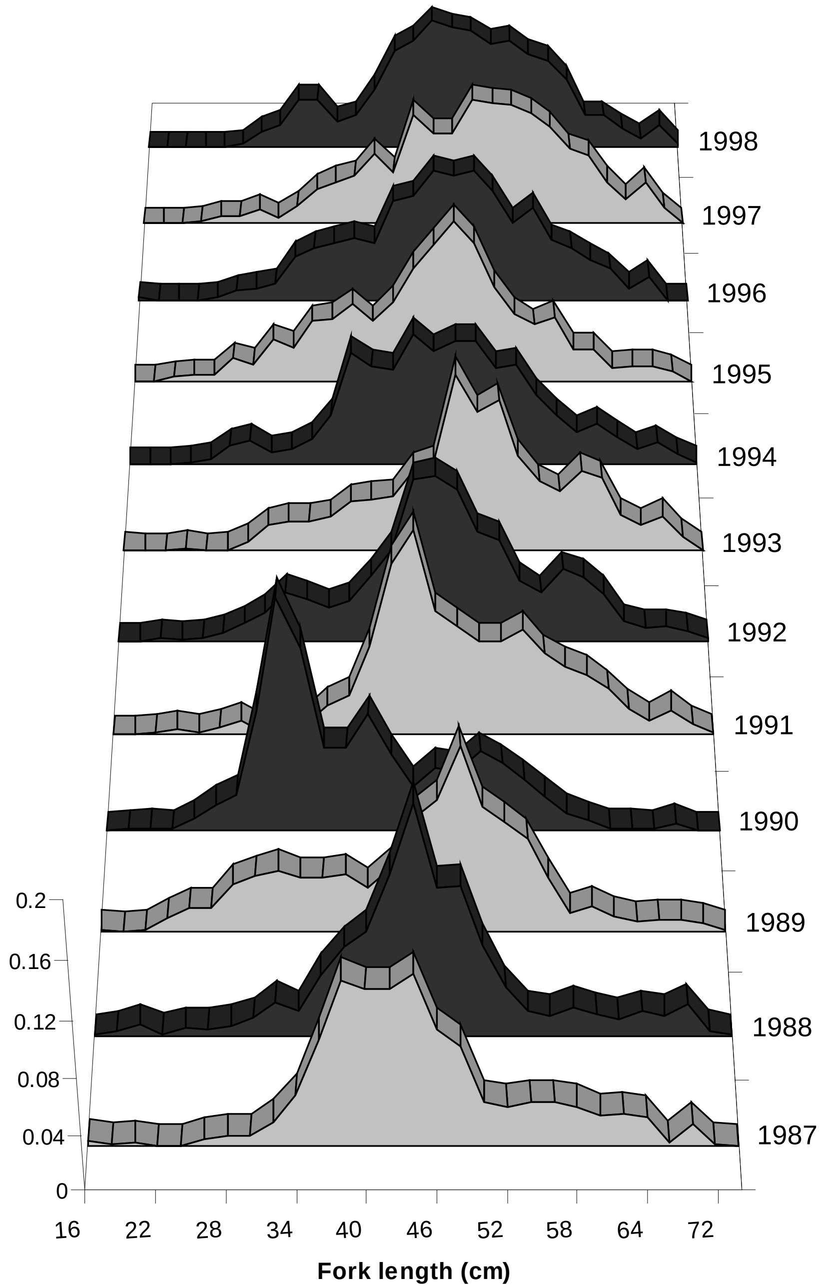

Figure 23. Length frequency distribution of sampled bocaccio from the central California CPFV observer program, 1987-1998.

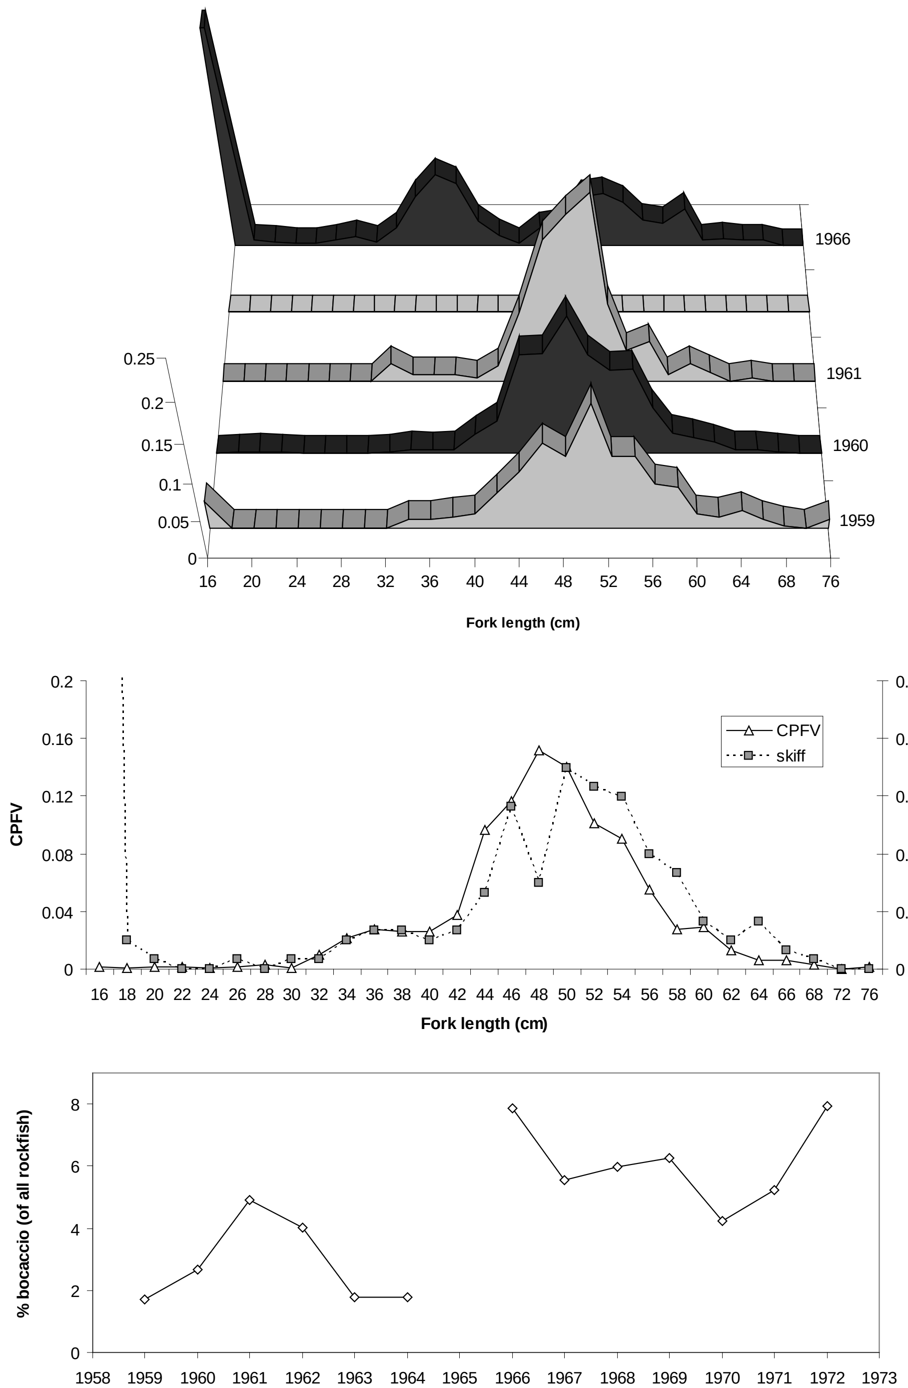

Figure 24a-c. 24a, Length frequency distribution for Monterey Bay CPFV and skiff recreational fisheries from the Miller and Gotshall monitoring efforts, 24b, pooled length frequencies showing difference between skiff and CPFV lengths, and 24c the percentage of the total recreational rockfish catch observed to be bocaccio in Monterey Bay, 1959-1972.

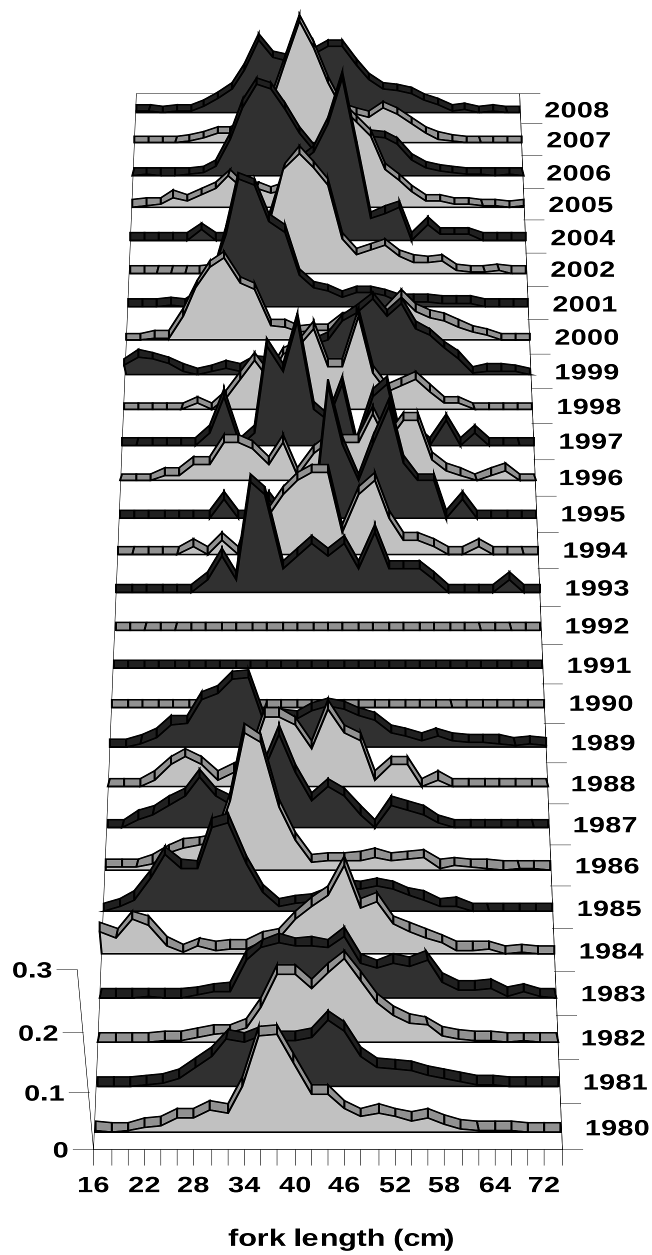

Figure 25. Length frequency composition of bocaccio for Southern California recreational fisheries (excluding shore modes) from the RecFIN database, 1980-2008. Note that no sex information is available, no data were collected from 1990-1992, and 1980-1989 data are derived from weight-frequency information.

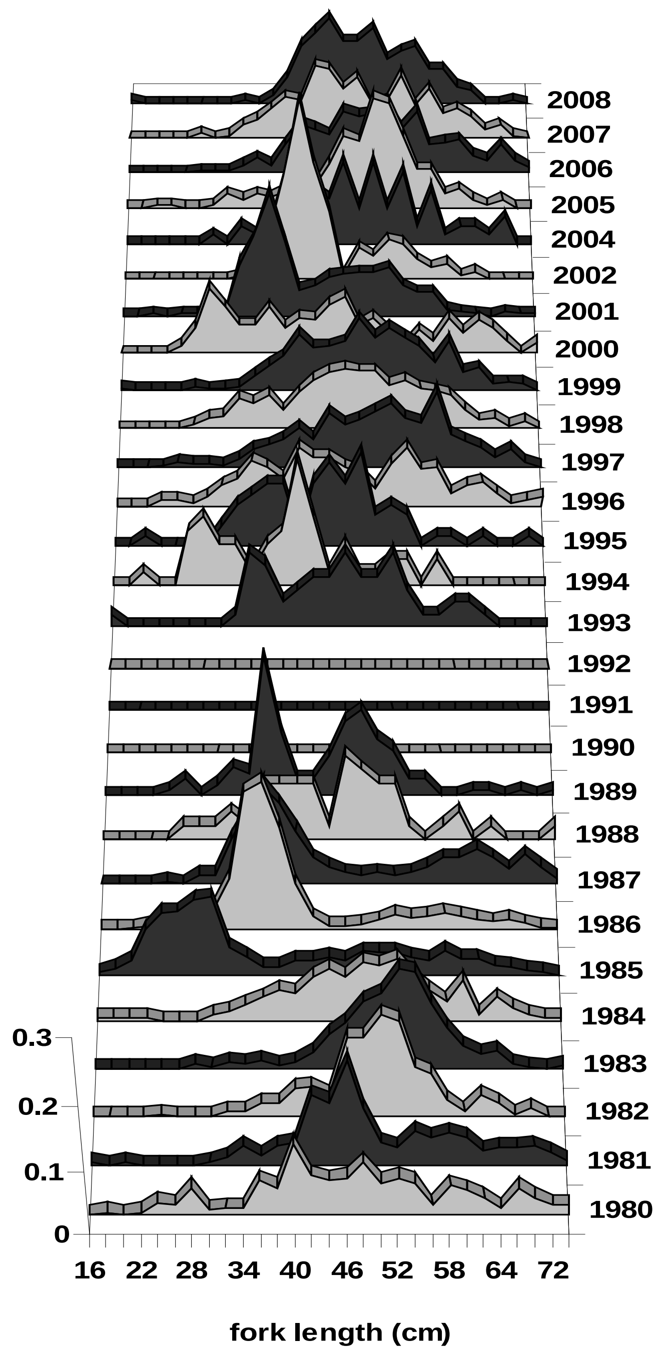

Figure 26. Length frequency composition of bocaccio sampled in central and northern California recreational fisheries (excluding shore modes) from the RecFIN database, 1980-2008. Note that no sex information is available, no data were collected from 1990-1992, and 1980-1989 data are derived from weight-frequency information.

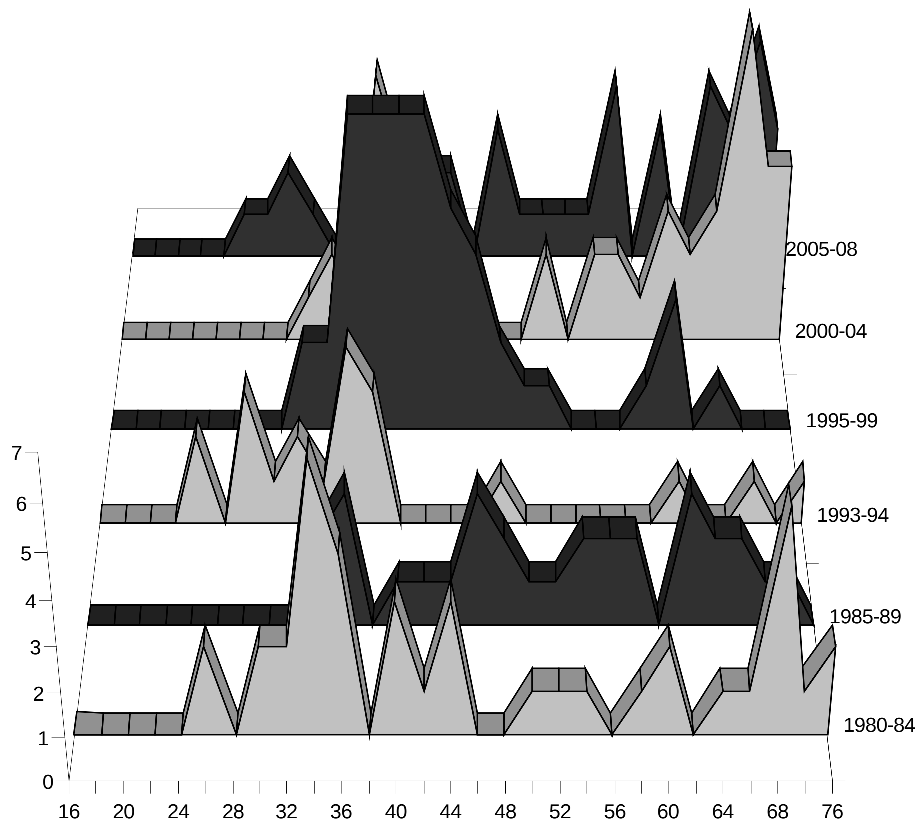

Figure 27. Length frequency composition of bocaccio sampled in Oregon and Washington recreational fisheries (excluding shore modes) from the RecFIN database, 1980-2008. As very limited information is available and many years had either no observations or only observations in single digits, data are pooled into 5-year intervals.

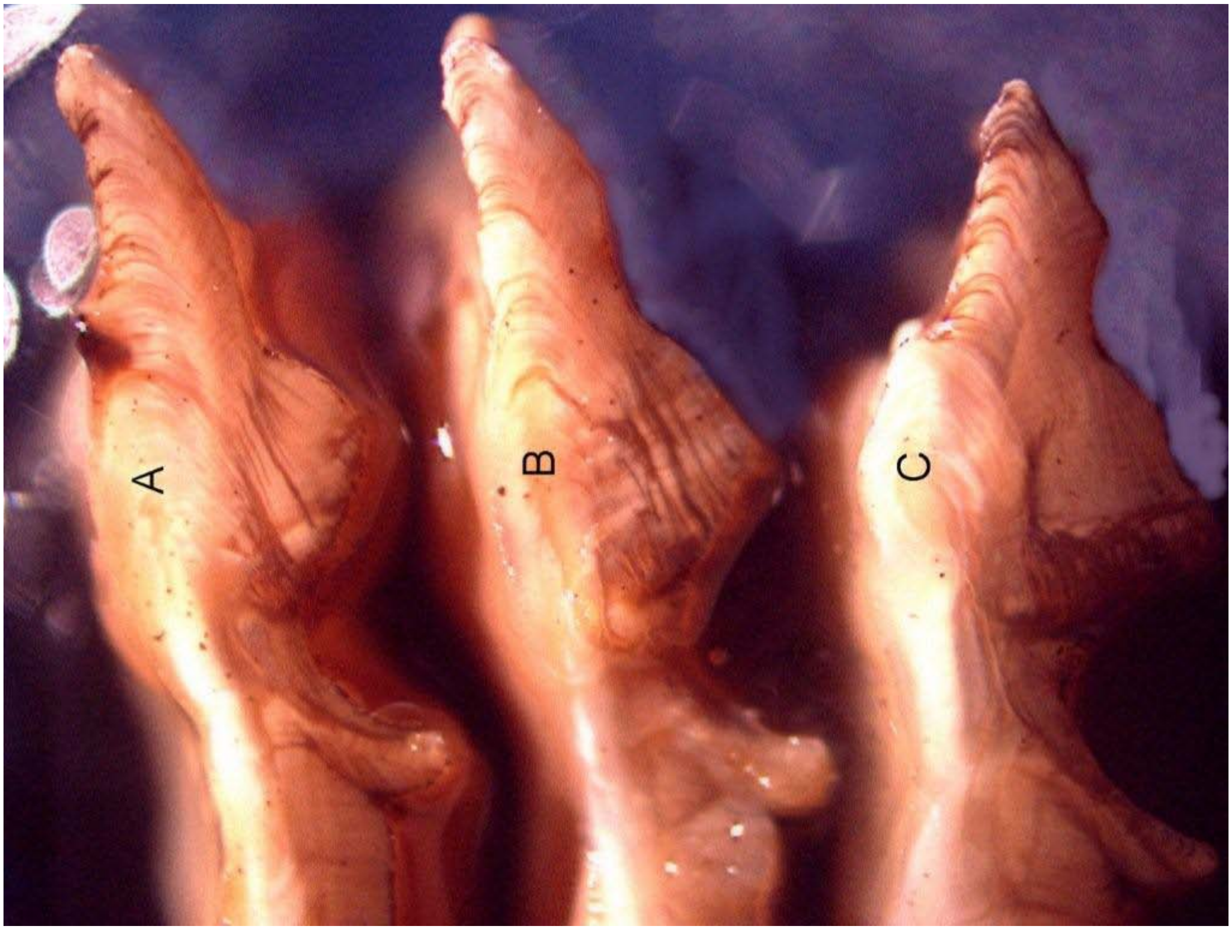

Figure 28. Three otoliths from similarly sized bocaccio along different regions of the west coast; otolith A: Washington, September 23, 2003: 55cm male, otolith B: Monterey, December 3, 1992: 57cm male, otolith C: Los Angeles, May 7, 1987: 56 cm male.

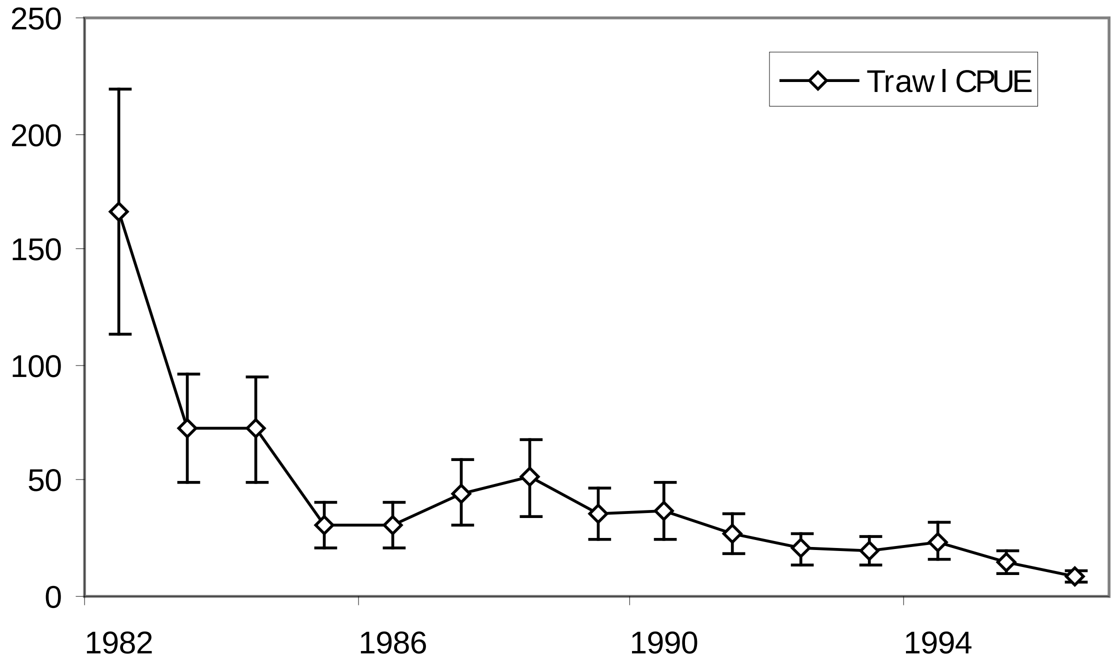

Figure 29. Trawl fishery CPUE index of bocaccio abundance developed in Ralston (1998)

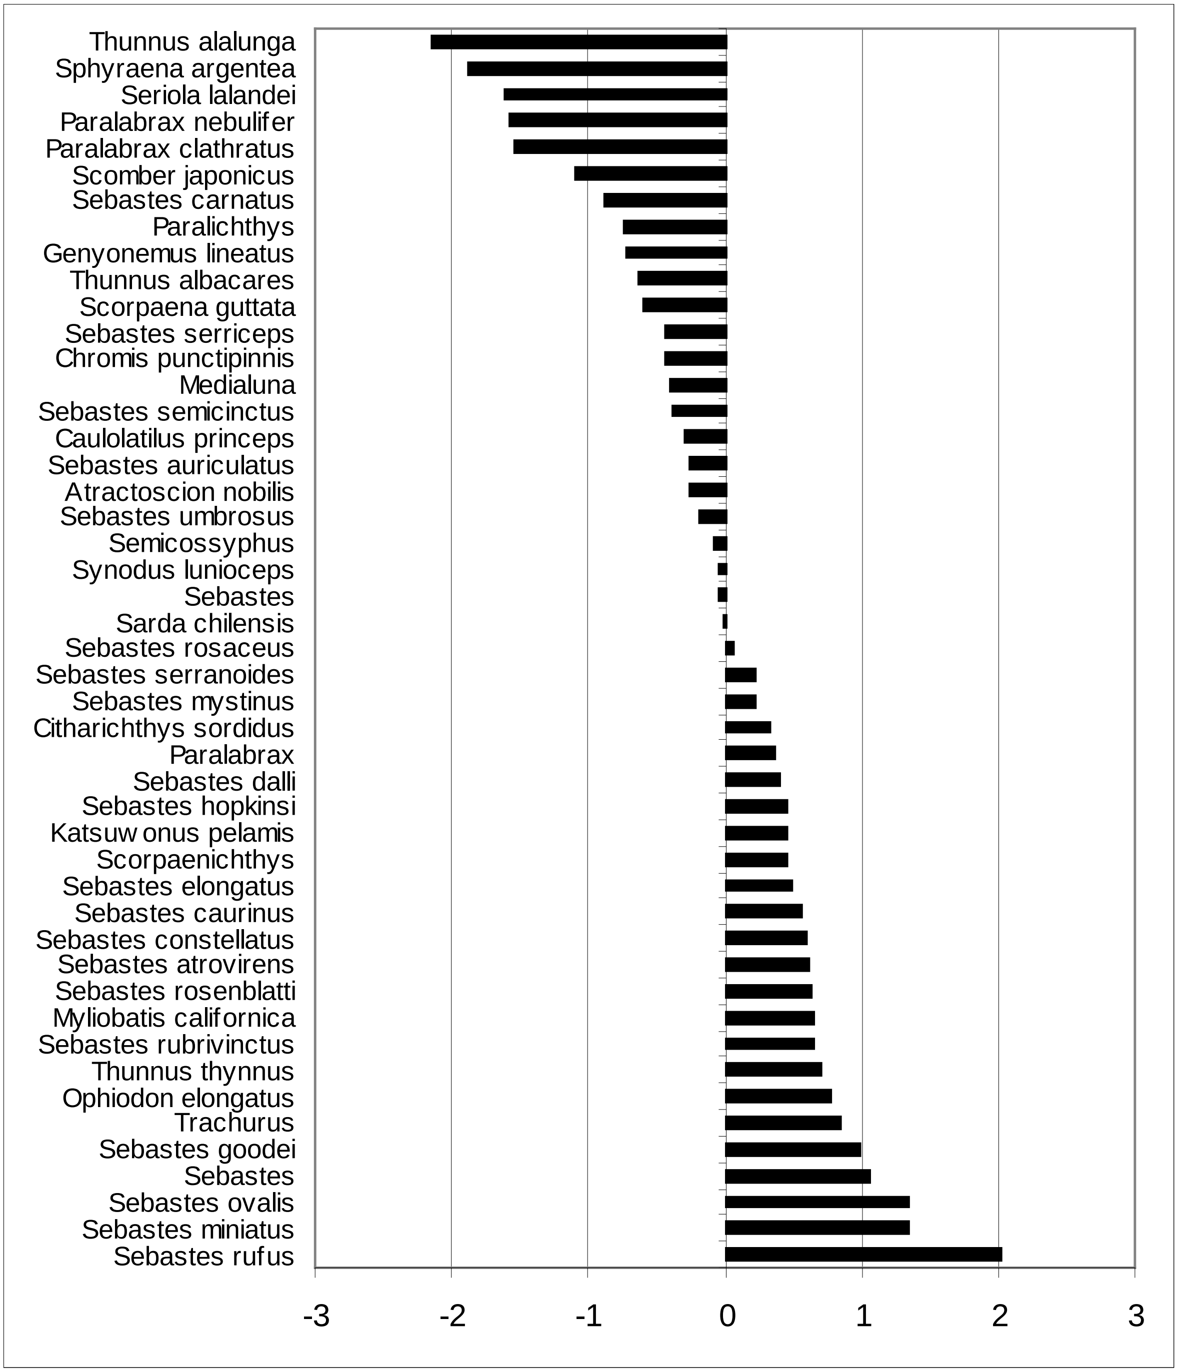

Figure 30. Species-specific catch coefficients developed to filter appropriate trips for the southern recreational fishery CPUE index of bocaccio abundance.

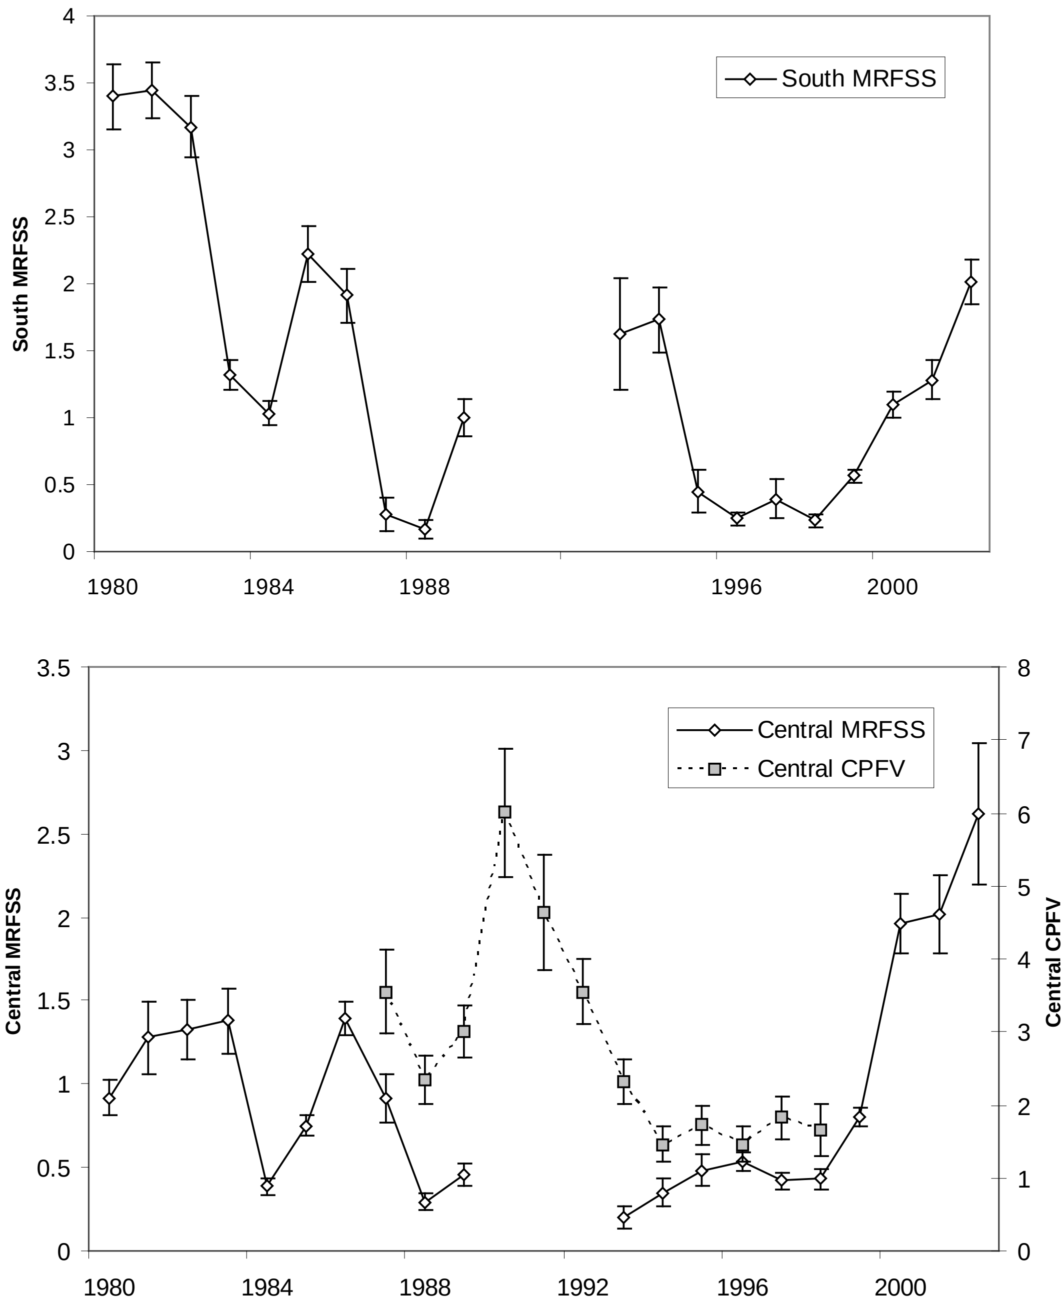

Figure 31a-b. Southern California recreational fishery CPUE index (top) and the two central/northern California recreational CPUE indices (bottom) of bocaccio abundance.

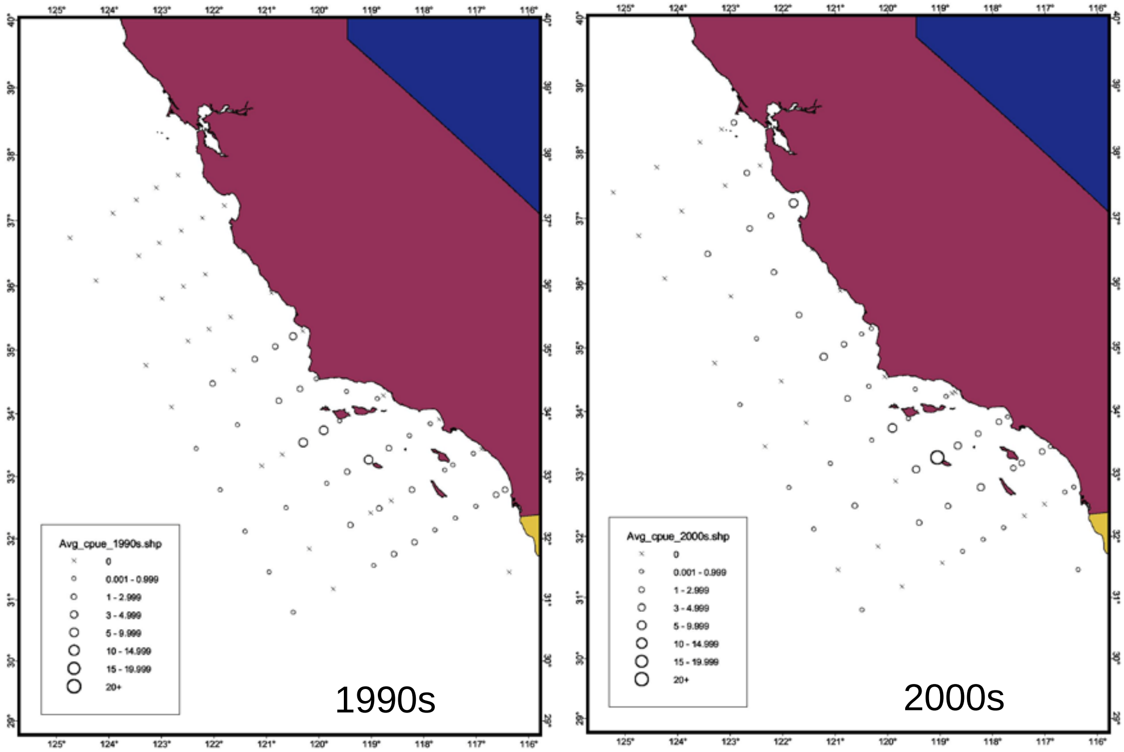
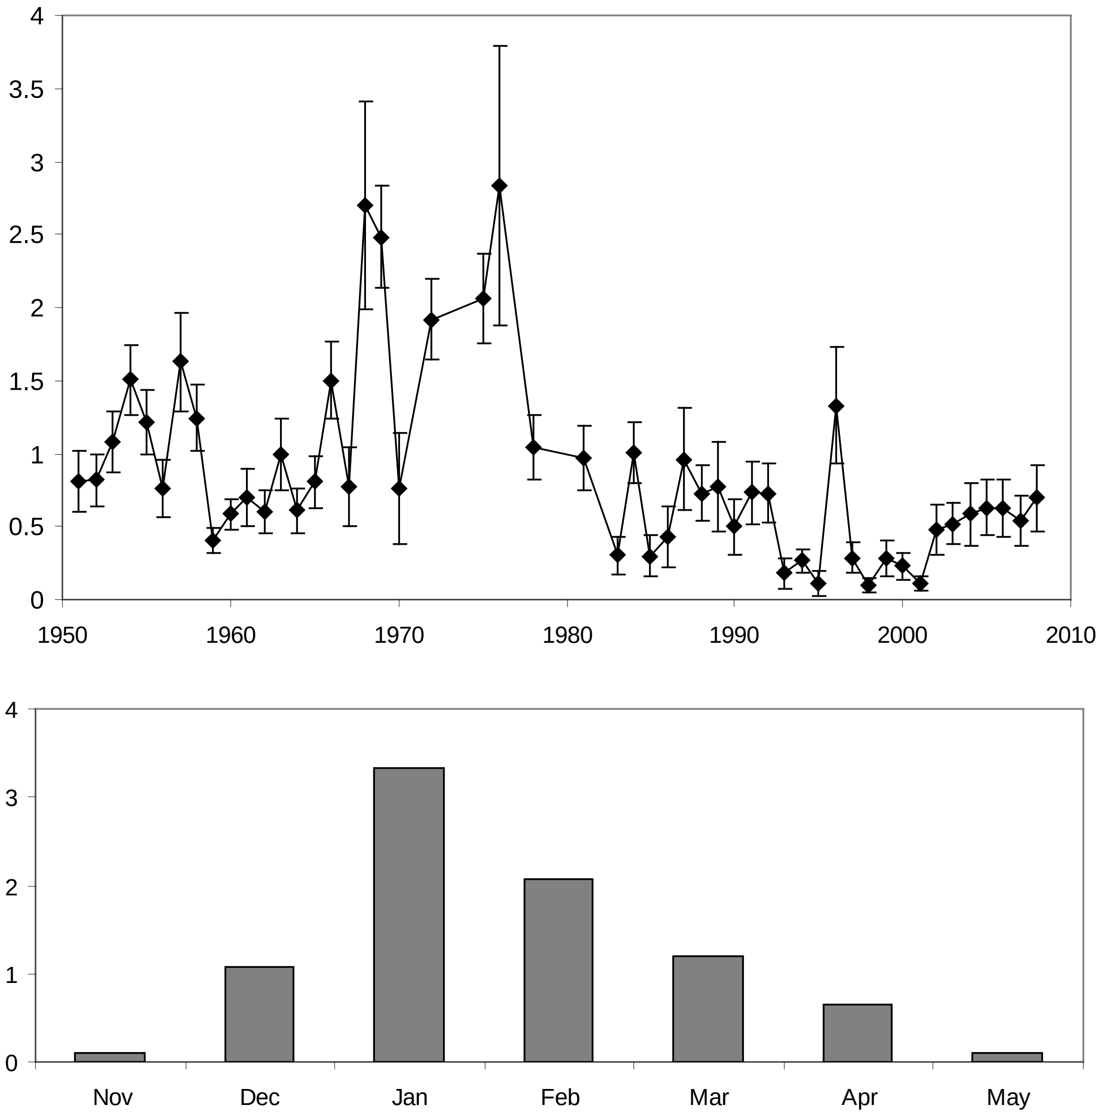
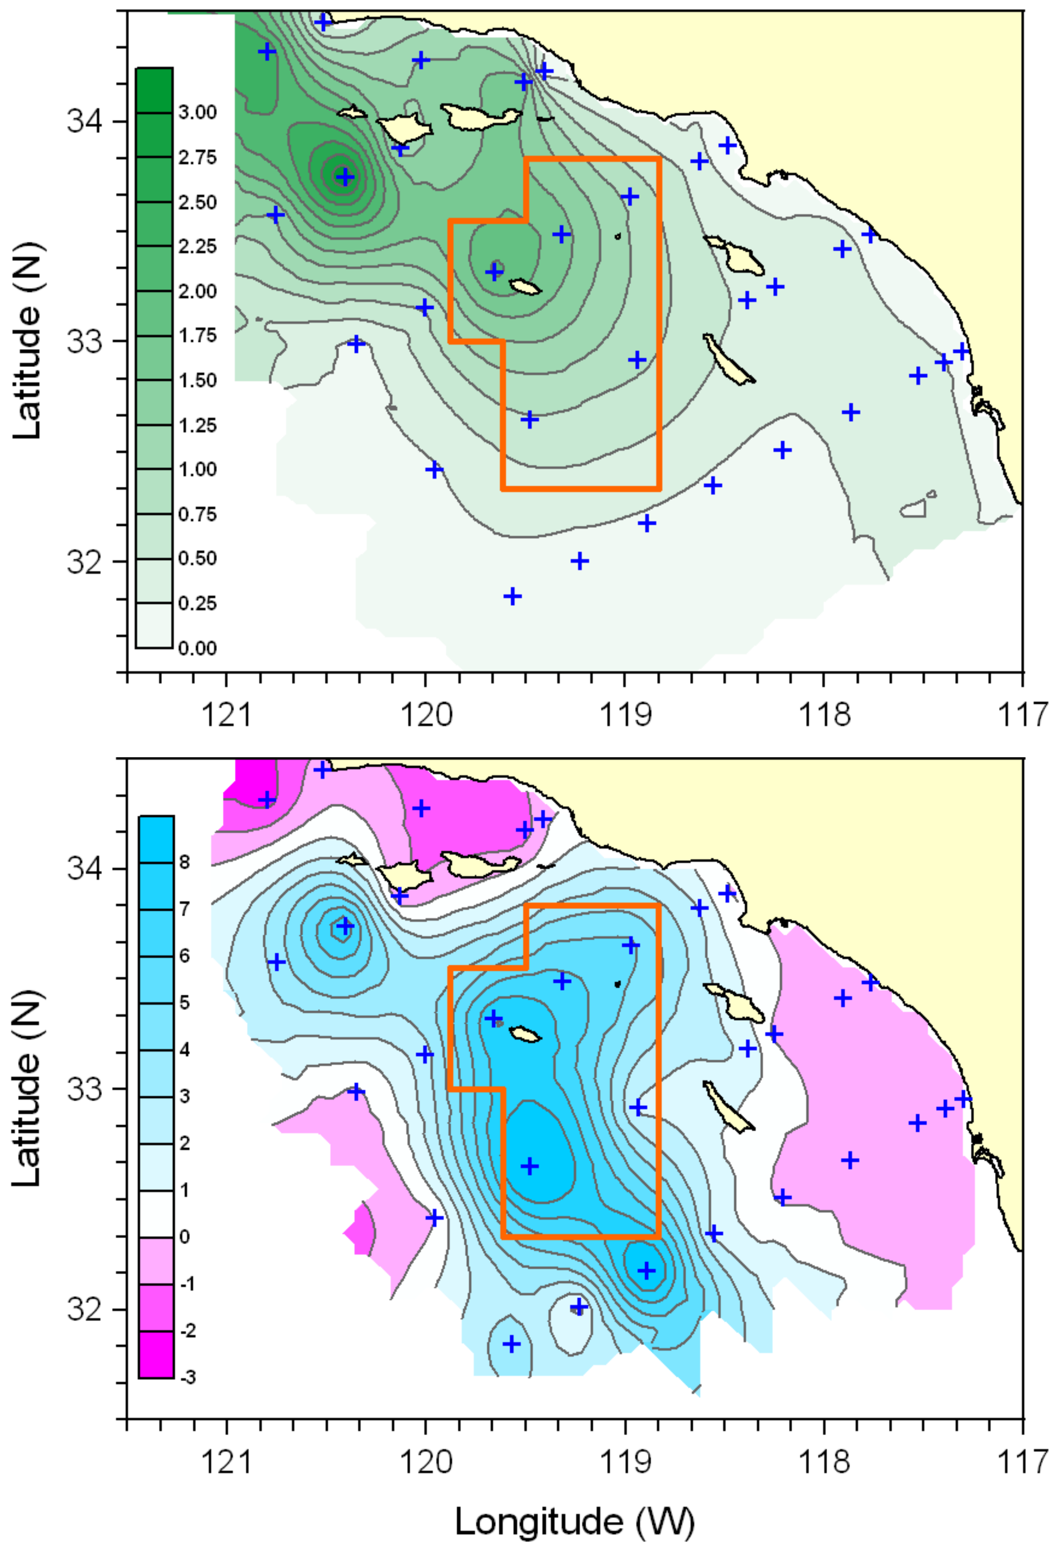
Figures 32a-d. CalCOFI mean CPUE rate of larval bocaccios by station and decade



Figures 32e-f. CalCOFI mean CPUE rate of larval bocaccios by station and decade



Figures 33a-b. CalCOFI larval abundance indices (top) for the coastwide bocaccio model, with asymptotic standard errors based on a jackknife routine; (bottom) month effects for the delta-GLM model.



Figures 34a-b. Spatial distribution of bocaccio larvae in the Southern California Bight (top) based on estimated station effects [#/10 m^2] from a delta-GLM analysis of the entire CalCOFI time series (1951-2005). Bottom figure reflects the spatial distribution of bocaccio larvae in 2002-03 represented as anomalies from the long-term mean distribution. From Ralston and MacFarlane (in review).

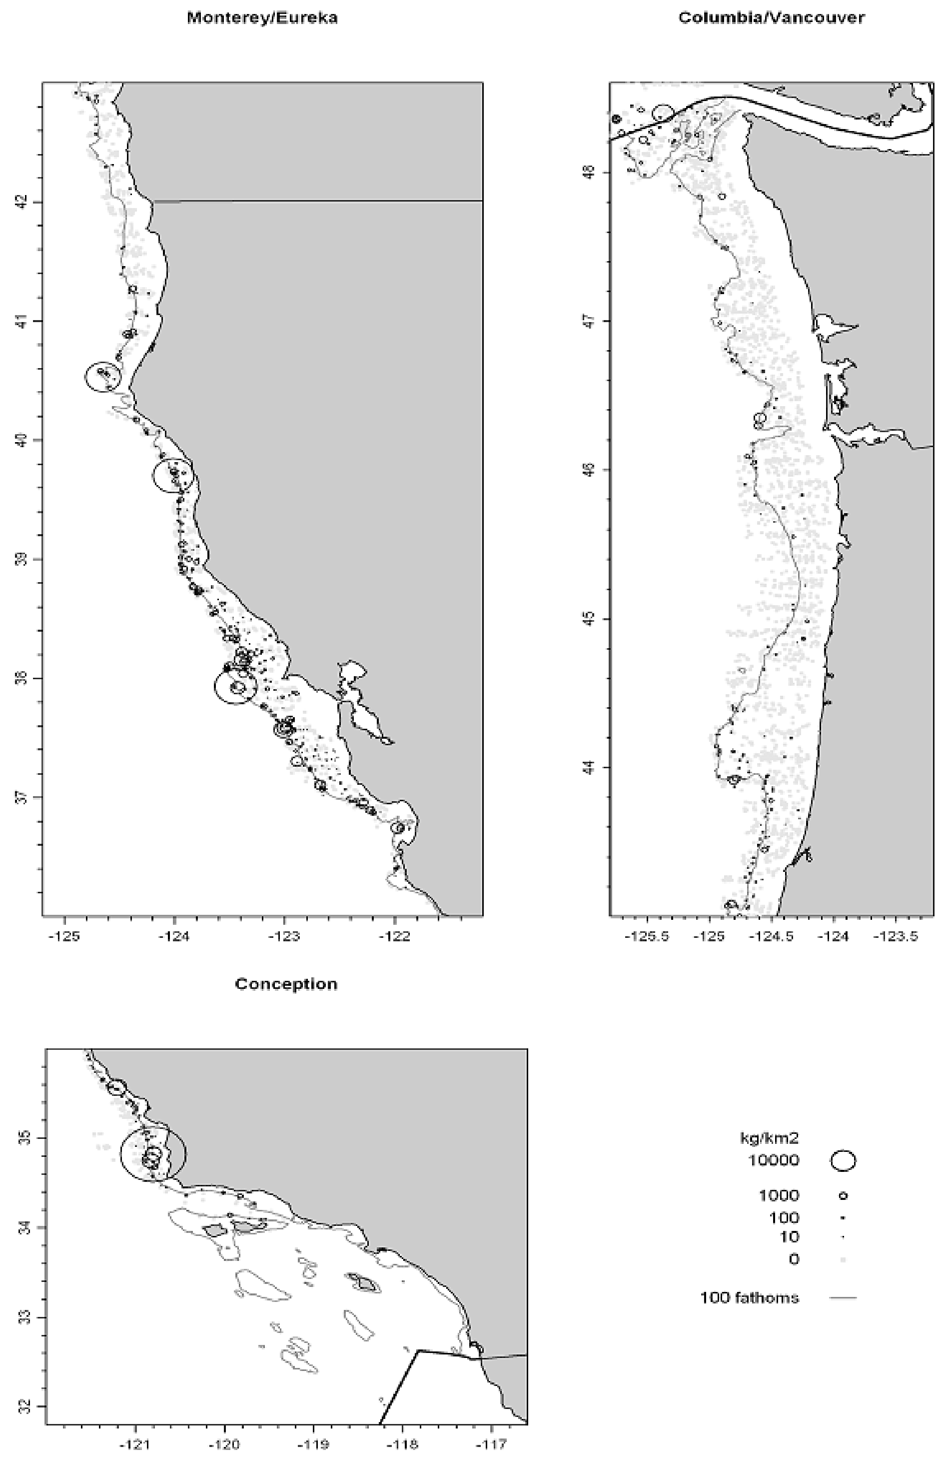


Figure 35: Triennial trawl survey CPUE over space, all years (1980-2004) combined.

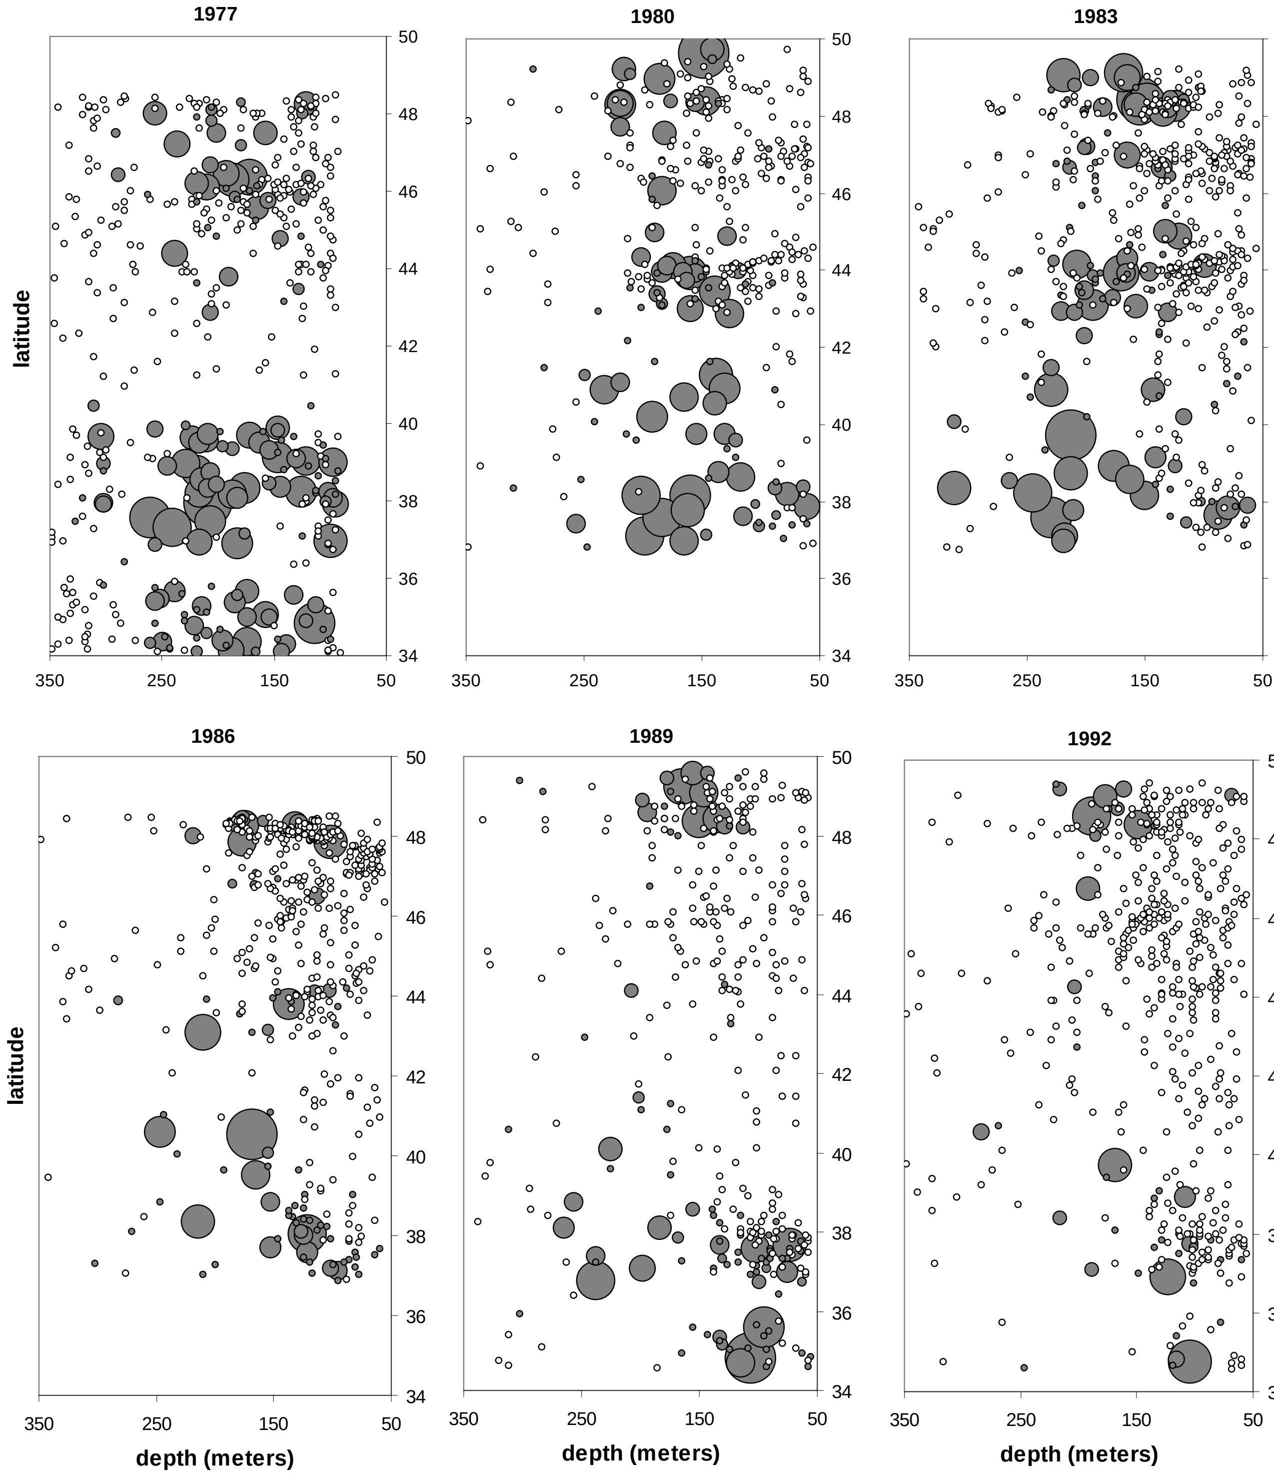
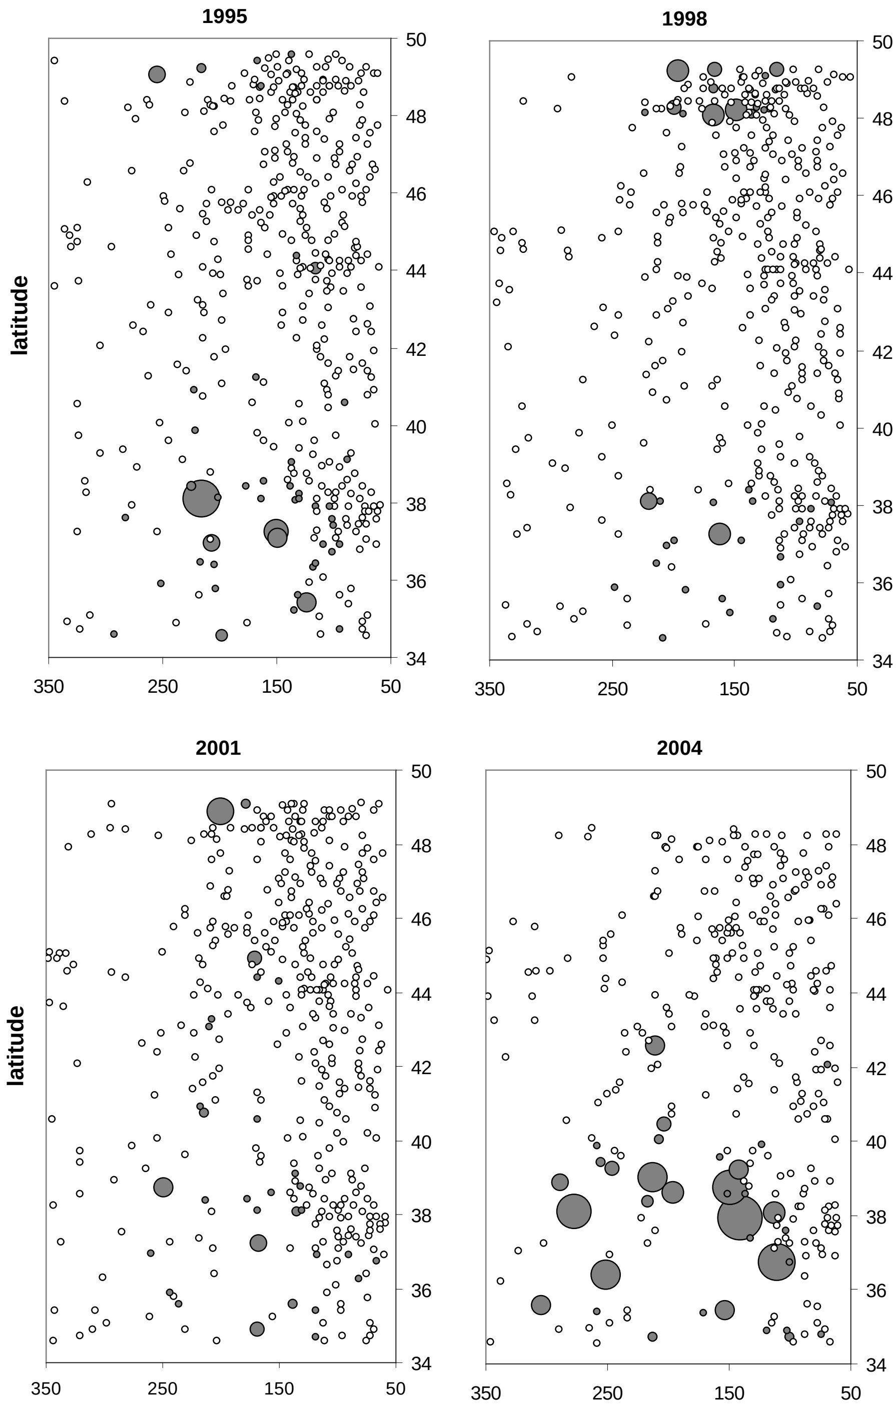


Figures 36a-f. Triennial trawl survey catches of bocaccio rockfish, 1977-1992, plotted as the log of the catch (with a minimum size threshold) by year, depth and latitude (note that longitude is absent). Empty circles represent non-positive hauls.



Figures 36g-j. Triennial trawl survey catches of bocaccio rockfish, 1977-1992, plotted as the log of the catch (with a minimum size threshold) by year, depth, and latitude (note that longitude is absent). Empty circles represent non-positive hauls.

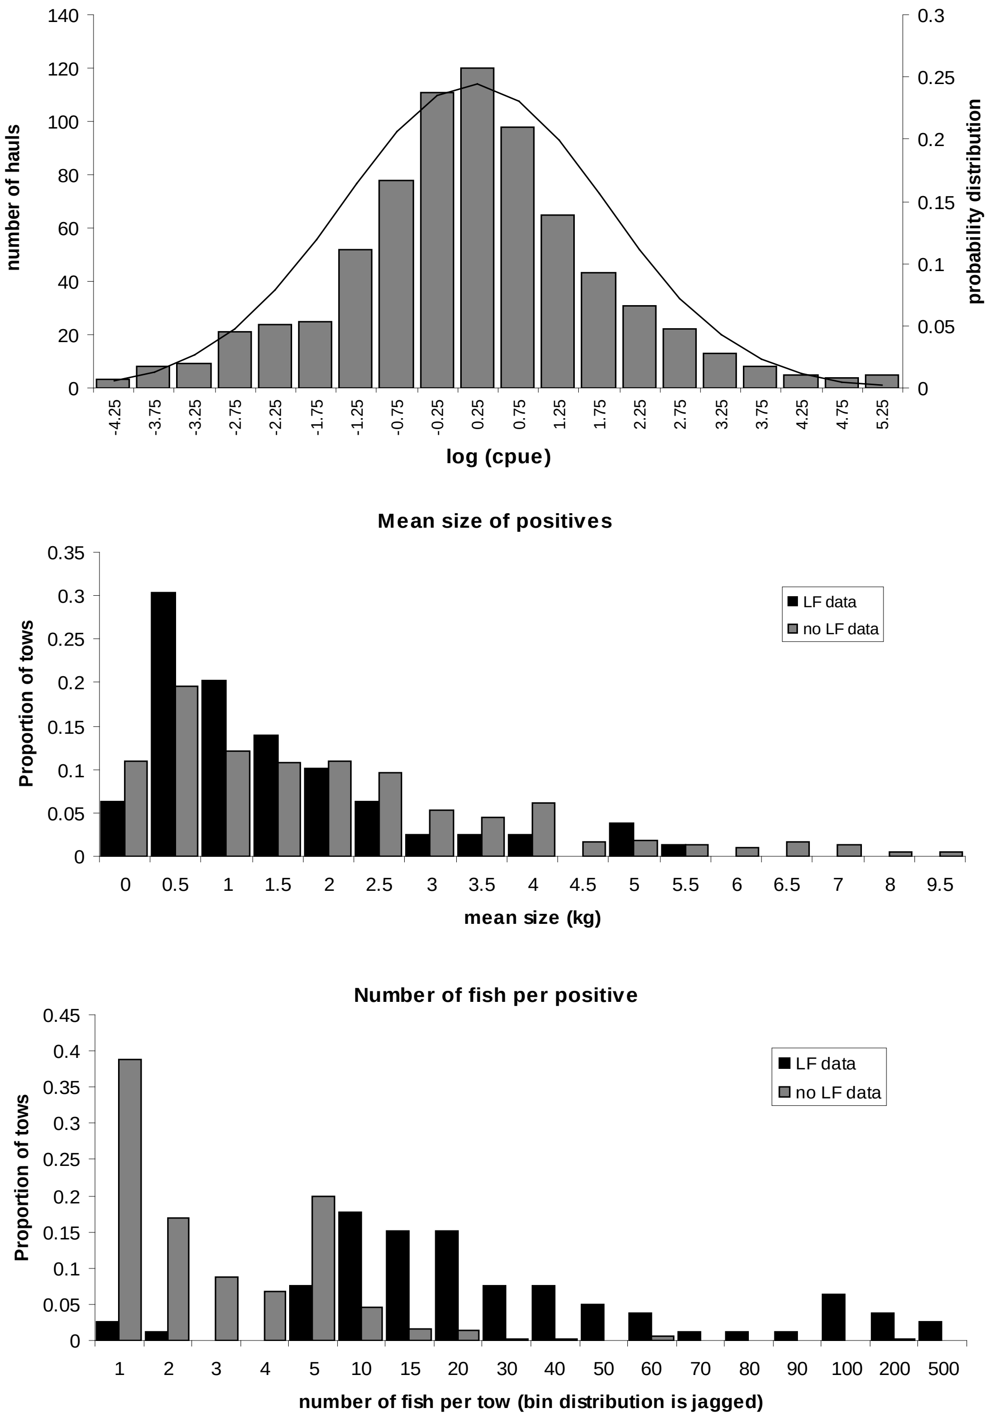


Figure 37a-c. Distribution of bocaccio CPUE for the triennial survey in log scale (top), distribution of average weight (center) and of the count (bottom) of bocaccio per haul for hauls in which length frequencies were taken versus hauls in which they were not.

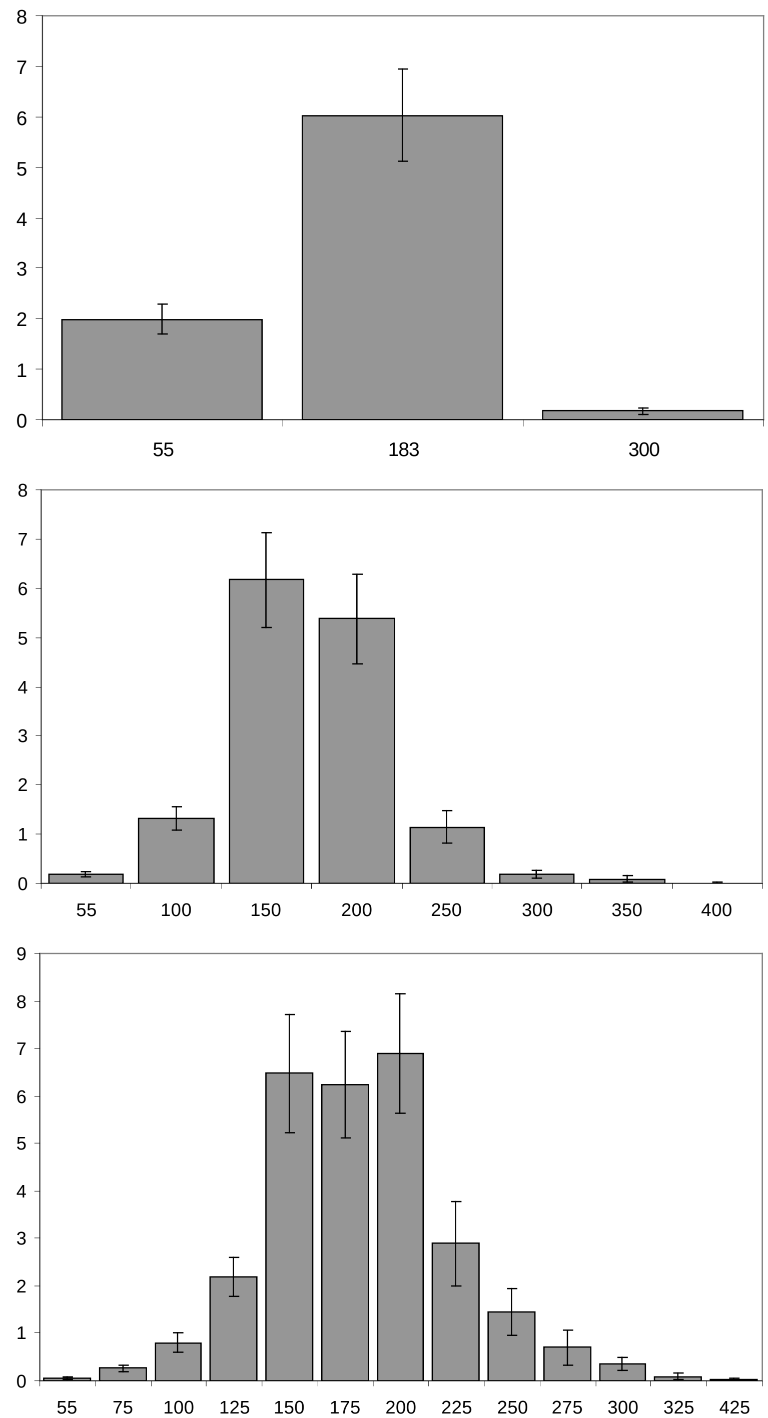

Figures 38a-c. Depth factor coefficients across a range of depth bins from GLM of triennial CPUE data (in all cases, year effects, and INPFC area effects also estimated). Standard errors based on a jackknife routine.

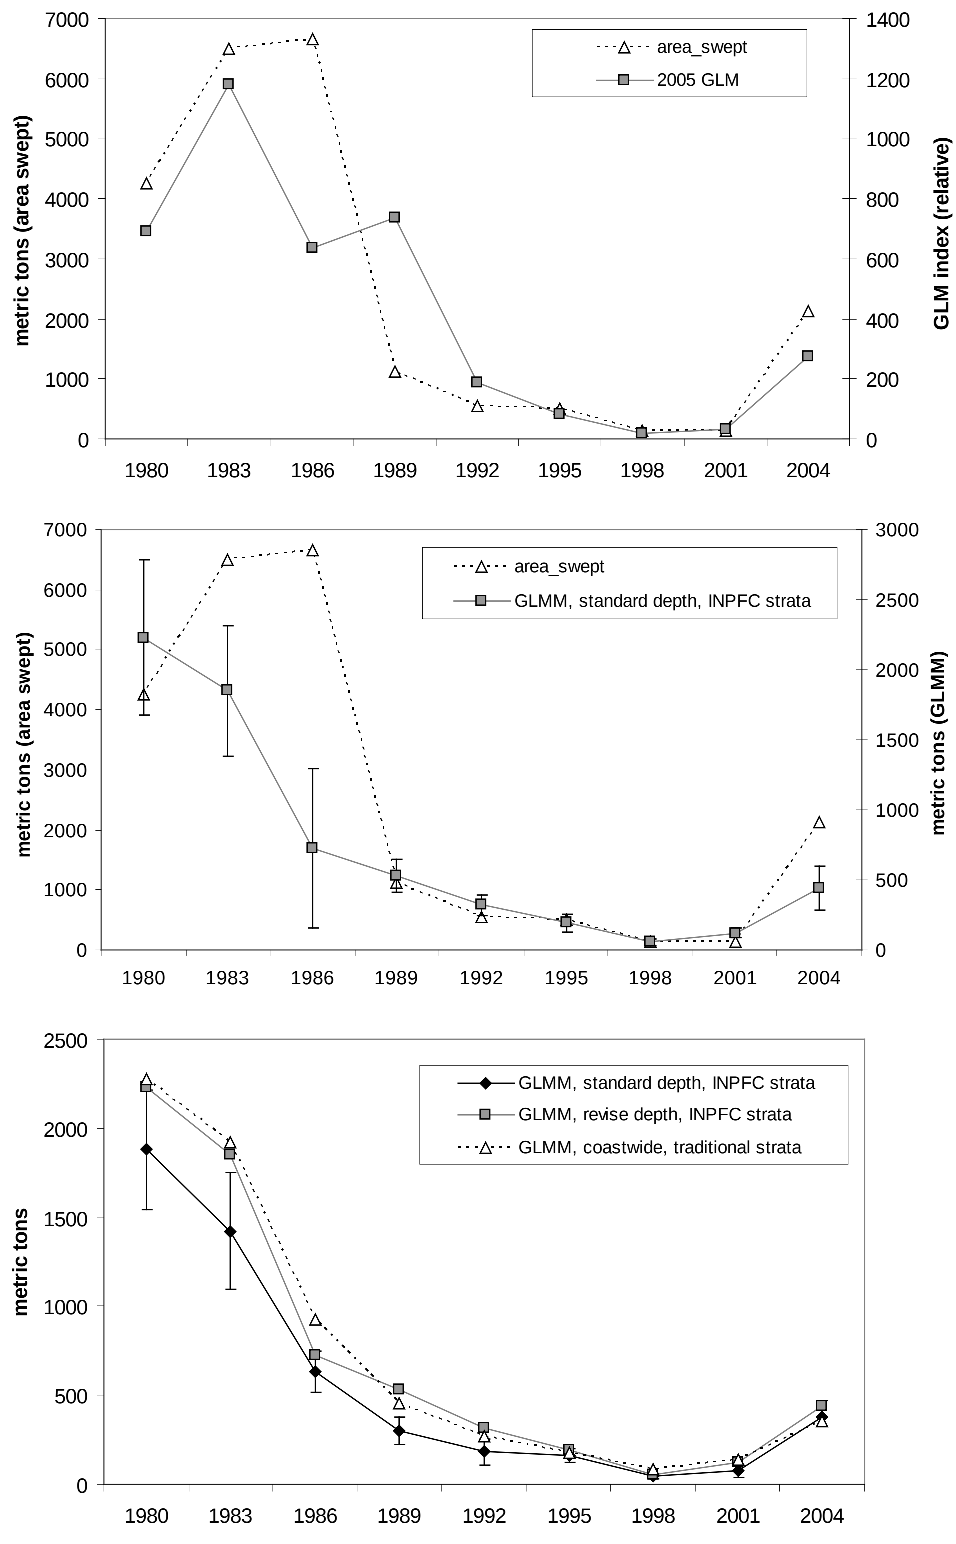

Figure 39a-c. Area swept (Monterey and Eureka INPFC areas only), 2005 assessment GLM (includes Conception INPFC observed and predicted) and GLMM estimates of relative abundance of bocaccio based on the 1980-2004 triennial survey data for this assessment. Error bars not shown for all indices to minimize confusion (CVs are also reported in Tables).

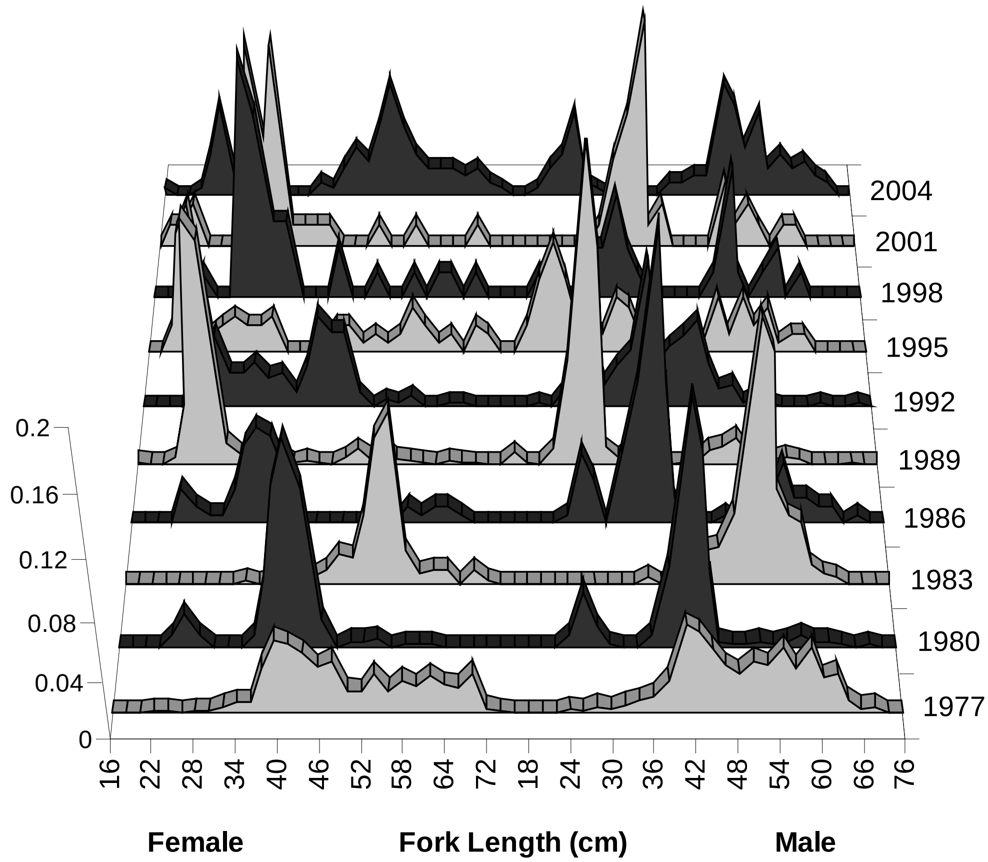

Figure 40. Length frequency information for bocaccio from the triennial trawl survey by year for the assessment area (south of Cape Blanco).

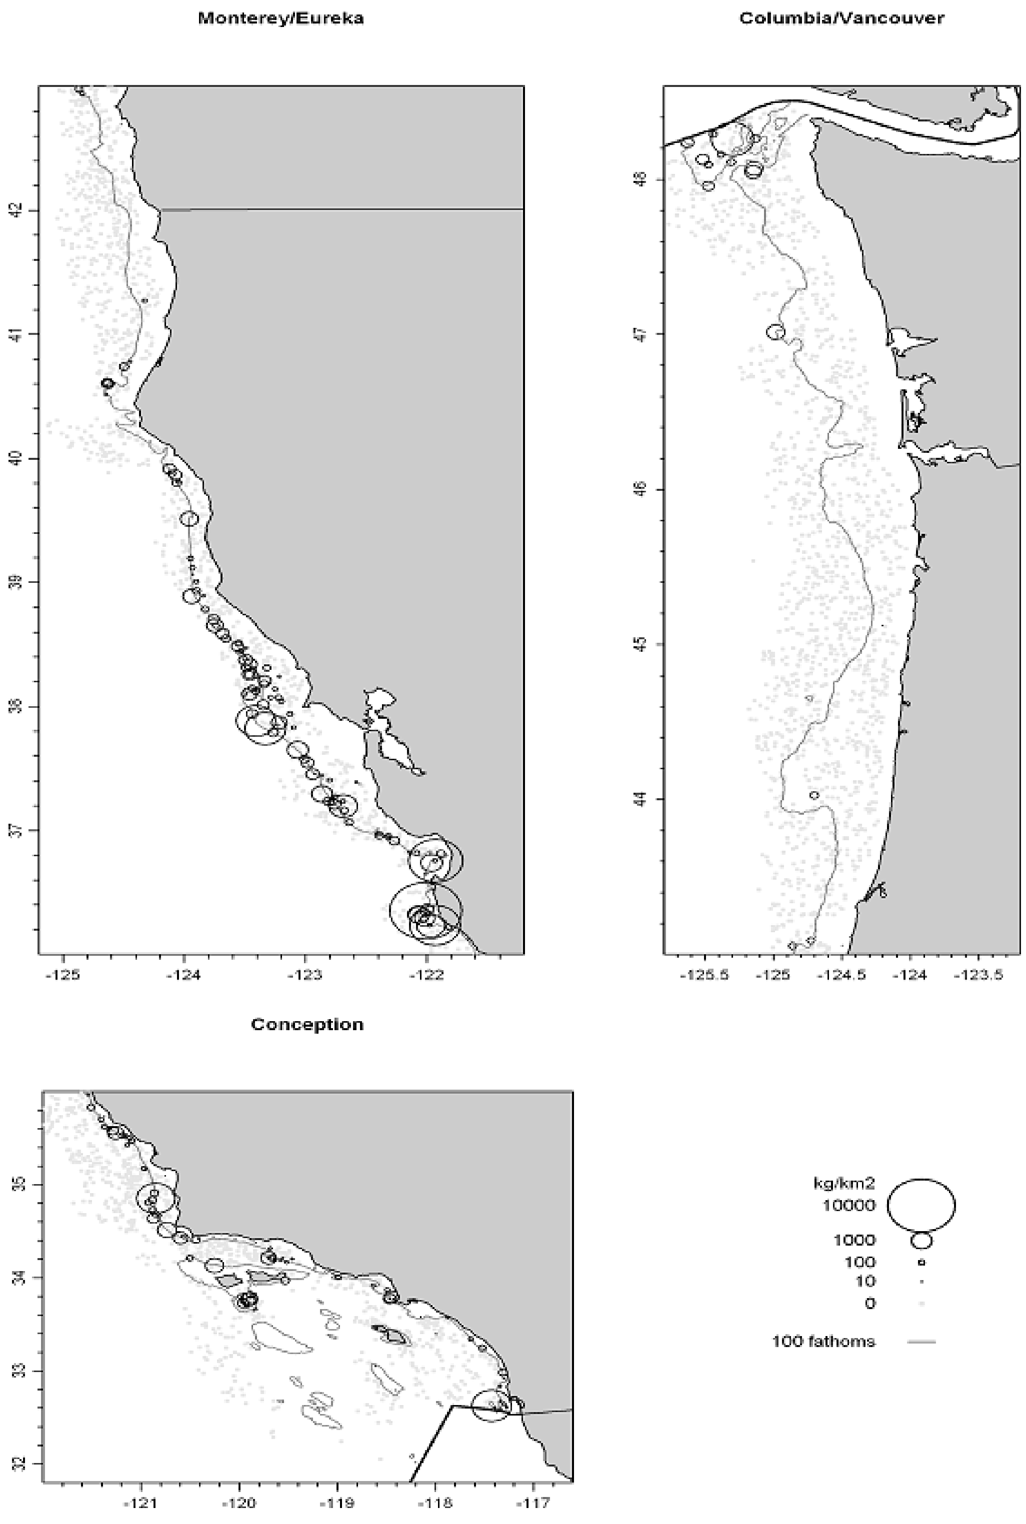

Figure 41: NWFSC Combined shelf-slope survey CPUE for bocaccio rockfish, all years (2003-2008) combined.

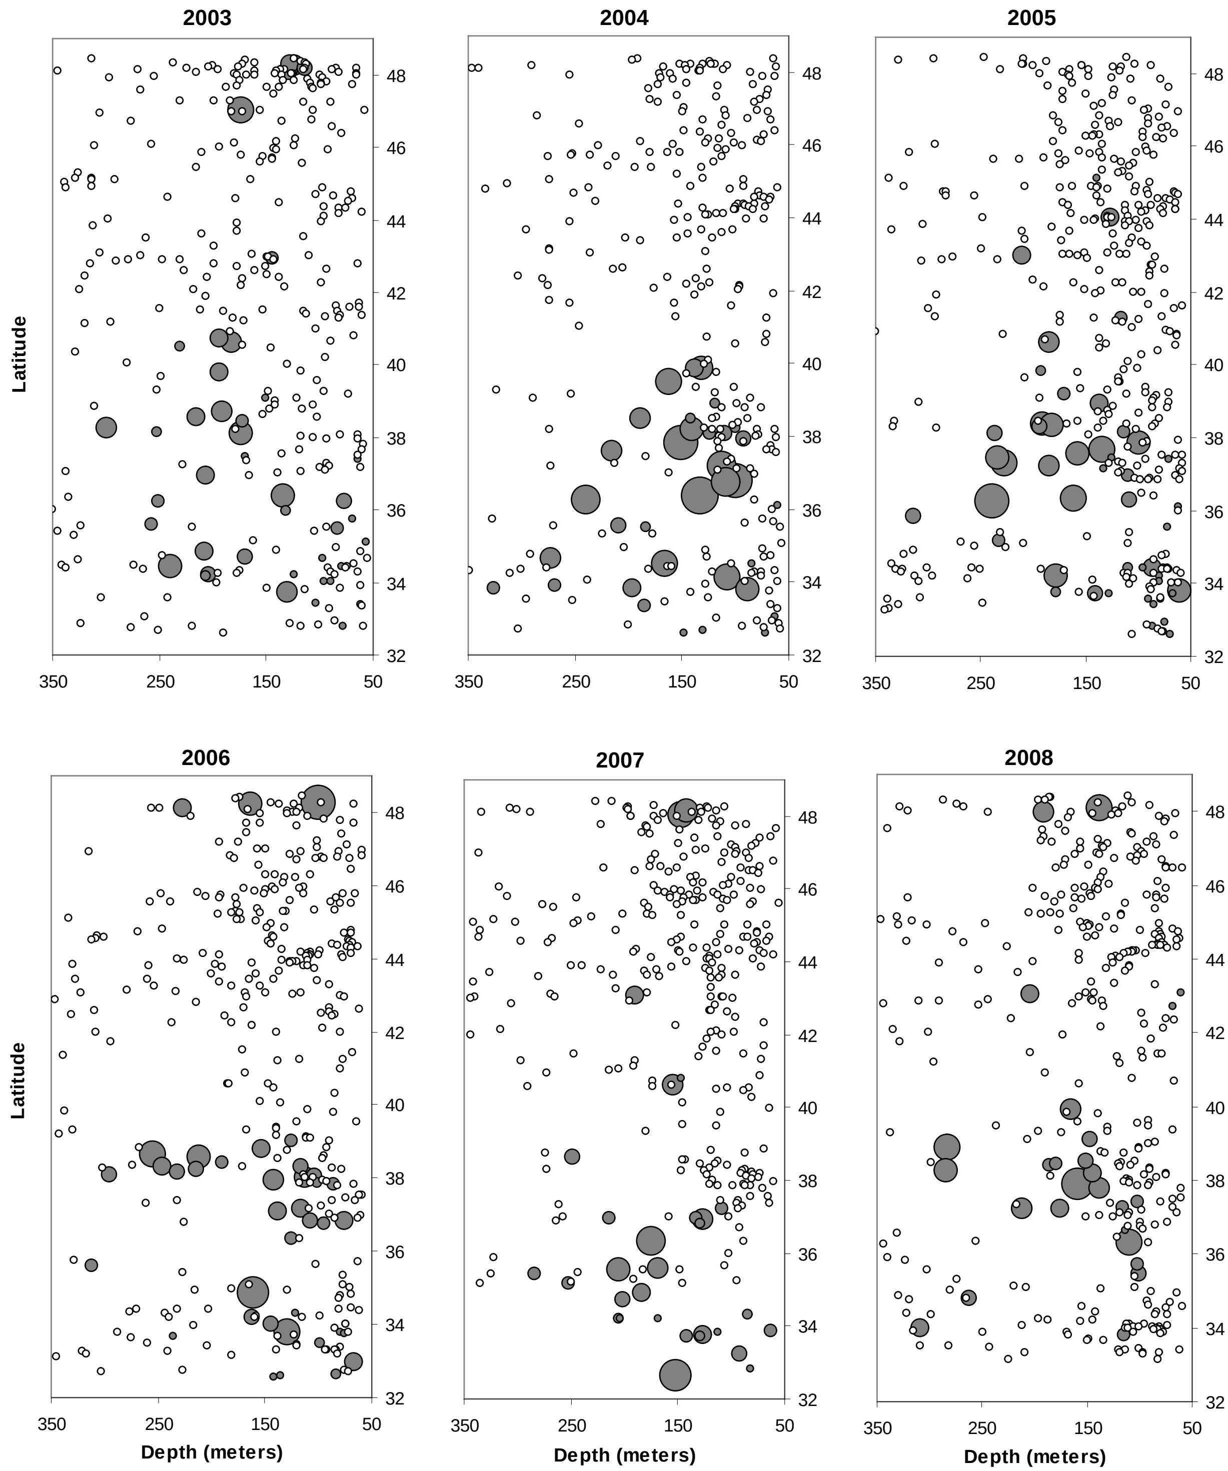
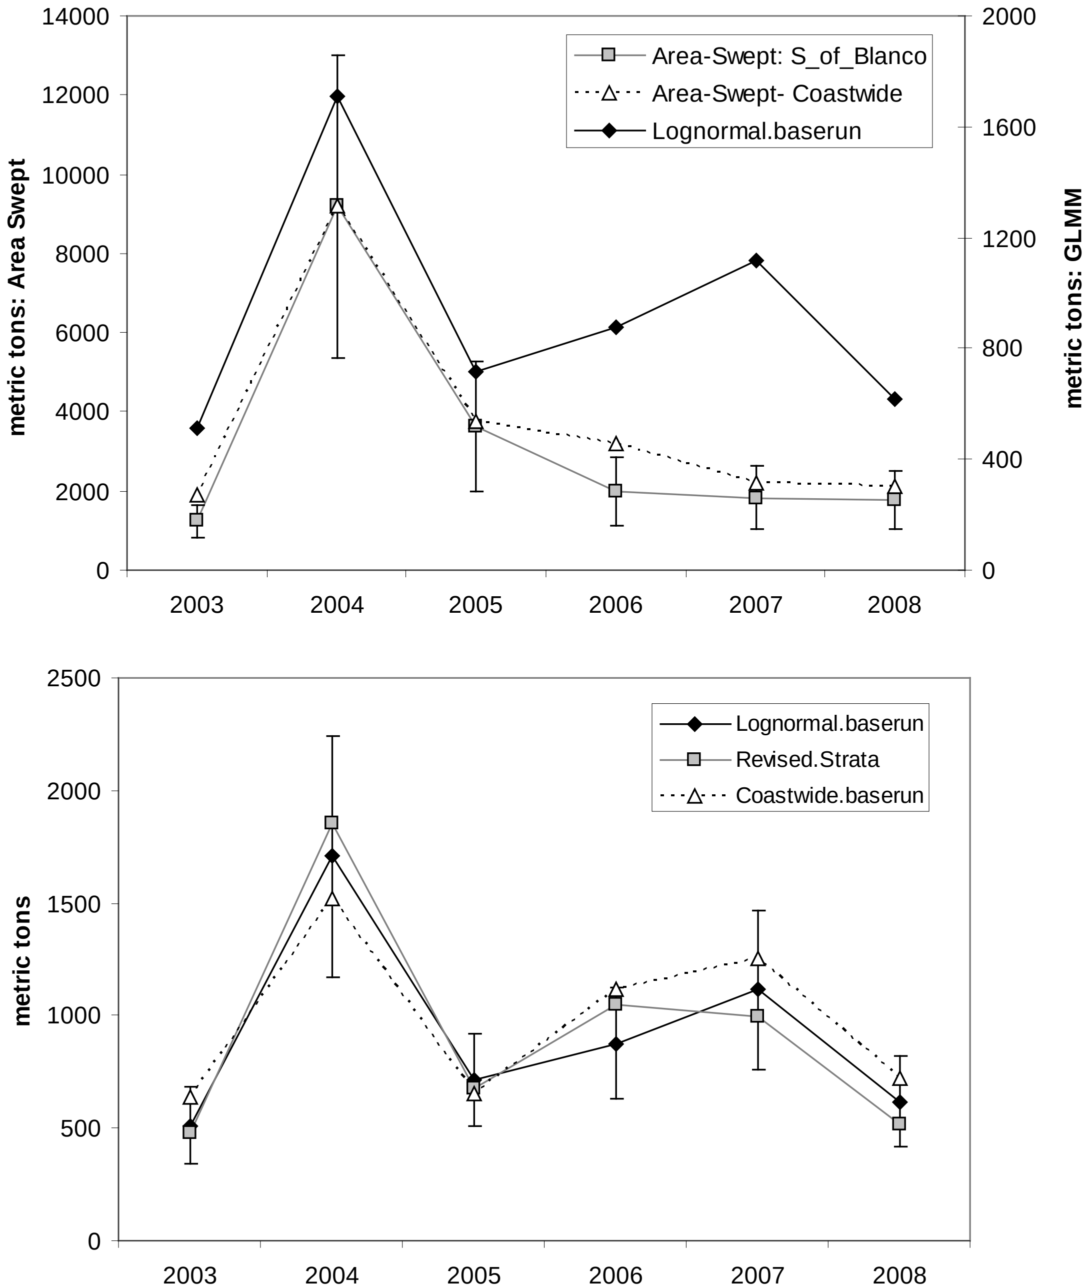


Figures 42a-f. Northwest Fisheries Science Center survey catches of bocaccio rockfish, plotted as the log of the catch (with a minimum size threshold) by year, depth and latitude (note that longitude is absent). Empty circles represent non-positive hauls.



Figures 43a-b. Comparison of area-swept versus GLMM abundance estimates for bocaccio rockfish from the NWFSC Combined survey (note different axes for different surveys).

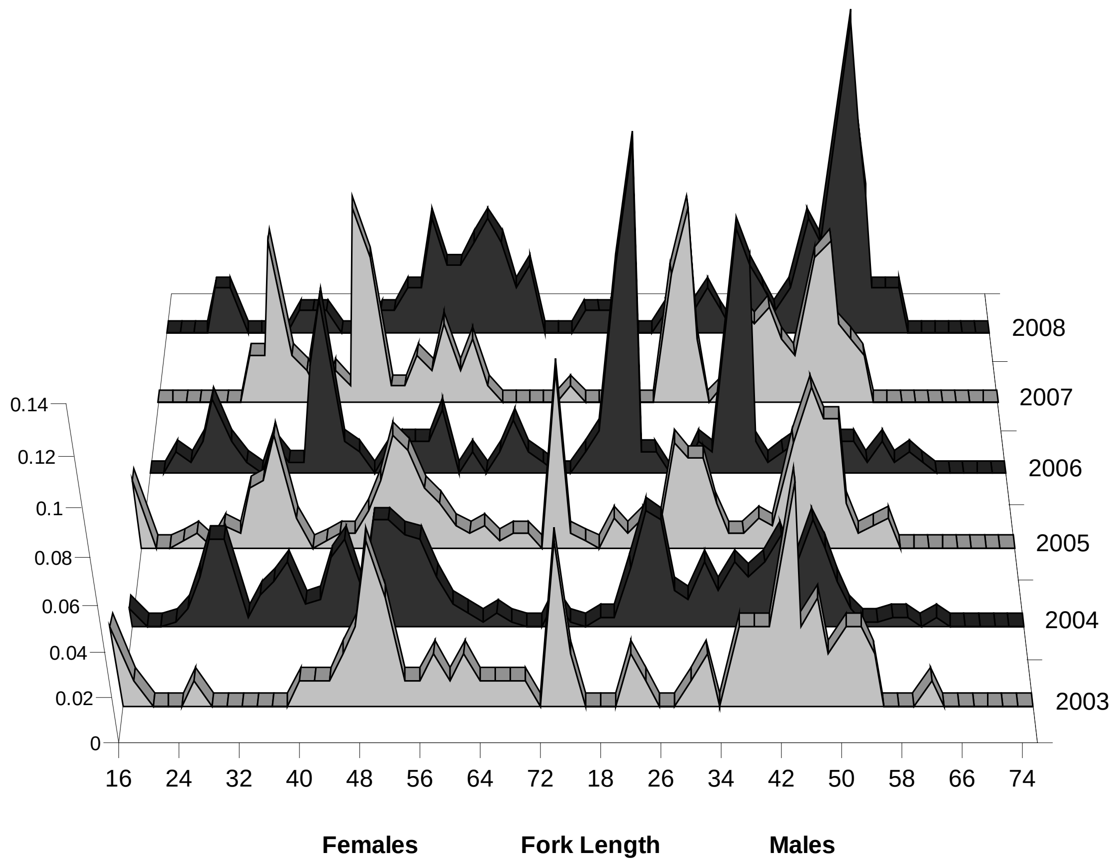


Figure 44. Length frequency information for bocaccio from the NWFSC combined survey (assessment area only).

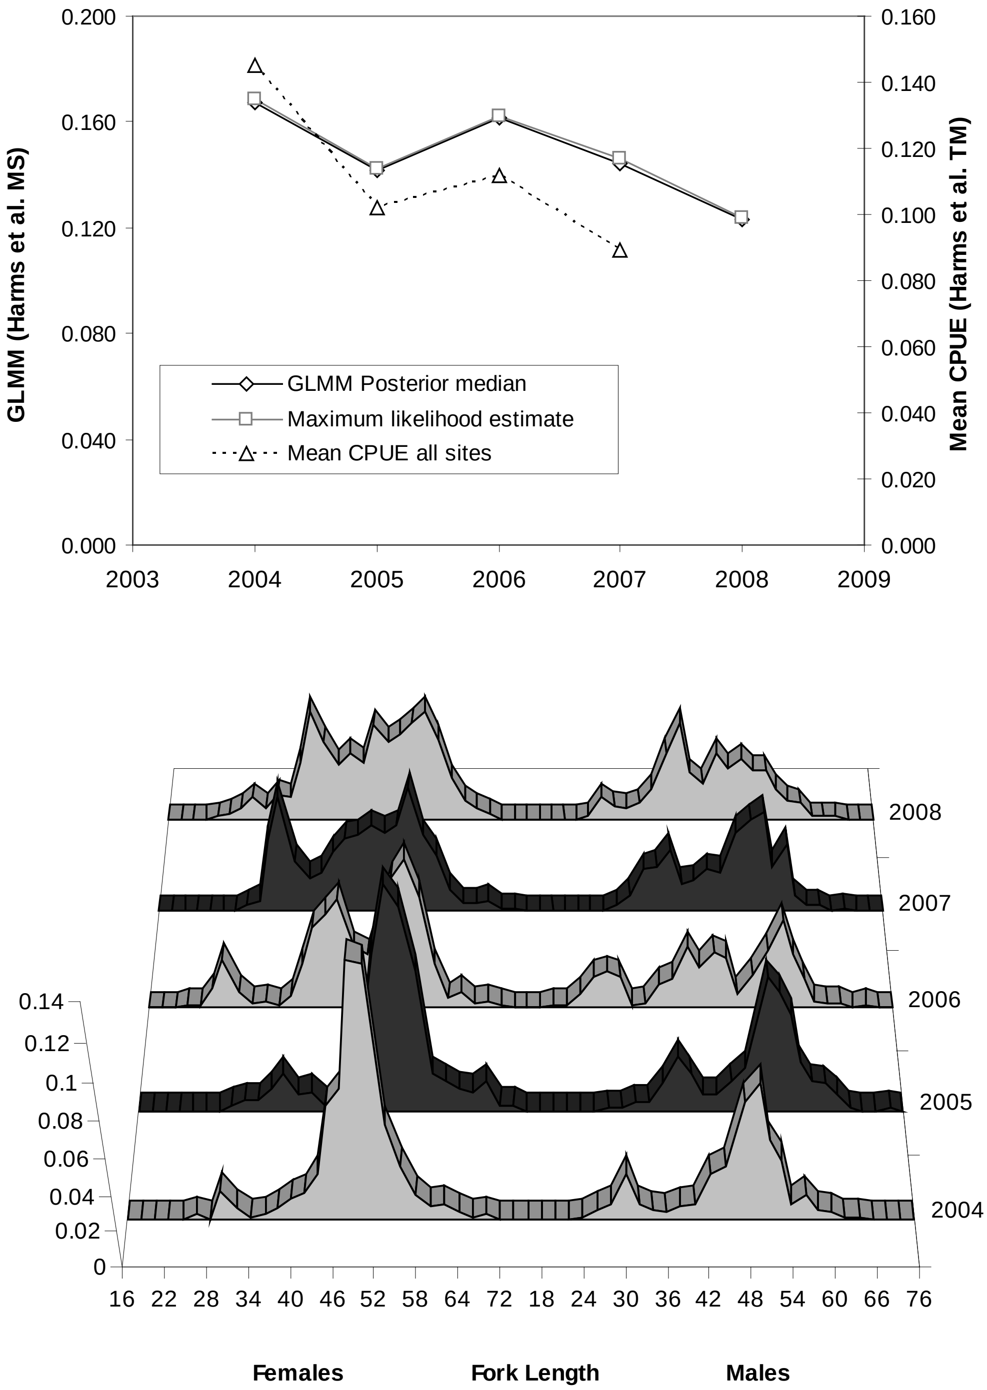

Figure 45a-b. Figure 45a (top) Catch rate indices of bocaccio abundance for the NWFSC hook-and-line survey in the Southern California Bight, 2004-2008 and Figure 45b (bottom), length frequency distribution for all bocaccio rockfish measured in the same survey.

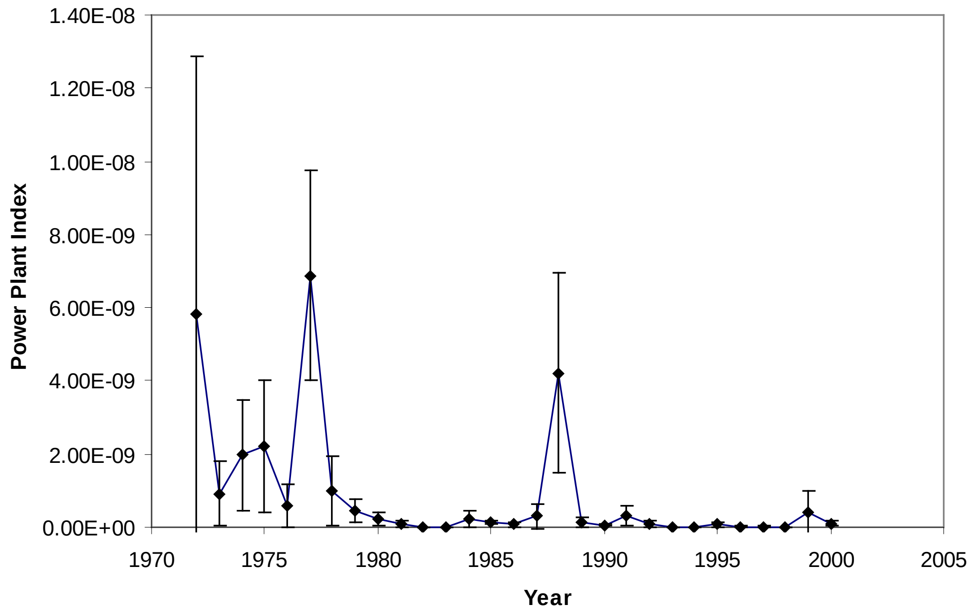
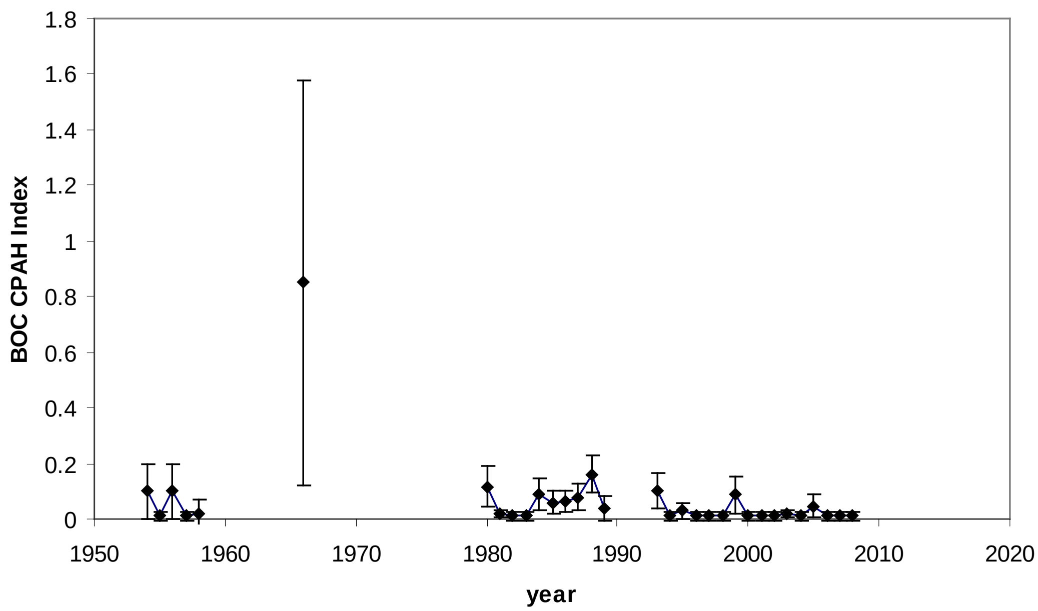
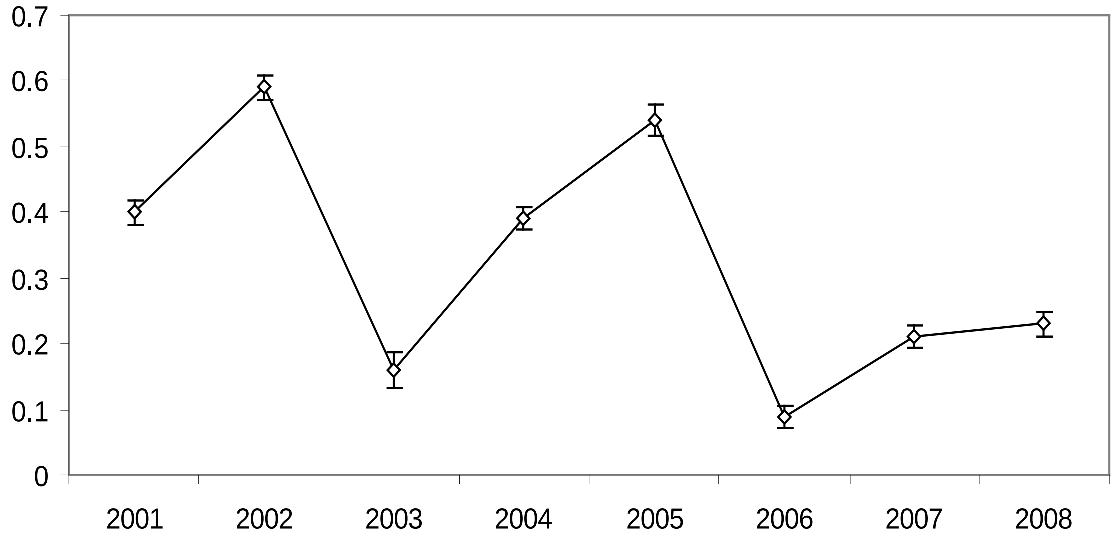
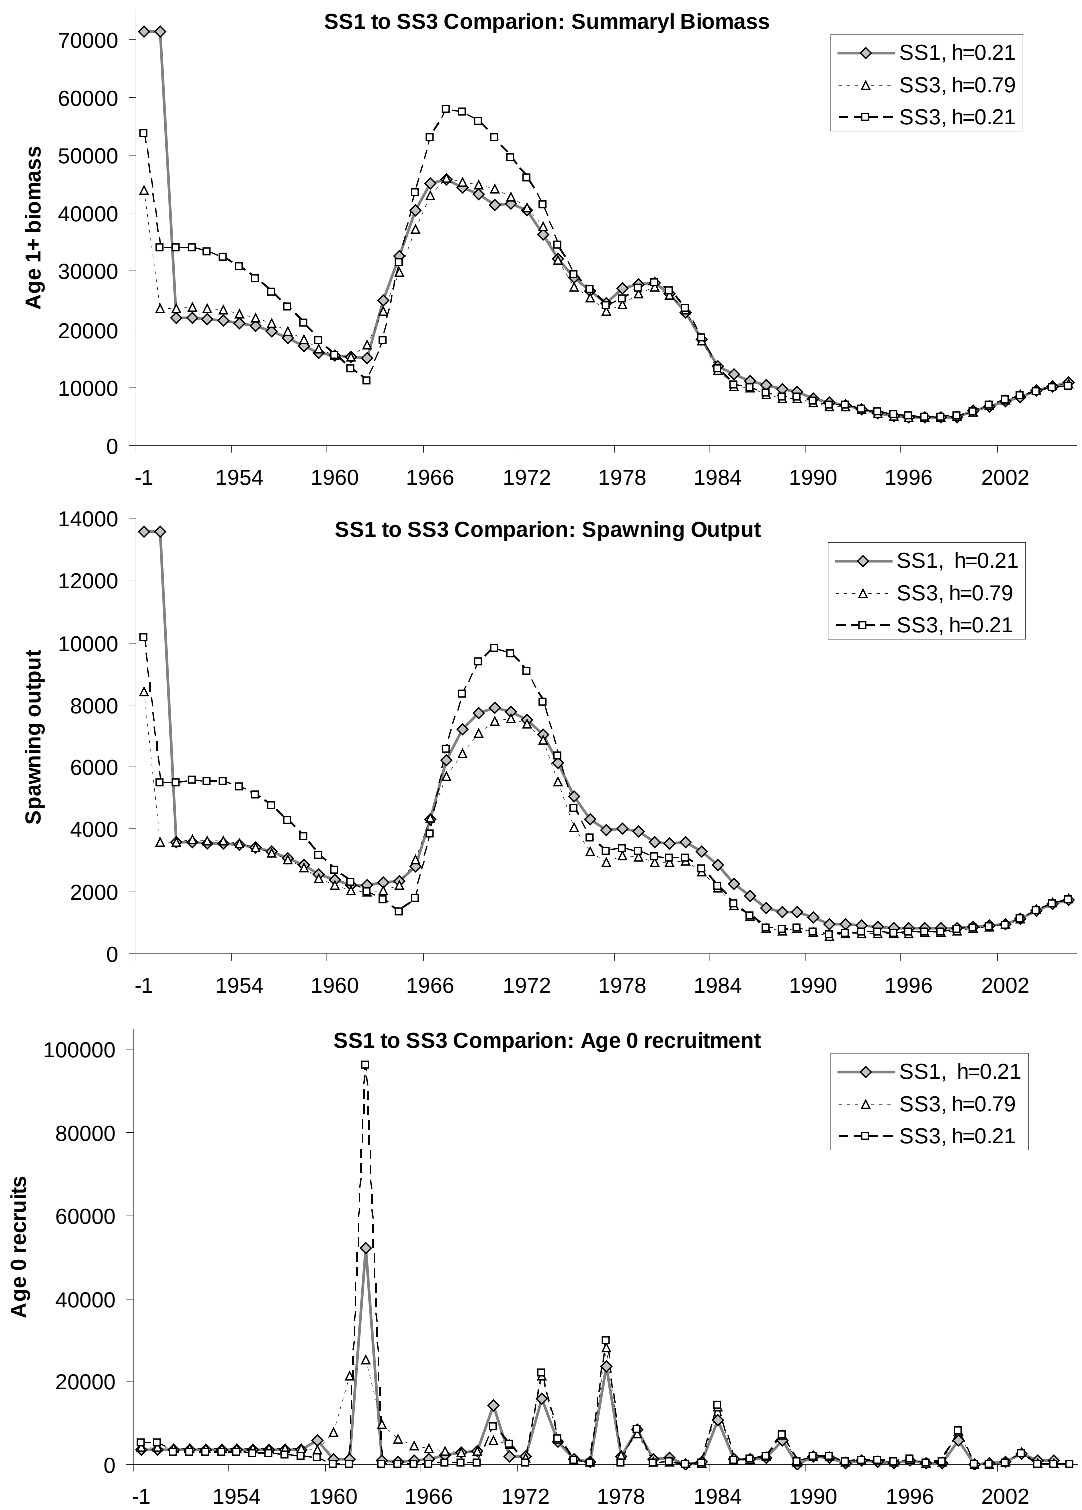




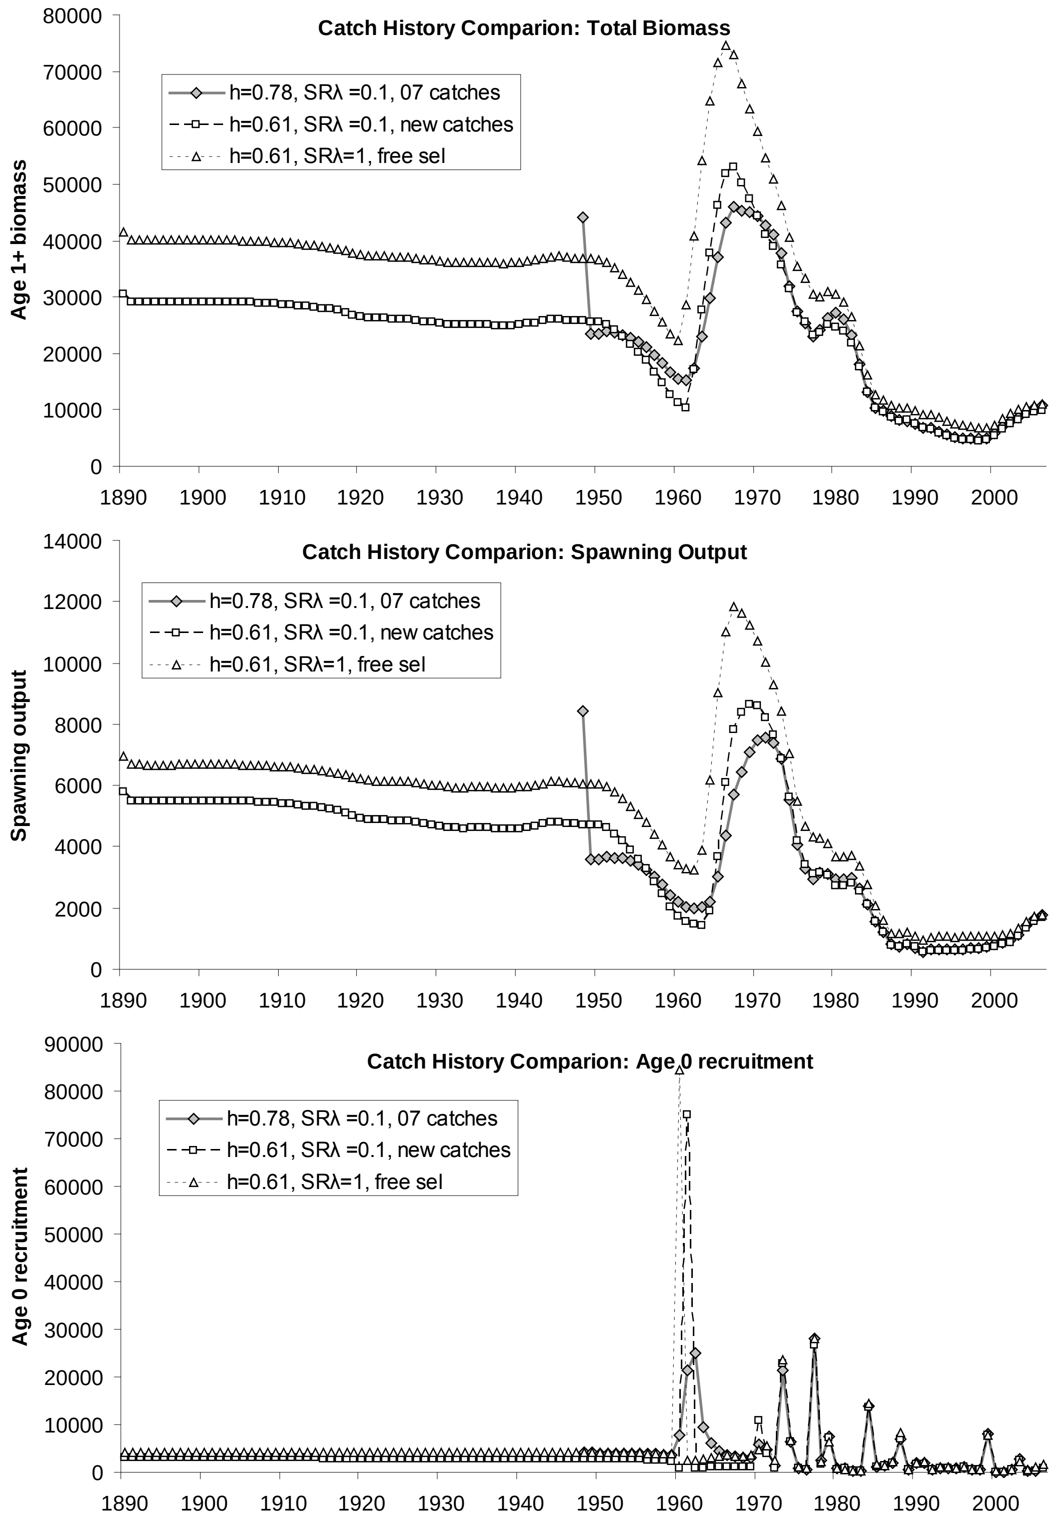
Figures 46a-b. Figure 46a (top) Juvenile indices of bocaccio recruitment for the power plant impingement index, and the pier survey index (Figure 46b, bottom).



Figures 47. The coastwide pelagic juvenile trawl survey index of bocaccio abundance.



Figures 48a-c. SS1 versus SS3 bocaccio model results (biomass, spawning biomass and recruitment) with alternative values of h for the SS3 model.



Figures 49a-c. The SS3 bocaccio model built to transition from the 2007 SS1 model (with h=0.78 and SR =0.1) with the 2007 catch history and start year, relative to the new catch history and start year developed for this assessment.

BOCACCIO ROCKFISH

STAR Panel Report

July 13-17, 2009

Southwest Fisheries Science Center
110 Shaffer Road, Santa Cruz, CA 95060

Panel Reviewers

Martin Dorn	Panel Chair, Scientific and Statistical Committee (SSC) Representative
Chris Francis	Center for Independent Experts (CIE)
Vladlena Gertseva	NMFS, Northwest Fisheries Science Center (NWFSC)
J. J. Maguire	Center for Independent Experts (CIE)

Panel Advisors

John DeVore	Pacific Fishery Management Council
Gerry Richter	Groundfish Advisory Subpanel (GAP) Representative
John Budrick	Groundfish Management Team (GMT) Representative

Stock Assessment (STAT) Team members present

John Field	NMFS, Southwest Fisheries Science Center (SWFSC)
Alec MacCall	NMFS, Southwest Fisheries Science Center (SWFSC)
E. J. Dick	NMFS, Southwest Fisheries Science Center (SWFSC)

Overview

A draft assessment of bocaccio rockfish (*Sebastes paucispinis*) off the west coast of the United States, from the U.S.-Mexico border to Cape Blanco, Oregon (Conception, Monterey and Eureka INPFC areas) was reviewed by the STAR panel during July 13-17, 2009. The population is treated as a single stock within the assessment area. Although the range of the species extends considerably further north, there is some evidence that there are two population centers of bocaccio, one in southern California and another off the west coast of British Columbia, with a relative scarcity of bocaccio in the region between Cape Mendocino and the mouth of the Columbia River.

This assessment used the Stock Synthesis platform (version 3.03a) and incorporated a variety of data sources. Catch and length-frequency data from six fisheries were used in the assessment, including two trawl fisheries (north and south of 38º N), one hook-and-line fishery, one set net (gillnet) fishery and two recreational fisheries (south and north of Point Conception). Fishery-dependent relative abundance (CPUE) indices used in the model were calculated from the trawl fishery and the two recreational fisheries. The model also uses a recruitment (age-0) index based on recreational pier fishing. Fishery-independent data included the CalCOFI larval abundance time series, the triennial trawl survey index, the NWFSC shelf-slope survey index, the NWFSC Southern California Bight hook-and-line survey, and the coastwide pelagic juvenile survey. No age data were used in this model as it is notably difficult to determine the age of bocaccio in the assessment area.

The last full assessment of bocaccio rockfish was done in 2003, and it was subsequently updated in 2005 and 2007. Major changes made in this assessment, compared with the previous assessment include:

- Use of SS3 modeling framework instead of previously employed SS1;
- Extension of the north boundary of the assessment area from Point Mendocino to Point Blanco;
- Extension of period modeled from 1951 to 1892;
- Use of two trawl fisheries rather than one, as was used in the past;
- Use of a revised catch history based on Ralston et al. (2009)
- Addition of NWFSC shelf-slope trawl survey (referred to as NWFSC combined survey in the assessment report);
- Use of revised triennial trawl survey estimates using a GLMM approach (instead of area-swept approach previously used);
- Addition of NWFSC Southern California Bight hook and line survey;
- Use of revised juvenile indices (Pier index and juvenile trawl survey index).

The STAR panel concluded that the bocaccio rockfish assessment constitutes the best available scientific information on the status of bocaccio rockfish off the U.S. west coast and recommends that it be used for status determination and management in the Council process. The STAR panel thanks the STAT team members for their hard work and willingness to respond to panel requests.

Analyses requested by the STAR Panel

The Panel requests were addressed using a base model (Mod50) slightly different than that in the draft assessment. It included a corrected fecundity relationship and CPFV observer length composition data split from those from RecFIN. These changes made the assessment slightly more pessimistic (depletion 25% compared to 26% in draft base model).

1. Eliminate the recreational index north of Point Conception (recCEN)

Rationale: These data could be misleading because they may be more indicative of changes in the spatial pattern of the fishery than in the fish stock.

Response: Dropping the recCen index changed the depletion from 25% to 22%. This run was treated as an interim base model for comparison with the runs below.

2. Iteratively up-weight each informative index (adjust lambdas) to determine the major conflicts in the model; estimate current biomass and depletion under each scenario.

Rationale: To identify major conflicts amongst the biomass indices and determine which indices were optimistic and which were pessimistic.

Response: Because of time constraints, and because it was already reasonably clear which of the indices were optimistic or pessimistic (see request 3), the STAT only partially filled this request, and focused on addressing these points in request 3.

3. Re-weight optimistic indices and pessimistic indices

Rationale: To provide a useful pair of runs to bracket uncertainty.

Response: This analysis highlighted a conflict between two pessimistic indices – triennial survey and trawlsou (both of which show a steep decline in the 1980s), and two optimistic indices – recSO and CalCOFI (which show stronger rebuilding in the early 2000s). Upweighting both pessimistic indices resulted in a better fit to the 1980s decline and changed depletion to 16%. Upweighting the optimistic indices produced a better fit to the 2000s incearse and indicated less depletion (39% when recSO was upweighted; 36% when CalCOFI was upweighted).

4. **Evaluate the effect of the relative weighting of the biomass indices and the compositional data by down-weighting the compositional data**

   Rationale: To determine whether there are any conflicts between the biomass and compositional data.

   Response: Down-weighting the compositional data made a small change in the total likelihood for the indices (~7 points), showing that there was no strong conflict between the compositional data and the indices. The depletion changed from to 22% to 19%.

5. **Do a model run that incorporates all coastwide catches and mirrors selectivity of the northern trawl fishery**

6. **Do an additional model run that incorporates all coastwide catches *and* compositional data**

   Rationale: These two requests evaluate the effect of uncertainty about the northern boundary of the stock.

   Response: The main effect of including OR and WA catches was just to scale up the biomass trajectory. The estimated current status was slightly more pessimistic (23% depletion). When the compositional data were also included, the assessment became more optimistic (28% depletion) but it was unclear why. The length composition data were poorly fitted (most likely because the length bins were not well structured for the large fish that are caught in OR/WA but not elsewhere). Another unsatisfactory aspect of this run is that there is no index for OR/WA.

7. **Fix M for older fish at 0.1 and allow M to be estimated for younger fish.**

   Rationale: Based on the Hoenig method, an M of 0.1 is more consistent with the longevity data than the current value of 0.15. There are also indications that mortality of younger fish (before settlement to demersal habitat) is probably higher that that of older fish..
   Response: Runs were done in which natural mortality had a value of M_{young} (estimated) for ages ≤ 3, M_{old} (fixed at 0.1) for "old" fish, and was interpolated for intermediate ages. When "old" was defined as ≥ 8 y, M_{young} was 0.17 and the depletion was 20%; when it was ≥ 10 y, M_{young} was 0.21 and the depletion was 19%. In these runs, the overall fit degraded (by 25 and 20 points, respectively), with improvement of the fits to triennial survey and trawlsou CPUE indices and degradation to CalCOFI and recSO indices. It was agreed not to change the value of M used in the base model, since assessment is sensitive to the definition of "old" fish age, and there is not enough data to reliably estimate M for "young" fish.

8. **Include in the assessment report reference to the proposed listing of bocaccio in Georgia Basin as endangered (under the terms of the Endangered Species Act).**

Rationale: A proposed listing of a distinct population segment of bocaccio rockfish is important background information that managers may want to consider when developing management measures for rebuilding the southern bocaccio stock.

Response: A new section has been drafted for the assessment report.

9. Assess the effect of the maturity curve by doing alternative runs using the maturity curves of Love et al. (1990) and Wyllie Echeverria (1987).

Rationale: To evaluate the sensitivity of the assessment to previously published maturity curves.

Response: Changing the maturity curve had negligible effect on depletion. Goodness of fit was very similar for all three maturity curves (a range of less than 2 likelihood units), but the Love et al. (1990) version fitted slightly better.

10. Specify the area covered by the assessment in the title of the assessment report.

Rationale: To improved clarity since the entire US west coast was not assessed.

Response: The report title was amended to include the area assessed.

11. Include recCEN index back in the base model (Mod50).

Rationale: It seemed more reasonable that this index be downweighted, rather than removed, and the tuning procedure already does this downeighting.

Response: Reintroducing the recCEN index changed the depletion from 22% to 25%.

12. Conduct two runs to bracket the uncertainty in the assessment: one upweighting triennial and trawlsou indices, and the other upweighting the recSO and CalCOFI indices.

Rationale: To bracket the uncertainty.

Response: Upweighting an index was done by setting the associated $\lambda = 10$. The depletion changed from 25% to 14% when the trennial & trawlsou indices were upweighted, and to 38% when recSO and CalCOFI were upweighted.

13. Provide confidence intervals for model outputs, with and without delta method (McCall, in prep.) contributions for uncertainty in steepness, h, and natural mortality, M.

Rationale: For models in which h and M are fixed, the usual confidence intervals (based on the inverse Hessian) may substantially underestimate uncertainty.

Response: When uncertainty in both M and h was included in the calculation of standard errors, this made the changes caused by the two bracketing runs (see request 12) approximately equivalent to ± 1 s.e. in depletion as estimated by the base model.

14. For the base model use the revised CalCOFI index (presented to the Panel) that utilizes a cloglog link in the binomial part of the GLM (instead of the usual logit link).

Rationale: An alternative GLM, using a cloglog link in the binomial model, rather than the previously used logit link, fit the CALCOFI data better (AIC decreased by 20).

Response: This change had only a slight effect on the biomass trajectory, changing the depletion from 25% to 26%.

15. Conduct run in which catches N of 40° 10´ were removed.

Rationale: To evaluate the consequences of using the assessment to manage bocaccio fisheries south of 40° 10´.

Response: This change had only a slight effect on the biomass trajectory, changing the depletion from 26% to 27%. The catch north of 40° 10´ throughout the assessment period was approximately 6.7% of the total catch. The 2009 spawning biomass for the model excluding the catch north of 40° 10´ is 5.4% lower, while the summary biomass is 5.0% lower.

Description of base case model and alternative models to bracket uncertainty

Start year of the model =1892; discard incorporated into total catch;
M fixed at 0.15yr^{-1} for both females and males; h estimated (but with Dorn's prior); $\sigma_R = 1$;
Von Bertalanffy growth parameters - $L_{\min}$ fixed, others estimated for females and males.

Fisheries

- Trawl south of 38^{o} N
- Trawl north of 38^{o} N
- Hook and line
- Set net
- Recreational south of 34.5^{o} N (Point Conception)
- Recreational north of 34.5^{o} N (Point Conception)

Abundance indices:

- Trawl fishery CPUE, abbreviated as trawlsou (1982-1996)
- RecFIN CPUE south, abbreviated as recSO (1980-2002)
- RecFIN CPUE north, abbreviated as recCEN (1980-2002)
- CalCOFI (1951-2008)
- Triennial trawl survey (1980-2004)
- CPFV CPUE (1987-1998)

NWFSC Southern California Bight hook and line survey (2004-2008)
NWFSC shelf-slope survey (2003-2008)
Pelagic juvenile index (2001-2008)
Recreational pier fishing recruitment index (1954-2008)

Length frequencies:

Trawl fishery (1978-2004)
Hook and line fishery (1979-2002)
Set net fishery (1978 -1998)
Recreational south of 34.5^o N (1975-2008)
Recreational north of 34.5^o N (1978-2008)
Trawl north of 38^o N (1978-2002)
Triennial trawl survey (1980-2004)
CPFV (1987–1998)
NWFSC Southern California Bight hook and line survey (2004-2008)
NWFSC shelf-slope survey (2003-2008)

Uncertainty was bracketed by regarding two alternative sets of indices to be more reliable indicators of stock trends. The low biomass scenario was obtained by upweighting ($\lambda = 10$) the triennial and trawlsou indices, while the high biomass scenario was obtained by upweighting ($\lambda = 10$) the recSO and CalCOFI indices. These scenarios also provided useful contrast between stock trends north of Point Conception (where recovery is apparently slower and may depend on an influx of fish from further south), and south of Point Conception (where trend data indicate more rapid recovery).

Technical merits of the assessment

This is a very thorough assessment, with good use of recent research results and sensitivity runs to evaluate alternative model assumptions. Recommendations from previous STAR panels were considered in detail. Substantial improvements were made to both the CalCOFI index and the maturity curve parameters. While there remain unresolved problems with the assessment, progress on these problems is likely to be difficult and incremental. Based on these considerations the Panel recommends that the next bocaccio rockfish assessment be an update rather than a full assessment.

Explanation of areas of disagreement regarding STAR panel recommendations

A. Among STAR panel members (including concerns raised by the GAP and GMT representatives

There were no areas of disagreement among STAR panel members.

B. Between the STAR panel and the STAT team

There were no areas of disagreement between the STAR panel and the STAT team.

Unresolved problems and major sources of uncertainty

Stock structure is a major uncertainty and unresolved problem – particularly the location of the northern and southern stock boundaries, and the extent of mixing with adjacent stocks. The apparent northwards diffusion of fish as they grow older also presents a difficulty for bocaccio assessment. The use of area-specific selectivities is an attempt to model this situation, but this is an imperfect solution because diffusion is likely to be a complex process that occurs sporadically and/or exhibits density-dependent characteristics. But given the limited data available, it is hard to see any alternative to this approach.

The value of natural mortality used in the assessment appears inconsistent with information on bocaccio longevity.

Finally, the lack of age data is a substantial limitation in the assessment.

Management, data, or fishery issues raised by the GAP and the GMT representatives

GMT and GAP representatives pointed out that extending northern boundary of the assessment from Cape Mendocino to Cape Blanco in this assessment raises issues for the management of bocaccio rockfish. While scientific information is the over-riding consideration for stock structure decisions, such information may not be able to identify precise stock boundaries. In these situations, advice from resource managers should be requested to ensure that management measures are no more burdensome nor complicated than necessary.

From a management perspective, there are distinct advantages to restricting the assessment to California waters. Approximately 6% of the coastwide catch occurs between Cape Mendocino and Cape Blanco, while only approximately 1% of the coastwide catch is taken from the California/Oregon border to Cape Blanco. Ending the assessment at the California/Oregon border would allow Oregon to avoid being held to an extremely low harvest guideline that would need to be tracked with imprecise in-season catch estimates. California would not be required to enter into catch sharing agreements or allocation discussions with Oregon regarding bocaccio, although there would still be implications for the management of the California trawl fishery and trawl IQs. Given the uncertainties in stock structure and the low proportion of the coastwide catch north of Cape Mendocino, alternative model runs extending to Cape Mendocino, the California/Oregon border, and Cape Blanco could be presented to the Council for consideration in determining the geographic region that is managed using the assessment results.

Prioritized recommendations for future research and data collection

- The location of the northern and southern boundaries of this stock, and the extent to which it mixes with the Canadian and Mexican stocks, are major uncertainties in this assessment. Three approaches which might help reduce these uncertainties are otolith elemental analysis, parasitology, and co-operative research with Canadian and Mexican colleagues (e.g., evaluation of data from the Mexican analogue of the CalCOFI survey).

- The reliability of the recCEN index could be improved by an evaluation of the spatial distribution of fishing effort and fish size.

- The Panel endorses the continued processing of historical CalCOFI samples from the northern transects, which will produce additional data for this assessment.

- Neither the triennial nor the NWFSC shelf-slope surveys are well suited to bocaccio. Research to develop a survey methodology that is more appropriate for species like bocaccio could improve the assessment.

- SS3 implements new options for bias adjustment of stock recruit relationships that have been used with little or no peer review. Simulation testing is needed to confirm that bias adjustment is justified in all cases. Guidelines should be developed on how to configure bias adjustment settings to reflect the biological characteristics of the stock and the available assessment information.

- Develop methods to incorporate uncertainty in natural mortality and/or steepness in model configurations in which these parameters are fixed. The delta method for propagating uncertainty (McCall in prep.) is promising approach that warrants further evaluation.

- The Panel recognises the difficulty of developing a precise age estimation method for this species but notes that such a method could substantially improve the assessment.

- The Panel notes that there is no recent histology to confirm macroscopic staging for determination of proportion mature at length, but acknowledges that the assessment is not particularly sensitive to the values used.

Acknowledgements

The Panel thanks staff at the SWFSC Santa Cruz laboratory their exceptional support and provisioning during the STAR meeting.

Table of Contents

Executive summary

Stock

This assessment applies to widow rockfish (*Sebastes entomelas*) located in the territorial waters of the U.S., including the Vancouver, Columbia, Eureka, Monterey, and Conception areas designated by the International North Pacific Fishery Commission (INPFC). The stock is assumed to be a single mixed stock and subject to four major fisheries.

Catches

The earliest records of landings of widow rockfish were in 1916. Major U.S. commercial catches of widow rockfish began in the late 1970s, peaking in 1981 (Figure ES1). Since the 1981 peak there has been a steady decline in the landings of widow rockfish to 52 mt in 2003 and to 254 mt in 2006 (Table ES1). Catches were mostly from commercial fisheries. Catches from recreational fisheries ranged from less than 2 mt in 2003 to 375 mt in 1982. The dominant gear type historically has been the midwater trawl. During the early 1990s, bottom trawl catches nearly matched the midwater trawl catches.

Table ES1. Recent catches (mt) of widow rockfish by four fisheries from 1999 to 2008.

Year	Vancouver, Columbia	Oregon Midwater Trawl	Oregon Bottom Trawl	Eureka, Monterey, and Conception	Total
1999	777	2016	923	1053	4768
2000	639	2665	18	1341	4664
2001	424	1220	45	590	2279
2002	65	310	7	50	432
2003	14	22	2	5	43
2004	32	34	10	26	101
2005	43	139	6	12	199
2006	45	155	3	13	215
2007	37	192	10	19	259
2008	97	106	2	38	243

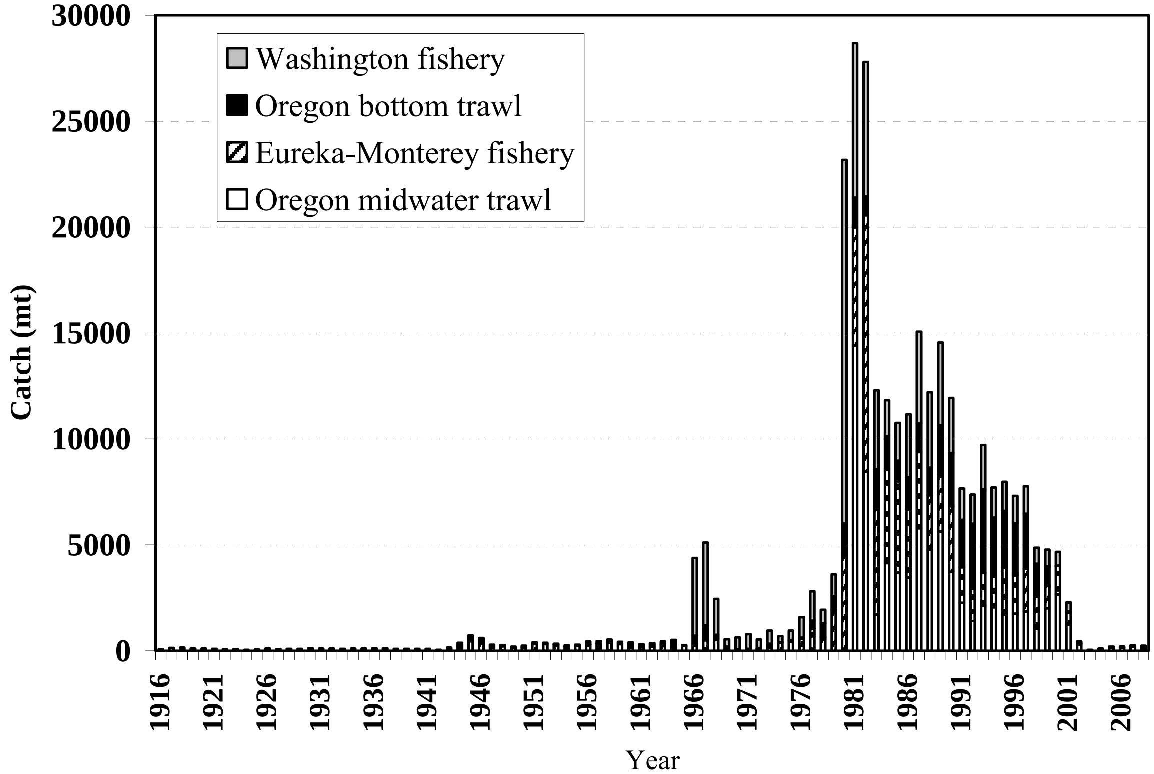

Figure ES1. Total catches of widow rockfish from 1916 to 2008.

Data and assessment

The last full assessment of widow rockfish was conducted in 2005 and was updated in 2007 using an age-based population model (written in AD Model Builder (ADMB), He et al. 2007a). The Stock Synthesis program (SS3) was used in this assessment. All fishery data, including landings, age composition, and logbook catch rates, were recently downloaded from the PacFIN, CALCOM, and NORPAC databases, or provided by state and federal agencies. Survey data, including the triennial survey and the Northwest Fisheries Science Center (NWFSC) combo survey, were also used in the assessment. Bycatch data from at-sea processing vessels were also included in the assessment.

Stock spawning output

Stock spawning output has shown a steady decline between 1980 and 2003, soon after major commercial fisheries for widow rockfish began. Since 2003, stock spawning output has shown an increasing trend. Table ES2 and Figure ES2 show time series of estimated spawning outputs, depletion, and their 95% confidence intervals from the base assessment model.

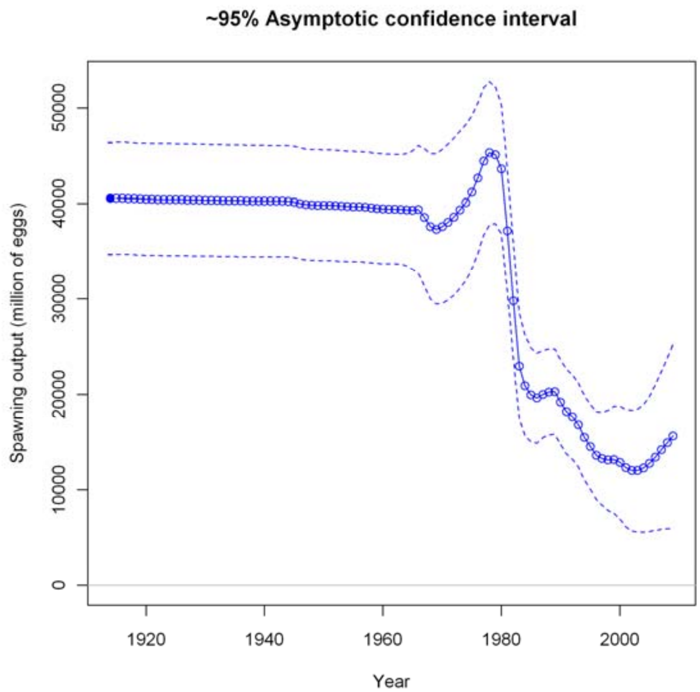

Figure ES2. Estimated spawning outputs of widow rockfish from 1916 to 2009 with 95% confidence intervals.

Table ES2. Estimated spawning outputs (million of eggs) and depletion levels of widow rockfish from 2000 to 2009. The 95% confidence intervals are also shown.

Year	Spawning output	Confidence interval (95%)	Depletion (%)	Confidence interval (95%)
2000	12852	6949-18755	31.7	17.8-45.6
2001	12294	6164-18425	30.3	15.7-44.9
2002	12000	5709-18290	29.6	14.5-44.7
2003	12024	5597-18452	29.7	14.1-45.2
2004	12259	5604-18914	30.2	14.0-46.5
2005	12735	5677-19794	31.4	14.0-48.8
2006	13403	2784-21021	33.1	14.1-52.0
2007	14171	5897-22445	34.9	14.3-55.6
2008	14908	5960-23856	36.8	14.2-59.3
2009	15625	5984-25266	38.5	14.2-62.9

Recruitment

The model estimated time series of recruitment of age-0 fish from 1958 to 2008. The highest recruitment occurred in 1970 (Figure ES3). Recruitments remained generally low in the early 1990s as well as since 2001 as compared to the long-term average (Figure ES3 and Table ES3). The 2007 assessment update indicated that the 2000 recruitment was strong, but this assessment does not confirm this is the case. As in the last assessments, uncertainties in estimation of recruitment remain high.

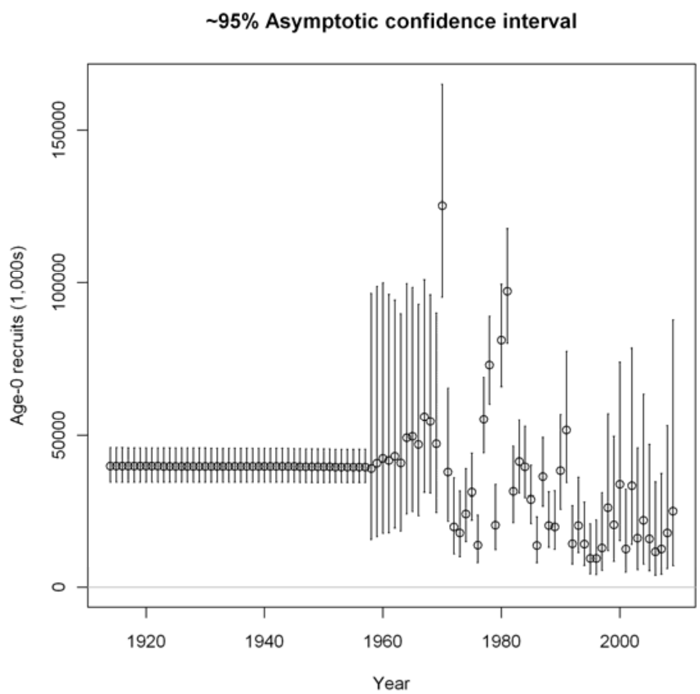

Figure ES3. Estimated recruitment of widow rockfish and 95% of asymptotic confidence intervals from 1916 to 2009.

Table ES3. Estimated recruitment with 95% confidence intervals from 2000 to 2009.

Year	Recruitment (*1000)	Confidence interval (95%)
2000	33828	15457-74031
2001	12686	5008-32140
2002	33395	14202-78523
2003	16309	5805-45818
2004	22192	7750-63549
2005	16046	5490-46901
2006	11746	3991-34575
2007	12698	4310-37408
2008	18038	6124-53125
2009	25135	7201-87732

Reference points

The spawning output in 2009 as a percentage of unfished spawning output is the population status (depletion). Depletion below 25% indicates an overfished stock, and depletion between 25% and 40% indicates a stock in the precautionary zone[1]. Depletion over 40% indicates a healthy stock. The estimated depletion in 2009 is 38.5% with 95% of confidence intervals of 14.2% and 62.9% (Table ES2 and Figure ES4). The management target for widow rockfish is 40% of unfished spawning output. The assessment estimates the unfished spawning output to be 40,547 million eggs, and 40% of the target to be 16,218 million eggs. A summary of reference points is listed in Table ES4.

[1] A stock that has declined to less than 25% of its unfished spawning output is considered "overfished" until it rebuilds to 40% of its unfished spawning output. Such a stock is managed under the rebuilding plan while it is in the precautionary zone and not under the normal control rules specified for a stock in the precautionary zone (i.e., the 40-10 rule).

Table ES4. Summary of reference points for widow rockfish from the base case model.

Reference term	Estimated value	Confidence interval (95%)
Unfished spawning output ($SB_{0,}$ millions of eggs)	40547	35108-46828
Unfished recruitment (*1000)	39790	34523-45860
Reference points based on $SB_{40\%}$		
MSY Proxy Spawning output ($SB_{40\%}$)	16218	14043-18731
SPR resulting in $B_{40\%}$ ($SPR_{SB40\%}$)	0.6193	0.4157-0.9227
Exploitation rate resulting in $SB_{40\%}$	0.0337	NA
Yield with $SPR_{SB40\%}$ at $SB_{40\%}$ (mt)	3518	1379-8972
Reference points based on SPR proxy for MSY		
Spawning output at SPR (SB_{SPR}) (millions of eggs)	8589	1335-55244
$SPR_{MSY\text{-}proxy}$	0.5	0.0479-0.0530
Exploitation rate corresponding to SPR	0.0504	NA
Yield with $SPR_{MSY\text{-}proxy}$ at SB_{SPR} (mt)	3031	472-19469
Reference points based on estimated MSY values		
Spawning output at *MSY* (SB_{MSY}) (millions of eggs)	15272	9698-23635
SPR_{MSY}	0.6045	0.3463-1.055
Exploitation Rate corresponding to SPR_{MSY}	0.0256	NA
MSY (mt)	3526	1353-9189

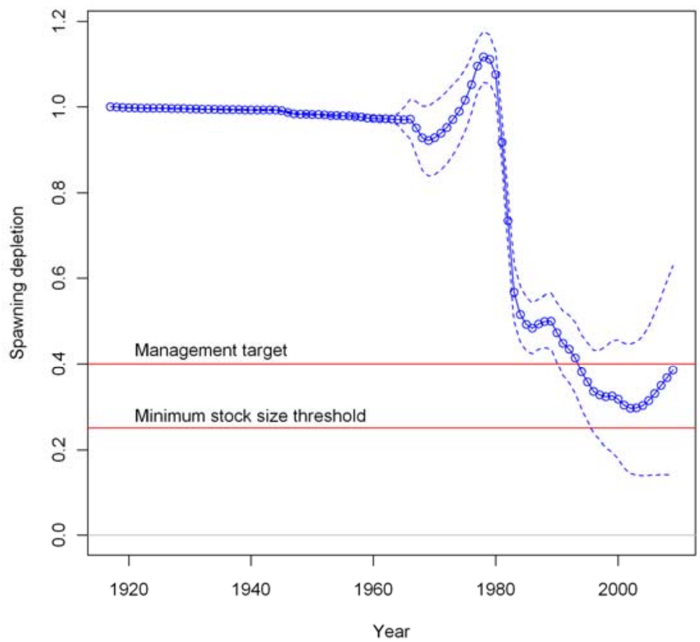

Figure ES4. Time series of depletion from 1916 to 2009 with 95% asymptotic intervals. Levels of management target and minimum stock size threshold are also shown.

Exploitation status

This assessment indicates that the widow rockfish population is at 38.5% of virgin spawning output in 2009 with an exploitation rate below 1% (Table ES5) and an equilibrium SPR of 95.7% (Figure ES5). However, the population is still below its target level of spawning output and is therefore still considered overfished (Figure ES6).

Table ES5. Time series of SPR (spawning potential ratio) and total exploitation rate of widow rockfish from 1999 to 2008.

Year	Spawning potential ratio (SPR)	Exploitation rate
1999	0.4881	0.0590
2000	0.4773	0.0602
2001	0.6536	0.0301
2002	0.9128	0.0057
2003	0.9905	0.0005
2004	0.9799	0.0012
2005	0.9648	0.0023
2006	0.9663	0.0024
2007	0.9627	0.0028
2008	0.9651	0.0026

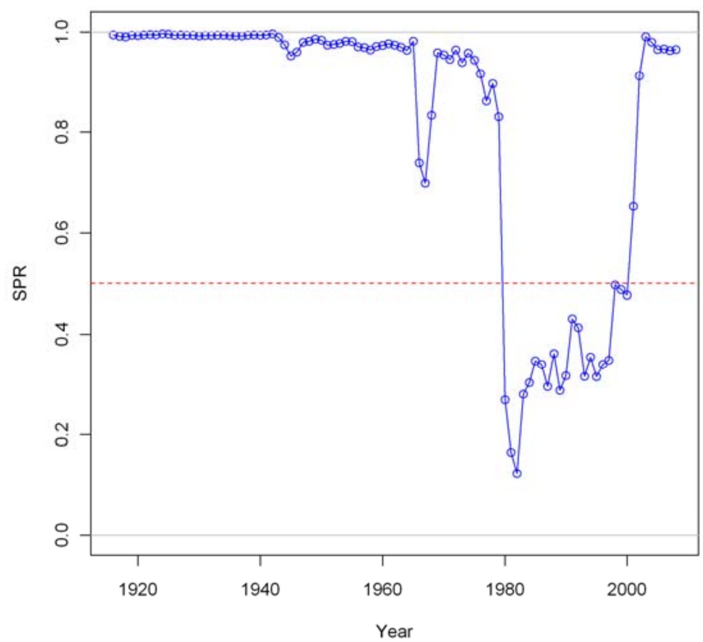

Figure ES5. Time series of estimated equilibrium spawning potential ratios (SPR) from 1916 to 2009. The target SPR level of 0.5 is also shown. Values below the target level indicate that overfishing occurred.

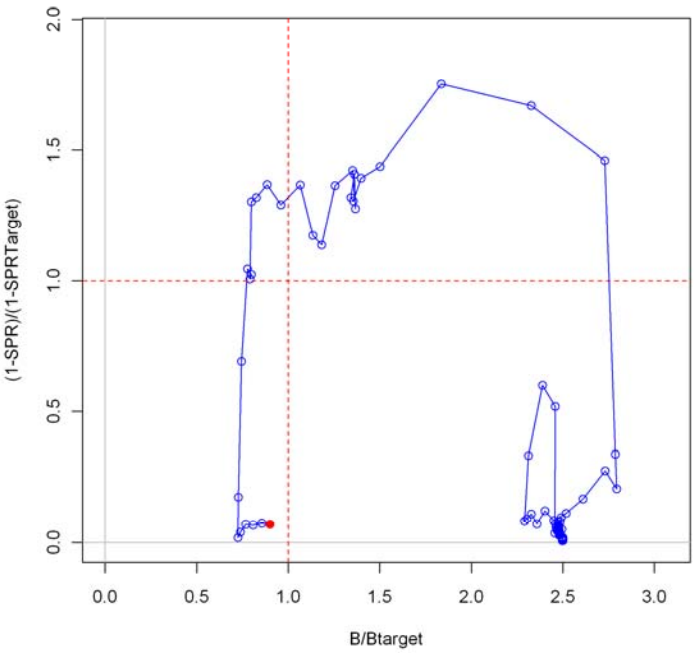

Figure ES6. Phase plot of estimated annual spawning potential ratios to the target of 0.5 and estimated spawning output relative to the target of SB40%. The last point on the lower-left quadrant corresponds to the estimated value in 2009.

Management performance
Widow rockfish was declared overfished in 2001. Optimal yield (OY), allowable biological catch (ABC), and catches of recent years are listed in Table ES6.

Table ES6. Management performance in obtaining the harvest guideline for widow rockfish. Harvest guideline and allowable biological catch (ABC) are taken from Council documents.

Year	Harvest Guideline or OY (mt)	Allowable Biological Catch (mt)	Catches (mt)
1999	5,090	5,750	4,136
2000	5,090	5,750	4,049

Unresolved problems and major uncertainties

1. The primary source of information on trends in abundance of widow rockfish is the Oregon bottom trawl logbook data, which is a questionable source of information for widow rockfish. In addition, no information after 1999 in the Oregon bottom trawl logbook data can be used in the assessment because the catch rates were very low due to trip limits and other management regulations. Based on a recommendation by the 2003 STAR panel, triennial survey indices have been used since 2005, but catches in the survey were low and the survey was discontinued in 2004. The NWFSC survey provided abundance indices in recent years, but the time series is short. Also, it is a bottom trawl survey, and does not adequately sample midwater habitat of widow rockfish.
2. Estimates of recruitment in recent years are highly uncertain and are key factors in determining how quickly the population will rebuild (He *et al*. 2003a, 2006b, 2007b). Age and length composition data from fisheries and surveys from the most recent years (2007 and 2008) suggest weak recruitment in 2002. This result contradicts the results in the 2007 assessment, which estimated the recruitment in 2002 to be a strong year class. More age and length data should be collected in 2009 and 2010 to resolve this issue.
3. As in the past assessments, there exist uncertainties in estimating the stock-recruitment relationship. These lead to greater uncertainties in the rebuilding analysis because it largely depends on how future recruitments are generated.
4. Stock structure issues, in particular the relationship to the Canadian stock, remain a source of uncertainty.

Forecasts
Widow rockfish was declared to be overfished in 2001. Forecasts will be provided as part of a forthcoming rebuilding analysis.

Decision table
As in the past assessments, there exist great uncertainties in estimating the stock-recruitment relationship. This is especially true for estimating recruitments in recent years, which are key factors in determing how quickly the population will rebuild. During the STAR Panel review, it was determined that a range of the steepness parameter (h) be used to bracket the recruitment uncertainties. Two alternative states of nature of h=0.25 and h=0.55 (versus h=0.406 in the base model) were chosen after a series of trial runs during the review. Future catch secenarios at F95% and F50% between 2011 and 2020 were used as alternative management decisions (Table ES7).

Table ES7. Decision table of 12-year projections for widow rockfish. Alternate states of nature and management options begin in 2011.

			State of nature					
			h = 0.25		Base case (h=0.4061)		*h* = 0.55

	2020	4028	10.3%	4469	32.1%	13021	47.1%	18623

Research and data needs

1. There are increasingly fewer reliable abundance indices for widow rockfish. Recent management measures have undermined the ability to continue a fishery-dependent time series of relative abundance from the Oregon bottom trawl fishery and the Pacific whiting fishery since 1999. The constant flux of the management regime suggests that there is little likelihood that meaningful CPUE indices can be developed from these fisheries in the future. The NWFSC combo survey provides some useful information on abundance of widow rockfish, but catches from the survey have been generally very low in recent years. It is desirable that a trawl survey (including midwater trawls) that targets widow-like rockfish be initiated. A long-term hydroacoustic survey would also be very useful.
2. The long-term recruitment index is a key time series in the stock assessment. Continuation of the NMFS/PWCC midwater juvenile trawl survey should provide key information on the recruitment strength of widow rockfish.
3. Sample sizes for existing age-collection programs as well as length measurements (by fishery and survey) should be increased substantially.
4. Effort on ageing of widow rockfish should include collecting information on length-age keys and growth rates for both the northern and southern areas.
5. A single-area assessment model should be considered in the next assessment.
6. Conduct an interagency ageing comparison and comparative analysis of break and burn and surface ageing methods.
7. Develop methods to incorporate uncertainty in natural mortality and/or steepness in model configurations in which these parameters are fixed. The delta method for propagating uncertainty (MacCall in prep.) is a promising approach that warrants further evaluation.

1. Introduction

Widow rockfish (*Sebastes entomelas*) is an important commercial groundfish species belonging to the scorpionfish family (Scorpaenidae). It ranges from southeastern Alaska to northern Baja California, where it frequents rocky banks at depths of 25-370m (Eschemeyer *et al*. 1983, Wilkins 1986). In those habitats it feeds on small pelagic crustaceans and fishes, including especially *Sergestes similis*, myctophids, and euphausiids (Adams 1987). There is no evidence that separate genetic stocks of widow rockfish occur along the Pacific coast and the species has been treated as one stock with four separate fisheries (Hightower and Lenarz 1990; Rogers and Lenarz 1993; Ralston and Pearson 1997, Williams *et al*. 2002, Field and Ralston 2005).

A midwater trawl fishery for widow rockfish developed rapidly in the late 1970s and increased rapidly in 1980-82 (Gunderson 1984, Quirollo 1987, Figure 1). Large concentrations of widow rockfish had evidently gone undetected because aggregations of this species form at night and disperse at dawn, an atypical pattern for rockfish. Since the fishery first developed, substantial landings of widow rockfish have been made in all three west-coast states.

Management of the fishery began in 1982 when 75,000 lbs trip limits were introduced in an effort to curb the rapid expansion of the fishery (Appendix A). These were reduced to 30,000 lbs in 1983 and the fishery was managed by alteration of trip limits within the fishing season. A 10,500 mt/yr Allowable Biological Catch (ABC) for widow rockfish was instituted in 1983, but no harvest guideline was established. This form of management continued with alterations in ABC and trip limits until 1989 when a 12,100 mt/yr harvest guideline was implemented (Appendix A). From 1994 to 1997 the harvest guideline was changed to 6,500 mt and then reduced to 5,090 mt for 1998 to 2000. Based on the 2000 stock assessment, the population was declared overfished (Williams *et al*. 2000), and a series of management actions were taken by the Pacific Fisheries Management Council to protect the stock (Appendix A). As consequence, stock assessments for the population were conducted in 2002, 2004, and in 2006 along with rebuilding analyses of the stock (He *et al*. 2003a, 2003b, 2006, 2006b, 2007, and 2007a). Table 1 shows the management performance and harvest guidelines for widow rockfish from 1989 to 2010.

This assessment used an age-based population model similar to those used in previous assessments (Ralston and Pearson 1997, Williams *et al*. 2000, He *et al*. 2003b, He *et al*. 2006a, He et al. 2007a). Like the previous assessments, this assessment used a two-area model, delineated by 43^{o} N latitude (Figure 2). Unlike the previous assessments, which used ADMB software, this assessment used the Stock Synthesis program developed by Richard Methot (Version 3.03a, Methot 2009).

2. Assessment

2.1 Biological data

Growth in length for widow rockfish has been described using von Bertalanffy growth equations in two papers by Lenarz (1987) and Pearson and Hightower (1991). In their analyses it was determined that females attain a larger size than males and fish from the northern part of the range tend to be larger at age in comparison with those in the south. For these reasons we chose to use the sex-specific and area-specific estimates of length-at-age. Furthermore, we chose to use the estimates listed in Pearson and Hightower (1991). The growth parameters were then transformed in the format of Schnute parameters, expressed as *L1*, *L2*, and *K*, and shown below and in Figure 3, because they are from a more recent and comprehensive analysis of widow rockfish growth compared to the analysis by Lenarz (1987). In order to match the fisheries, we used the Columbia-Eureka INPFC area border (43^{o} N latitude) to delineate north from south.

Parameter	Females (north)	Males (north)	Females (south)	Males (south)
L1 (age=3)	22.7	28.5	22.3	23.2
L2 (age=18)	47.7	42.9	46.2	41.0
K	0.14	0.18	0.2	0.25

Sex-specific weight-at-age estimates were computed using the length-at-age estimates above in combination with sex-specific length-weight regressions for widow rockfish that were developed by Barss and Echeverria (1987). The length-weight regression equation is $W = \alpha L^{\beta}$, where *W* is the weight (g) and *L* is the length (cm). The sex-specific parameter values used in this assessment are listed below:

Parameter	Females	Males
α	0.00545	0.01188
β	3.28781	3.06631

Estimates of maturity and fecundity of female widow rockfish were obtained from Barss and Echeverria (1987) and Boehlert *et al*. (1982), respectively. Age-specific maturity estimates were taken directly from the literature instead of fitting a parametric model (Figure 4), while age-specific fecundity was computed using the weight-fecundity regression:

$$F = 605.71W - 261830.7$$

where *F* is fecundity (number of eggs) and *W* is weight (g). The weight-fecundity regression applied to the southern weight-at-age estimates resulted in negative values for ages 3 and 4. The weight-fecundity regression developed by Boehlert et al. (1982) was based on fish captured from Oregon and apparently does not apply to widow rockfish in the south. Recent work indicates that there is no significant relationship between body weight and weight specific fecundity in widow rockfish (Dick 2009). The maturity estimates indicate a substantial difference in maturity-at-age between the north and south, with the northern fish maturing at an older age. Lacking any other estimate of fecundity for the south, we applied the weight-fecundity regression from the north and modified the estimates for ages 3-5 to approximate an asymptote to 0.

2.2 Fishery-dependent data

2.2.1 Landings

All landings were summarized into four fisheries: (1) Vancouver-Columbia in Washington State (WAFishery1); (2) Oregon mid-water trawl (ORMWTraw); (3) Oregon bottom trawl (ORBTraw); and (4) Eureka, Monterey, and Conception (EMFishery) (Figure 1). Landings statistics used in this assessment were derived from six sources:

1. All commercial landings from 1981 were extracted from the PacFIN database. Landings from at-sea-processing (ASP) were not included in the assessment. They were replaced by the bycatch estimates (see #6 below).
2. The very small annual recreational take of widow rockfish from 1980 to 2008 was extracted from the Marine Recreational Fishing Statistics Survey (MRFSS) database. Because there were no estimates in the database between 1990 and 1992, catches for these three years were linearly interpolated.
3. All landings from 1966 to 1972, and some landings from 1973 to 1976 were directly taken from a summary table in Rogers (2003), who compiled summaries of foreign catches in the period.
4. Some landings from 1973 to 1976 and all landings from 1977 to 1979 were directly copied from the 2000 assessment (Williams *et al*. 2000).
5. Historical California catch data from 1916 to 1968 recently reconstructed by Ralston *et al*. (2009).
6. Historical Oregon bottom trawl catch data from 1938 to 1975 estimated from catch reports.
7. Bycatch estimates from 1991 to 2001 were provided by the NWFSC (Jim Hastie and Eliza Heery, personal communication).
8. Total catch (total mortality) between 2002 and 2007 were reconstructed from West Coast Groundfish Observer Program.

Summarized catches by year and fishery are presented in Table 2 and Figure 1. As in the past assessments of widow rockfish, the data were pooled over states into INPFC area blocks. These in turn were collapsed into northern and southern areas, representing the U.S. Vancouver and Columbia areas (WAFishery1, ORMWTraw, and ORBTraw) and the Eureka, Monterey, and Conception areas (EMFishery), respectively. The northern and southern areas are conveniently delineated by the 43^o N. latitude line. Within the southern area, widow rockfish landings were further condensed by summing over gears (i.e., trawl, other commercial, and recreational), providing annual estimates of landings from the southern area fishery. In the northern area, however, landings were partitioned into three separate fisheries: the Oregon midwater trawl fishery, the Oregon bottom trawl fishery, and the remaining catch of widow rockfish, referred to as the WAFishery1 (Vancouver-Columbia fishery). Because identification of gear types in Oregon (midwater or bottom trawl) did not begin until 1983, all landings in the northern area prior to that time were assigned to the Vancouver-Columbia "trawl" fishery. These fishery definitions are consistent with all previous widow rockfish stock assessments.

A revised approach for estimating historical catches of widow rockfish in Oregon and Washington fisheries was developed. Widow rockfish catches for the period from 1963 through 1975 are based on a dataset compiled by Jack Taggart (WDFW; unpublished manuscript 1975) from data reported in Barss and Niska (1978), DiDonato and Pattie (1968), Pattie (1973) and Tagart and Kimura (1982). We queried the total estimated catches of widow rockfish in this database for PMFC areas 2A through 3B (CA/OR border to the U.S./Canada border), and compared that to the total estimated catch of all rockfish in this region. We also compared the Tagart database estimates to those reported by Douglas (1998) for Oregon trawl fisheries, and found the results consistent with the Tagart estimated catches. These estimates suggest that widow made up a small fraction (35-370 mt per year, generally less than 5% of the total rockfish catch), although there seems to have been a large pulse of widow rockfish landings in 1967. For the period from 1938 through 1962, we compiled total rockfish catches from the "red book"

(Bureau of Commercial Fisheries) reports for 1938 through 1955, and from the Historical Annotated Database (Lynde 1984) for the period from 1956 through 1962. We then applied a ratio estimator based on the average fraction of total rockfish catch estimated to be widow rockfish from the Tagart database between 1963 and 1965 (2.4%) to these total landings. The resulting estimate was then used as the Oregon bottom trawl historical catches. As total rockfish catches were very modest prior to World War II (when balloon trawl fisheries developed), and most catches tended to be from fixed gear, we assume zero catches in Oregon and Washington prior to 1938. This method is intended to be a placeholder, until estimated historical catches by species are available from ongoing catch reconstruction efforts.

Recently estimated bycatch from at-sea processing (ASP) on widow rockfish from 1991 to 2001 were provided by the Northwest Fisheries Science Center and are included in the total landing estimates (Table 3) (Jim Hastie and Eliza Heery, NMFS Northwest Fisheries Science Center, personal communications). These landings were grouped into either the Vancouver-Columbia fishery or the Oregon mid-water trawl fishery, proportioned by number of hauls observed north or south of 43^{o}N latitude. Widow rockfish total catches between 2002 and 2007 were reconstructed from West Coast Groundfish Observer Program total mortality estimates and at-sea whiting fishery bycatch estimates, provided by the Northwest Fisheries Science Center. All Washington catches from the Groundfish Observer Program were assigned to the Washington fishery. Oregon midwater trawl catches were assigned to the Oregon midwater trawl fishery, and Oregon non-midwater trawl catches were assigned to the Oregon bottom trawl fishery. All California catches were assigned to the California fishery. Widow bycatch in the at-sea whiting fishery was added to the Oregon midwater trawl fishery. For 2008, landings data from PacFIN and the widow bycatch estimate in the at-sea whiting fishery were used, and no additional discard was added. The only 2008 discard information for widow rockfish available at the time of STAR Panel was the discard estimate from the PacFIN quota-species monitoring report, and this value was minimal.

2.2.2 Age composition data

Widow rockfish otolith samples collected coastwide since 1989 have been aged at the NMFS SWFSC Fisheries Ecology Division in Santa Cruz (formerly the Tiburon Laboratory) using the break-and-burn aging method (Pearson and Hightower 1991). Most fish were aged by Fisheries Ecology Division staff (Don Pearson) using the break-and-burn ageing technique. Prior to 1989, the ages of all Vancouver-Columbia fish were obtained by researchers in the State of Washington, who used surface readings. Prior to 1982, Oregon widow rockfish were aged by investigators in Oregon, who used the break-and-burn ageing method.

Age validation of widow rockfish was conducted by marginal increment analysis (Lenarz 1987). Hyaline-zone formation, the measure of annual growth, appears to occur between December and April (Pearson 1996). For convenience all widow rockfish are assumed to be born on January 1. Variation in the timing of hyaline-zone formation occurs between fish from Washington and California, which could affect age determination. Knowledge of this timing variation can be used to avoid mis-ageing and ultimately, variation in hyaline-zone formation is unlikely to result in major age discrepancies (Pearson 1996).

Washington provided ageing data from samples collected during commercial market sampling. The data were then expanded using relative catches from US Vancouver and Columbia areas. Oregon provided raw sample data which were expanded using methods described in Sampson and Crone (1997). California age data were extracted and expanded from the CALCOM database (Pearson and Erwin 1997). Summaries of age samples for four fisheries from 1978 to 2008 were presented in Table 4. Complete age compositions (proportion-at-age) of both sexes for the four fisheries from 1978 to 2008 are presented in Figures 5 to 8.

2.2.3 Oregon bottom trawl logbook

Oregon logbook data from 1984 to 1986 were provided by the Oregon Department of Fish and Wildlife, and data from 1987 to 2002 were extracted from the PacFIN database. Catch per unit effort (CPUE) was computed as pounds of fish caught per hour trawled. The data were filtered before the analysis. Only records meeting the following criteria were used in the analysis: (1) the fishing gear code corresponded to bottom trawl or roller gear, (2) hauls were conducted during the months of January, February, or March, and (3) the location of the reported haul fell in the range of 42°30' N to 46°30' N latitude and 124°36' W to 124°54' W longitude. In addition, records associated with any vessel code or spatial unit that had less than 1000 pounds of widow catch over the entire period (1984 to 2002) were also deleted. Data from 2000 to 2002 were not used in the analysis because widow catches in those three years were very low due to trip limits and other management regulations that had been implemented.

Annual CPUE indices were derived using the Delta-GLM (Generalized Linear Model) method with an additional factor (vessel) included:

$$\log(CPUE) = \mu + Y_i + V_j + L_k + \varepsilon_{ijkl}$$

where μ is the average $\log(CPUE)$, Y_i is a year effect, V_j is a vessel effect, L_k is a spatial (latitude and longitude) effect, and ε_{ijkl} is a normal error term with mean zero and variance σ_ε^2. The back-transformed year-specific CPUE, with bias-correction, was then calculated as:

$$CPUE_i = \exp\left(\mu + Y_i + \bar{V} + \bar{L} + \frac{\sigma_\varepsilon^2}{2}\right)\pi_i$$

where $\bar{V}$ and $\bar{L}$ are the mean effects of vessel and spatial unit, respectively, and π_i is a binomial coefficient:

$$\pi_i = \frac{\exp(\mu' + y_i' + \bar{V}' + \bar{L})}{1 + \exp(\mu' + y_i' + \bar{V}' + \bar{L})}$$

where μ' is the average, y' is year effect, $\bar{V}'$ is average vessel effect, and $\bar{L}$ is average spatial effect. Derived annual CPUE indices are presented in Table 5, which are identical to those used in the past assessments.

2.2.4. Pacific whiting bycatch indices

As in the previous assessments (Rogers and Lenarz 1993, Ralston and Pearson 1997, Williams et al. 2000), CPUE indices were computed that measured the incidental catch rate of widow rockfish in the at-sea Pacific whiting fishery. Data from the foreign fishery, joint-venture fishery and recent domestic fishery were extracted from the NORPAC database.

Full descriptions of how the CPUE indices were derived are in Appendix A of the 2005 Assessment (He *et al*. 2006a). An approach similar to the Delta-GLM analysis of Oregon bottom trawl logbook was used for estimation of the bycatch indices. Annual CPUE indices for bycatch in the foreign fishery, joint-venture fishery, and domestic fisheries are presented in Table 6. As recommended by the 2003 STAR Panel, annual CPUE indices from the domestic fishery after 1998 were excluded from the analysis because changes in management measures are expected to have more influence on the CPUE statistic than changes in stock size.

2.3 Fishery-independent data

2.3.1 Midwater trawl pelagic juvenile survey

Every year since 1983 the Groundfish Analysis Branch at NMFS Fisheries Ecology Division in Santa Cruz/Tiburon Laboratory has conducted a midwater trawl survey, which is designed to assess the reproductive success of rockfish spawning, including widow rockfish. Since 2001, the survey was expanded to a coastwide, combined industry and NMFS survey (PWCC/NWFSC: Pacific Whiting Conservation Cooperative and Northwest Fisheries Science Center) (Sakuma et al. 2006). An ANOVA analysis was used to fit all data from the combined survey (Steve Ralston, personal communication). Annual indices along with CVs from 2001 to 2008 are presented in Table 7. The index shows relatively high age-0 abundance in 2002.

2.3.2 Triennial trawl survey index

The AFSC/NWFSC triennial trawl survey index was not used in the 2003 assessment because of very limited widow catches by the survey and very poor fit of the index in the assessment model (He *et al*. 2003b). The 2003 STAR panel recommended the index be analyzed further and be considered for inclusion in the assessment. In the 2005 and 2007 assessments, the analysis of the triennial survey data uses the same Delta-GLM method as for the Pacific whiting bycatch indices. Detailed description of the analysis is in Appendix B of the 2005 assessment (He et al. 2006a). For this assessment, separate and distinct indices were developed for northern and southern areas, delineated by 43^{o} N latitude. The analysis was conducted using a GLMM method developed by staff at the NWFSC (John Wallace and Beth Horness, personal communication). The CVs were generated from MCMC sampling of 15 million runs. Derived index values and associated CVs are presented in Table 8.

Length frequency data from the triennial survey were also compiled and used in this assessment. The numbers of fish measured in length from 1980 to 2004 are presented in Table 9. Length composition (proportion-at-length) data of both sexes for the northern and southern areas are presented in Figures 9 and 10. Although the mean dates of the triennial survey changed from middle August between 1980 to 1992 to middle July between 1995 to 2004, this assessment assumes that it has no effect on the index and all data from 1980 to 2004 were treated as one continuous time series. This is because there is no evidence that indicates seasonal migration of widow rockfish. In addition, too few data, both in catches and length compositions, would be available if the time series were broken into two times series.

2.3.3 NWFSC trawl survey

Since 2003 NWFSC has conducted an annual shelf and slope trawl survey. This is the first time these trawl survey data are used in a widow rockfish assessment, since the survey now has a six-year time series. The survey is based on a stratified random-grid design, covering the coastal waters from a depth of 55 m to 1,280 m from Washington to California. Detailed survey information can be found in Keller *et al*. (2007).

As in the triennial survey, separate indices were developed for both the northern and southern areas, delineated by 43^{o} N latitude. The analysis was conducted using a GLMM method developed by the NWFSC staff (John Wallace and Beth Horness, personal communication). The CVs were generated from MCMC sampling of 15 million runs. Derived index values and associated CVs are presented in Table 10.

Age and length composition data were also compiled from the survey and were used in this assessment (Figures 11 to 14). Numbers of fish measured for length compositions and numbers of fish aged for age compositions from the survey are presented in Table 11. Note that sample sizes, in terms of numbers of fish measured, are very small in comparison to the commercial fisheries data.

2.4 History of modeling approaches

Previous assessments of widow rockfish were performed in 1989, 1990, 1993, 1997, 2000, 2003, 2005, and 2007 (Hightower and Lenarz 1989, 1990; Rogers and Lenarz 1993; Ralston and Pearson 1997, Williams *et al.* 2000, He *et al*. 2003b, He *et al*. 2006a, He *et al*. 2007). In 1989 the assessment involved the use of both cohort analysis and the Stock Synthesis program (Methot 1998). In 1993 and 1997, the age-based version of the stock synthesis program was used to assess the status of widow rockfish. In 2000, 2003, and 2005, the assessment of widow rockfish was implemented in ADMB software (Otter Research, Ltd. 2001), and applied an age-based analysis of the population with methods very similar to those used in the Stock Synthesis program. A full description of the ADMB model can be found in the previous assessment documents (He *et al*. 2003b and He *et al*. 2006a). In 2007, an update of the 2005 assessment was conducted (He *et al*. 2007a). The current assessment uses the Stock Synthesis program (SS3) (Version 3.03a, Methot 2009). A comparison between the ADMB-based assessment and an SS2-based model was conducted in November 2007, and it showed that the results between two programming approaches were very similar (He and Methot, Appendix B).

In the 2000 assessment, a starting year of 1968 was chosen based on the assumption that the 1965 year class was the earliest recruitment which could be reasonably estimated given a starting year of 1980 for the age composition information. The model tracked numbers and catches of male and female widow rockfish in age classes 3-20 (age 20 is an age-plus group). In the 2003 assessment, the starting year was extended backward to 1958 because the new landing data from 1966 to 1972 were added. Recruitment estimates prior to 1958 are assumed equal to the 1958 estimate in the model, so that the model is estimating recruitment at age 3 for the years 1958-1999. The same time frame was used in the 2005 and 2007 assessments.

2.4.1 Response to the 2002 STAR Panel recommendations

The last full assessment was reviewed by the STAR Panel in August 2005 (STAR Panel Report 2005). Generic recommendations and recommendations for future research are outlined below.

1. Find alternative indices. The recent trawl survey conducted by the NWFSC has been included in the assessment. Although it is not most suitable for widow rockfish, the survey has provided useful information on status of the population. The Panel also recommended hydro-acoustic surveys to be considered, but the technology and survey have not been fully developed.
2. Juvenile survey. As recommended by the STAR Panel and various workshops, the assessment uses the coast-wide surveys conducted by the SWFSC and PWCC/NWFSC vessels.

3. Increase age sample sizes. Sample sizes for widow rockfish ageing have been increased in the most recent years, most notably from the Oregon bottom trawl fishery.
4. Two-area assessment models. Given that there is no evidence that recruitments of widow rockfish between two areas were independent, this assessment still uses a two-area assessment model with linkage of recruitment.
5. Using and comparing the ADMB-based assessment with one done using the Stock Synthesis program. This assessment uses SS3 and comparisons between this assessment and the previous assessment are included in this report.
6. Priors for steepness. This assessment uses general priors developed by Martin Dorn for west coast rockfish. The steepness prior functions developed by He et al. (He *et al*. 2006) were used in the previous assessment. But it was not used in this assessment because it was not implemented in the current SS3 program.

2.4.2 Assessment update in 2007

An update assessment was conducted in 2007 and reviewed by the SCC. Depletion of the widow rockfish population was estimated to be 35.5% (He *et al*. 2007).

2.5 Model description

2.5.1 General

In this assessment, the population model begins in 1916 since the historical catch data from 1916 were provided by the California Reconstruction Project (Ralston *et al*., in review). The data used in this assessment that are also used in the previous assessments include four fishery catch-at-age compositions, landings in weight for each fishery, a midwater juvenile survey index, an Oregon bottom trawl logbook CPUE index, three whiting bycatch indices, and triennial survey indices. The new data sets, those not used in the previous assessments, include a NWFSC trawl survey index, length composition data from the triennial survey, and length and age composition data from the NWFSC survey.

Double-logistic selectivity functions by age were used to estimate female selectivities of each fishery. Selectivities for males were modeled as offsets of female selectivities. Double-normal selectivity was considered for age selectivity, but it was dropped from further consideration because no male offset function has been implemented in the current SS3 program. Experimental runs with no male offsets between double-logistic and double-normal selectivities indicated that the results were similar. Double-normal selectivity functions for length data were used to estimate female selectivities for both surveys along with male offsets.

A constant CV of 0.05 is assumed for catch estimates. Year-specific fishing mortalities are computed for each fishery for those years in which there are landings estimates available. In this assessment, a hybrid fishing mortality estimate was used for all fisheries (SS3 documentation, Methot 2009). Catchabilities for all indices, including fishery-dependent and -independent indices, were estimated in the model.

2.5.2 Natural mortality

Natural mortality (M) is assumed to be constant for all ages and in all years. In the 2003 assessment, the initial model estimated a slightly higher natural mortality for males than females based on the observation that there were more old females than males in the age data. The model was presented to the 2003 STAR Panel. It was noted that greater proportions of males at younger ages could be due to differences in selectivity by gender. The 2005 STAR Panel requested that natural mortality be estimated in the model. After a series of model runs, it was decided natural mortality should be fixed at 0.125 for the assessment model. In this assessment, the same natural mortality rate (0.125) was used.

2.5.3 Age compositions

The age data are modeled as multinomial random variables, with the year-specific sample sizes set equal to the number of samples collected, rather than the number of fish which often overstates the confidence of the data (Quinn and Deriso 1999). However, this assessment also examined an iterative reweighting method (model tuning) to determine the effective sample size in the likelihood functions (details in the model turning section).

The only information available for determination of ageing error was based on two point estimates of percent ageing agreement from the last two assessments (Rogers and Lenarz 1993; Ralston and Pearson 1997). From the previous assessments an estimate of 75% agreement for age 5 fish and 66% agreement for age 20 fish was modeled by assuming a linear relationship of percent agreement with age. These estimates of percent agreement at age were then fit to a set of age-specific normal distributions, which approximated the level of ageing agreement. The resulting matrix of true age versus reader age was then modeled in the past assessments:

$$A_t = EA_r$$

where A_t and A_r are n*n matrices for true age and reader age, respectively, n is number of age classes, and E is a n*n matrix for ageing error with the sum across each column equal to one.

Because the SS3 program does not accept ageing error matrices as inputs, standard deviations of ageing error for each age were computed from the ageing error matrix.

2.5.4 Proportion of recruitment to northern area

Since area-specific (north and south) growth and maturity is evident in widow rockfish, the population has been assessed using two-area models since 1989. The key component for the two-area model is how to allocate recruits of each year to each area. In all previous assessments, the proportions of recruitments to each area were determined by using averaged proportions of domestic landings by each area. Specifically, we used the sum of the domestic landings in the Vancouver-Columbia and both Oregon trawl fisheries relative to the total landings as an estimate of the proportion of recruitments to the northern area (He *et al*. 2006a). Figure 15 shows the proportions and moving averages of landings to the northern area that were used in the 2007 assessment.

In this assessment, the proportion of recruitment to the northern areas was estimated in the model. Annual deviations of the estimated proportion were also analyzed between 1978 and 2003 as a sensitivity analysis since age-composition data were available during that time period.

2.5.5 Discards and bycatch

The discards of widow rockfish are virtually unknown in most years. Age compositions of discards and landings can be very different (typically smaller fish are discarded) and can be important in determining discard rates (Williams *et al*. 1999). In the past assessments, a value of 6% of total weight was assumed for the years 1958-1982 and 16% of total weight for the years 1983-2006 (Hightower and Lenarz 1990, Williams *et al*. 2000, He *et al*. 2003b). The 16% estimate of discards is based on a dated study by Pikitch *et al*. (1988), which indicated most of the discards of widow rockfish were induced by regulations. The earlier 6% estimated is based on an ad hoc adjustment of the 16% estimate by previous assessment authors (Hightower and Lenarz 1990). The 16% assumed discard rate has likely become more uncertain in recent years due to changes in regulations.

Since the last assessment update in 2007, estimates of bycatch for the at-sea processing vessels (ASP) have been provided by the NWFSC (Table 3). Since no age or length composition data are available from these sources of bycatch, estimates of selectivities for these catches cannot be made. These bycatch amounts were added to the total catches of the two northern fleets (Vancouver-Columbia fishery and Oregon mid-water trawl).

2.5.6 Logbook and bycatch indices

The Oregon bottom trawl logbook indices and whiting bycatch indices are treated as biomass indices and are estimated in the model with a catchability parameter estimated for each index. Because there were no new data since the 2003 assessment, the same Oregon bottom trawl logbook indices from the 2002 assessment are used in this assessment. The whiting bycatch indices are recalculated according to the 2003 STAR panel recommendation. Details regarding the calculations of the whiting bycatch indices using Delta-GLM methods are in Appendix A of the 2005 Assessment.

2.5.7 Survey indices

Three survey indices are used in the assessment: the midwater juvenile trawl survey, the triennial trawl survey, and the NWFSC trawl survey. The CV for the midwater juvenile trawl survey was fixed during the tuning process and was set to equal to σ_R since the time period of the survey is short and it is the only data series that measures recruitment strength in recent years. The CVs for the other two surveys were set to equal to root mean squared errors (RMSEs) during the tuning process (see below). Time series of all indices (scaled to the mean of each index) were plotted in Figures 16 and 17.

2.5.8 Model tuning

An iterative weighting method was used in this assessment for model tuning. In addition, a downweighting of composition data developed by Francis was applied in this assessment (Appendix C). The initial sample sizes for age and length composition data were from actual sample sizes or numbers of fish measured, and the initial CVs for each index were derived externally to the model. The first step was to replace sample sizes of length and age composition data with effective sample sizes that include both sample trips and number of fished measured or aged. This method was developed by Ian Stewart of the NWFSC and has been used in other stock assessments. The second step repeated these same procedures. The last step involved applying Francis' method of down-weighting composition data (Appendix C).

Comparisons of time series of spawning outputs, recruitments and key parameters and model outputs are presented in Table 12 and Figures 18 and 19.

2.6 Model selection and evaluation

The initial model used untuned CVs for indices and the original sample sizes of age and length composition data. Many steps were taken during the model selection and evaluation process. These included selection of starting models that had few parameters, e.g. assuming the same selectivities for fisheries and surveys, and no male offsets in selectivities. Alternative definitions of periods of early recruitment and late recruitment were evaluated during the process. Different selectivity functions (such as double-logistic and/or double-normal functions) were also evaluated along with fixing some of the terminal selectivity parameters.

2.7 Responses to STAR panel requests

- Date Requests 1, 2, and 3: These requestes include splitting Oregon catches prior to 1983 out of the Washington fishery, providing new estimates for Vancouver-Columbia for 1916 to 1976, and providing discard rates by state and gears from the West Coast observer program for 2002 to 2008 and using total mortality estimates from the same program for 2007 to 2008. These requests were implemented during the Panel review with little effects on the modeling results.
- Date Request 4: Providing a graph of the abundance indices scaled to their own average for a common time period so that they are on a similar scale. The request was implemented in Figures 15 and 16.
- Modeling Request 5: Reset all effective Ns using Stewart's method with number of trips and number of fish for fisheries; for the surveys, use Stewart's method with the number of positive hauls. Do the re-tuning with effective N multipliers for the composition data sets, rather than adjusting each individual year. This request was implemented during the Panel review and used in the setup of the base model for this assessment.
- Modeling Request 6: Provide a run with one asymptotic length-based selectivity for all surveys, genders and areas combined. Also provide a run with separate asymptotic length-based selectivity curves for each survey, but combining genders and areas. The first part of this request deteriodrated the model fit and resulted in unreasonable selectivities. The second part of the request (one selectivity for each survey) resulted in more stable model and was used in the base model.
- Modeling Request 7: Provide a run with the abundance index for juveniles up-weighted and the age and length compositions down-weighted. This run resulted in a close fit to the juvenile abundance index. The down-weighting of the age and length composition data were later incoporated in the base model.
- Modeling Request 8: Provide a new base case using the Francis multipliers applied to the N-multipliers from the last re-weighted run. This request was implemented in the base model (also see Appendix C).
- Modeling Requests 9 to 11: These requests include using h=0.25 and h=0.55 to bracket the uncertainties, providing runs with the proportion of recruits to the northern area at 0.68 and 0.80, and providing a likelihood profile on steepness. These requests were conducted during the Panel review and included in this report.
- Modeling Request 12: Examine the contribution of age 1 male of Oregon mid-water trawl in 2007 to the total likelihood. Examining the model fit indicated relatively large likelihood value from this datum point (=0.71). This is because the Pearson residual tends to be large when expected values are near zero even with small observed values. In this case, one fish of age 1 was observed.
- Modeling Request 13: The original report presented to the STAR Panel shows stacked fishing mortalities by area. Provide different graphs for northern and southern areas. A new graph that shows fishing mortalities by area is included in this report.

- Provide a run with single area model re-combining the Triennial and NWFSC surveys into one series and the age compositions. If results are significantly different, try to explain the differences. This request will be examined in the next assessment.

2.8 Base case model results

Results from the base model run are presented in Tables 13 to 15 and Figures 20 to 52. Overall, time series patterns of biomass, spawning output, recruitment, and depletion are similar to those in the 2007 assessment. The trends were also very similar between the northern and southern areas (Figure 20). Spawning outputs showed steep decline in the early 1980s and almost continuous decline until the early 2000s (Figure 21). However, spawning outputs have shown an increasing trend in recent years. Depletion in recent years has been in the precautionary zone, with the lowest depletion of 27.39% in 2003 (Figure 22). The 95% confidence intervals of depletion for the most recent years were wide and ranged from below the overfished level to above the target biomass level of 40% of initial biomass (Figure 22). This suggests that there is high uncertainty in estimates of recent year depletion levels.

The stock-recruit relationship and recruitment deviations are presented in Table 14 and Figures 23 to 26. The input value of the standard deviation of log recruitment (σ_R) is 0.6, which is about 10% higher than the estimated RMSE value of 0.485 in the base model. Like many other rockfish species, recruitment of widow rockfish has been highly variable. The estimated steepness is 0.4061, suggesting this species is not very productive at low abundance. This value is low compared to the prior expected value of 0.721 compiled by Martin Dorn for west coast groundfish species (Martin Dorn, personal communication). It is also important to point out that recruitment of widow rockfish has been very low in recent years. The 2007 assessment indicated that there was a strong recruitment in 2000 (He *et al*. 2007a), which is not the case in this assessment. More discussion regarding estimation of recent year recruitments is in the section describing sensitivity analyses.

A time series of fishing mortalities is presented in Figure 27. Fishing mortalities were very high between 1980 and the early 2000s, and have been very low in recent years due to management regulations.

Model fits to indices are presented in Figures 28 to 36. The fits to these indices were generally good. The CVs for both the triennial and NWFSC surveys were large, mainly because few widow rockfish were caught in these surveys.

Estimated selectivity curves for four fisheries and all surveys are presented in Figures 37 to 42, and residuals from model fits to age and length compositions are presented in Figures 43 to 52. Patterns of age selectivity curves for four fisheries (Figures 37 to 40) were very similar to those in the past assessments, even though selectivities of male offsets were applied in this assessment. Residuals of the model fits to age composition data for these four fisheries showed no strong evidence of lack of fit to the data (Figures 43 to 48). Some residuals were large (e.g. male age 1 fit in 2007 of the Oregon mid-water trawl fishery in Figure 44). This is because the Pearson residual tends to be large when expected values are near zero even with small observed values. In this case, one fish of age 1 was observed. Estimated length selectivity curves for the triennial surveys in both northern and southern areas are plotted in Figures 41 to 42. Residuals of the model fits to the age and length composition data for all surveys fit relatively well (Figures 47 to 52). Model fits for all age and length composition data are provided as Appendix C.

2.9 Uncertainty and sensitivity analyses

2.9.1 Sensitivity analyses

A set of sensitivity analyses were performed to test model assumptions and to explore uncertainty in estimations of key model parameters (see also the likelihood profile section). During the model set up and the STAR review, the following three parameters to be included in sensitivity analyses: (1) recruitment distribution parameters to be estimated annually between 1978 to 2003, as compared to one parameter to be estimated in the base model; (2) using no *h* prior; and (3) CV for juvenile survey to be fixed at 0.2. Results of these sensitivity analyses are presented in Table 16 and Figures 53 and 54. Overall, model outputs from these runs were similar.

A detailed comparisons of key parameters and model outputs between the base model and two fixed proportions of recruitments to the northern area (0.6875 abd 0.75) were presented in Table 17 and Figures 55 and 56. It showed the importance of the recruitment distribution. With the range between 0.6875 abd 0.75, the stock was less depleted if less recruits were distributed to the northern area. More results of the recruitment distribution are presented in the profile run section.

2.9.2 Retrospective analysis

Retrospective analysis of the base model was performed by using the data only through 2007, 2006, and 2004 (Table 18 and Figures 57 to 58). The results indicated that data from the most recent years (2007 and 2008) had moderate effects on the model outputs. If data from the last two years (2007 and 2008) were not used, the model would show that the population is less depleted (depletion equals to 40.6% in 2007) with the steepness value of 0.535 (Table 18 and Figure 57). It also showed that recruitment in 2002 was higher than that estimated in the base model (Figure 58).

2.9.3 Likelihood profiles

Likelihood profiles for the proportion of recruitment to the northern area, steepness, and natural mortality were provided to investigate their effects on model outputs. These are important population parameters and, more importantly, these parameter estimates are highly uncertain in the assessment given the fact that no reliable abundance data exists in recent years for widow rockfish. Figures 59 to 61 show the likelihood profiles as well as effects of those parameters on the estimated depletion in 2009.

Figure 59 shows that when the proportion of recruitment to the northern area (PRNA) was at 0.75, the stock was most depleted. It is interesting to point out that the estimated PRNA value of 0.717 is very close to the proportions of landings in the northern area during the 1990s (Figure 15), which was used as the proportions of recruitments to the northern area in the previous assessments.

The profile on steepness showed that the stock was more depleted as steepness decreased (Figure 60). All previous stock assessments had shown that steepness of widow rockfish was low even with relatively high priors of steepness applied in the assessments (He *et al*. 2006a). This suggests that widow rockfish might be less productive than other rockfish species in west coast waters.

Figure 61 shows the profile of natural mortality (*M*) and related depletion of the stock in 2009. The likelihood profile indicates that natural mortality of widow rockfish, with current data and model settings, is most likely to be around 0.125, which was the assumed *M* in the assessment model. The stock was more depleted when *M* was assumed to be higher than 0.125 (most depleted at $M \approx 0.15$). This is because virgin biomass is estimated to be lower with higher *M* values. Consequently, virgin biomass is estimated to be higher with low *M* values.

2.9.4 Comparisons between this assessment and the past assessments

Comparisons of spawning outputs and recruitments between this assessment and the past assessments (2000, 2003, 2005, and 2009) are presented in Figures 62 and 63. Comparisons of key parameters between this assessment and the 2007 assessment are presented in Table 19. Overall, the patterns of time series of spawning outputs were similar among all assessments, which show steep declines in the early 1980s, and steady declines from the middle 1980s to early 2000s. Comparisons of the time series of recruitments estimated by all assessments also showed similar trends (Figure 63).

However, there some differences between this assessment and the 2007 assessment. For example, the 2007 assessment indicated much higher virgin spawning output than the current assessment (Figure 62). The higher virgin biomass in the 2007 assessment could have been the result of a relatively short catch history or that no recruitment bias-adjustment was applied in the assessment, or both. The 2007 assessment also indicated much higher recruitment in 2000 (Figure 63), which resulted in a projection of stock recovery within two years (see the rebuilding analysis, He *et al*. 2007b).

3 Rebuilding parameters

A separate rebuilding analysis will be conducted since the widow rockfish has been overfished**.**

4 Reference points

Virgin spawning output for widow rockfish is estimated to be 40,547 million eggs. The current depletion is 38.5% of the virgin spawning output. The management target for widow rockfish is 40% of virgin spawning output (16,218 million of eggs). The time series of estimated equilibrium spawning potential ratio (SPR) is shown in Figure 64. A phase plot of annual equilibrium SPR relative to its target and estimated spawning output relative its target is shown in Figure 65. An equilibrium yield curve is plotted in Figure 66.

5 Decision table

Decision table of 12-year projections with two alternate states of nature is presented in Table 20.

6 Management Recommendations

The stock has declined since fishing began in the late 1970s. The 2000 assessment showed that the spawning output in 1999 was just below 25% of unfished spawning output. This assessment shows that the spawning output in 2009 is within the precautionary zone and is yet to be rebuilt. Therefore, it is necessary to conduct a rebuilding analysis to determine harvest levels and related risks of not successfully rebuilding the stock by the target year in the rebuilding plan under alternative harvest levels.

7 Research needs

1. There are increasingly fewer reliable abundance indices for widow rockfish. Recent management measures have undermined the ability to continue a fishery-dependent time series of relative abundance from the Oregon bottom trawl fishery and the Pacific whiting fishery since 1999. The constant flux of the management regime suggests that there is little likelihood that meaningful CPUE indices can be developed from these fisheries in the future. The NWFSC combo survey provides some useful information on abundance of widow rockfish, but catches from the survey have been generally very low in recent years. It is desirable that a trawl survey (including midwater trawls) that targets widow like rockfish be initiated. A long-term hydroacoustic survey will also be very useful.
2. The long-term recruitment index is a key time series in the stock assessment. Continuation of the NMFS/PWCC midwater juvenile trawl survey should provide key information on the recruitment strength of widow rockfish.
3. Sample sizes for existing age-collection programs as well as length measurements (by fishery and survey) should be increased substantially.
4. Effort on ageing of widow rockfish should include collecting information on length-age keys and growth rates for both the northern and southern areas.
5. One area assessment model should be considered in the next assessment.
6. Conuduct an interagency ageing comparison and comparative analysis of break and burn and surface ageing methods.
7. Develop methods to incorporate uncertainty in natural mortality and/or steepness in model configurations in which these parameters are fixed. The delta method for propagating uncertainty (MacCall in prep.) is promising approach that warrants further evaluation.

8 Acknowledgements

We would like to thank Richard Methot of the NWFSC for providing extensive help in setting up and running SS3 programs. We would also like to thank Theresa Tsou of the Washington Department of Fish and Wildlife for providing catch-at-age data for Washington fisheries, Mark Karnowski of the Oregon Department of Fish and Wildlife for providing catch-at-age data for Oregon fisheries, Martin Dorn of the Alaska Fisheries Science Center for providing Pacific whiting catch data, Jim Hastie, Beth Horness, Eliza Heery, and Marlene Bellman of the NWFSC for providing recent widow bycatch estimates and survey data, and John DeVore of the Pacific Fishery Management Council for providing the recent regulatory history of widow rockfish. We would also like to thank John Wallace of the NWFSC for running his R programs for analyzing survey data and MCMC analysis, and Ian Taly and Ian Stewart of the NWFSC for revising R4SS programs for multi-area outputs. We would also like to thank the STAR Panel for their throughout review on the assessment.

11 Figures

Figure 1. U.S. catches of widow rockfish by four fisheries from 1916 to 2008. Four fisheries are defined by area and gear type. Bycatches are included. Detail numbers are presented in Table 1.

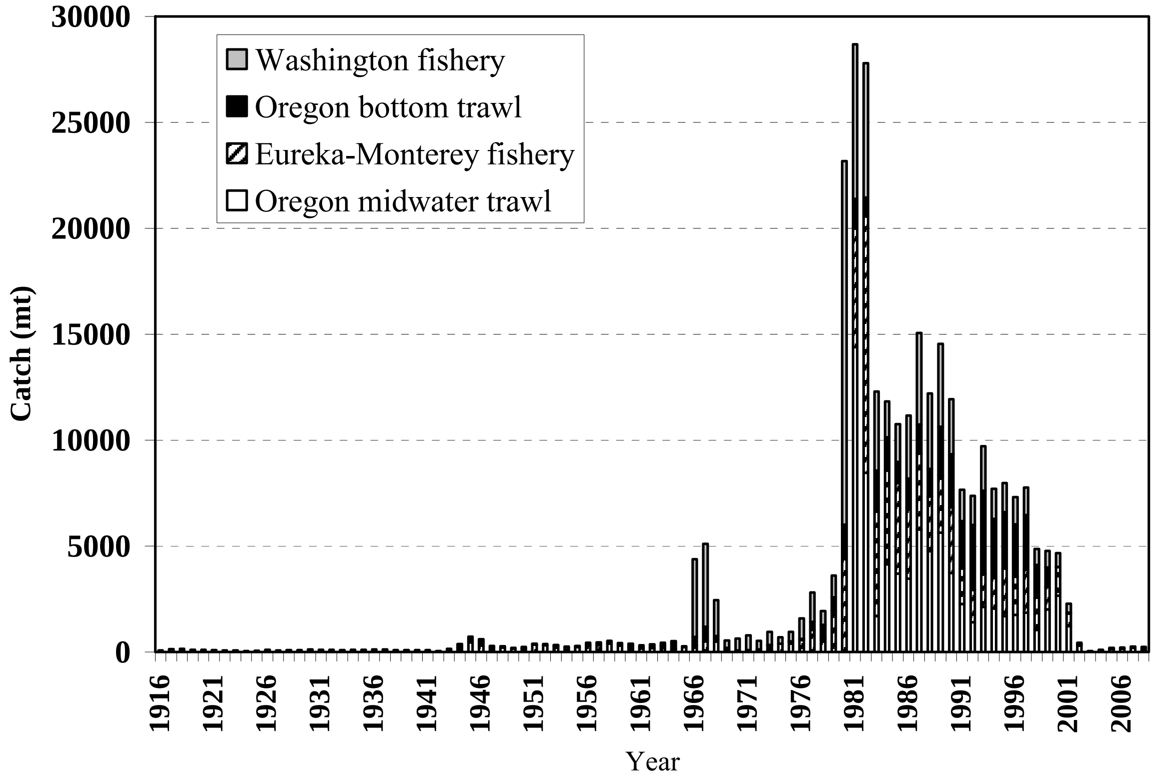

Figure 2. Area map that shows the northern and southern areas delineated by 43° N latitude.

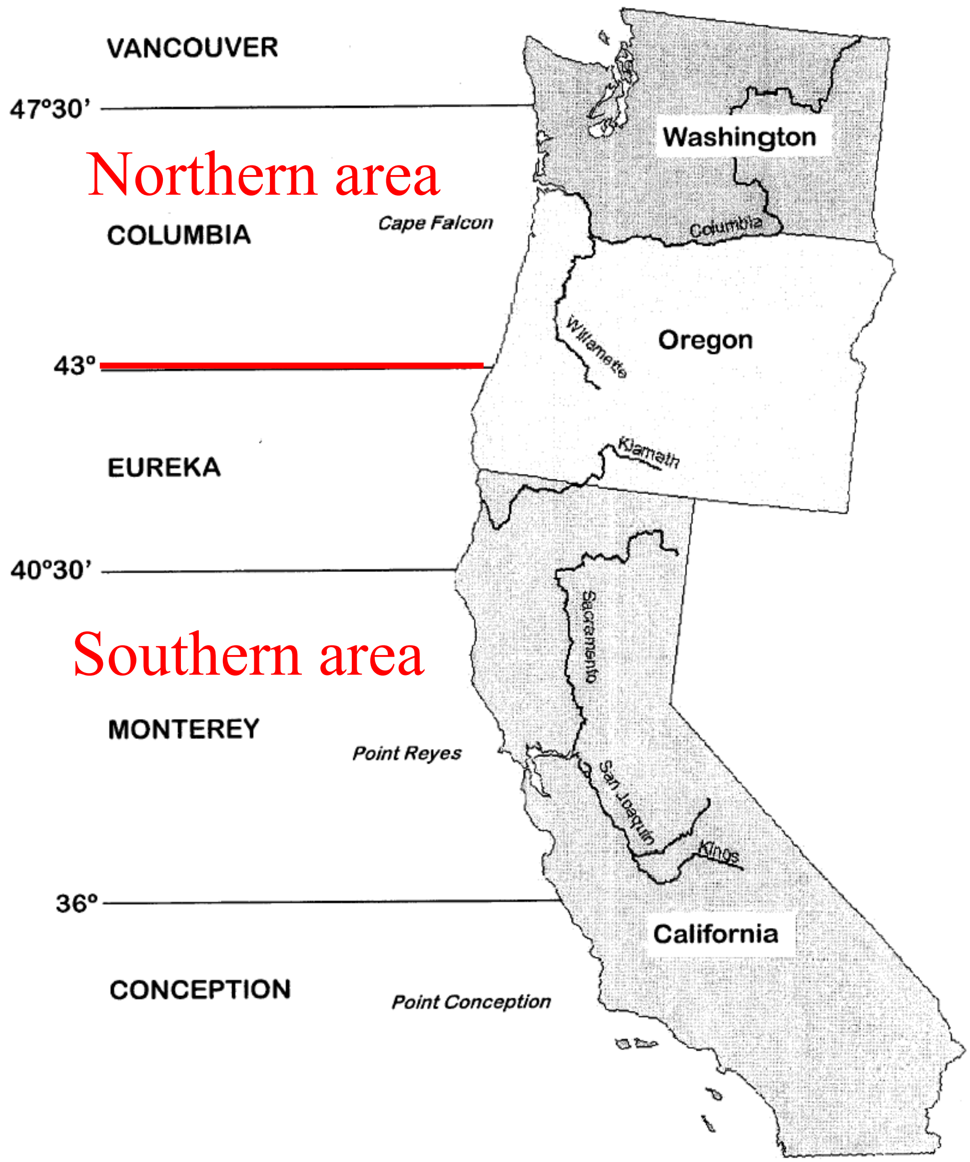

Figure 3. Growth functions for both sexes of widow rockfish for northern and southern areas.

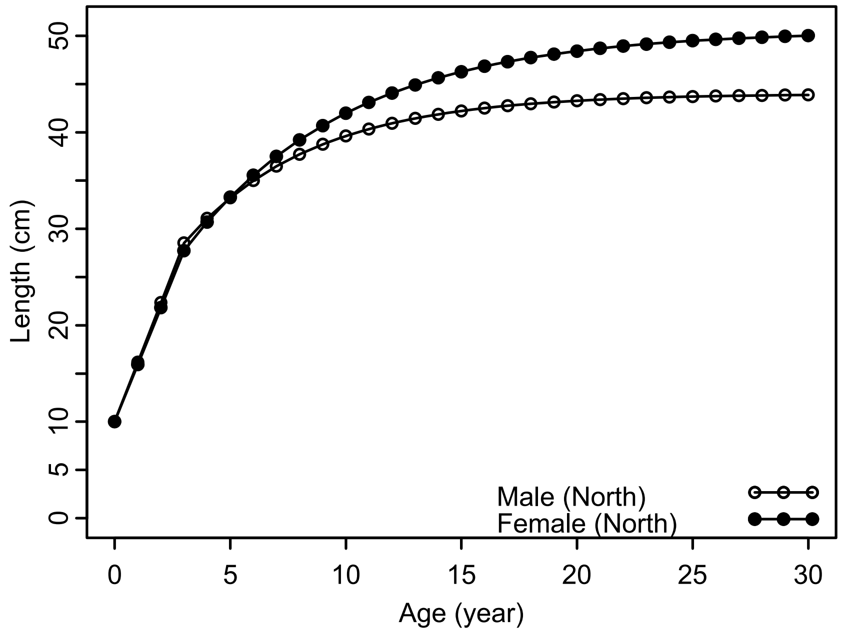

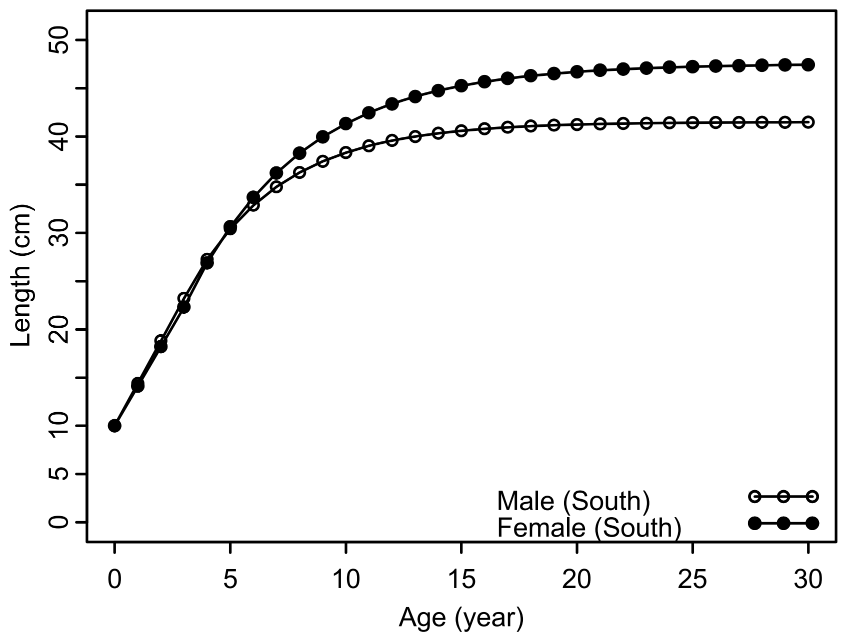

Figure 4. Fecundity of widow rockfish for northern and southern areas.

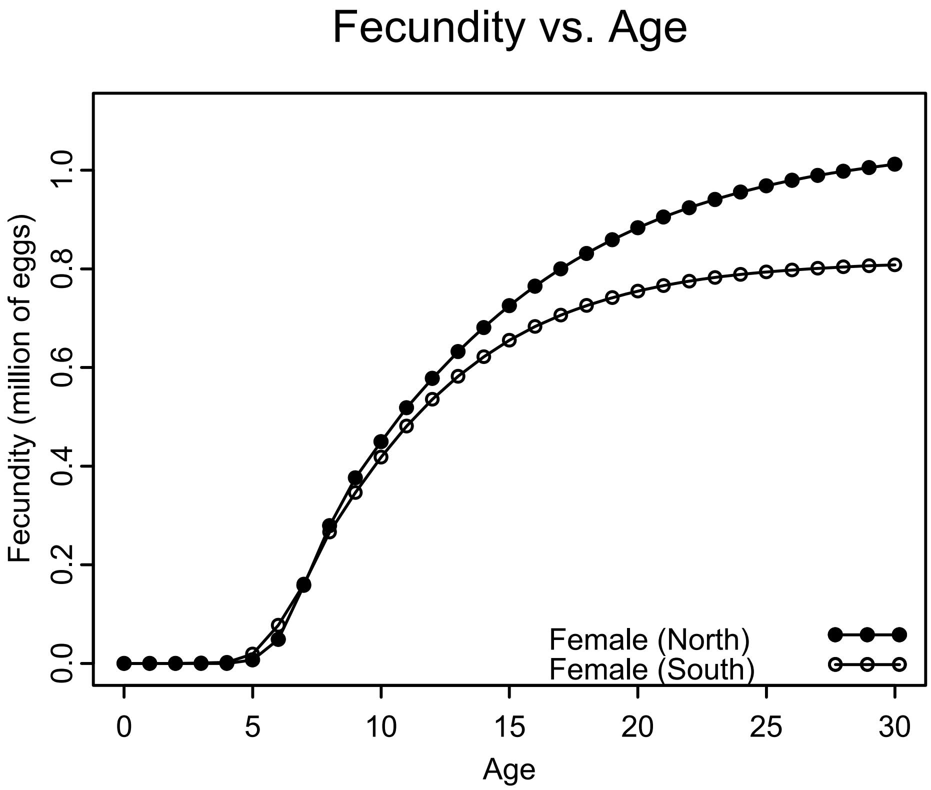

Figure 5. Age composition data from the Vancouver-Columbia fishery from 1980 to 2008.

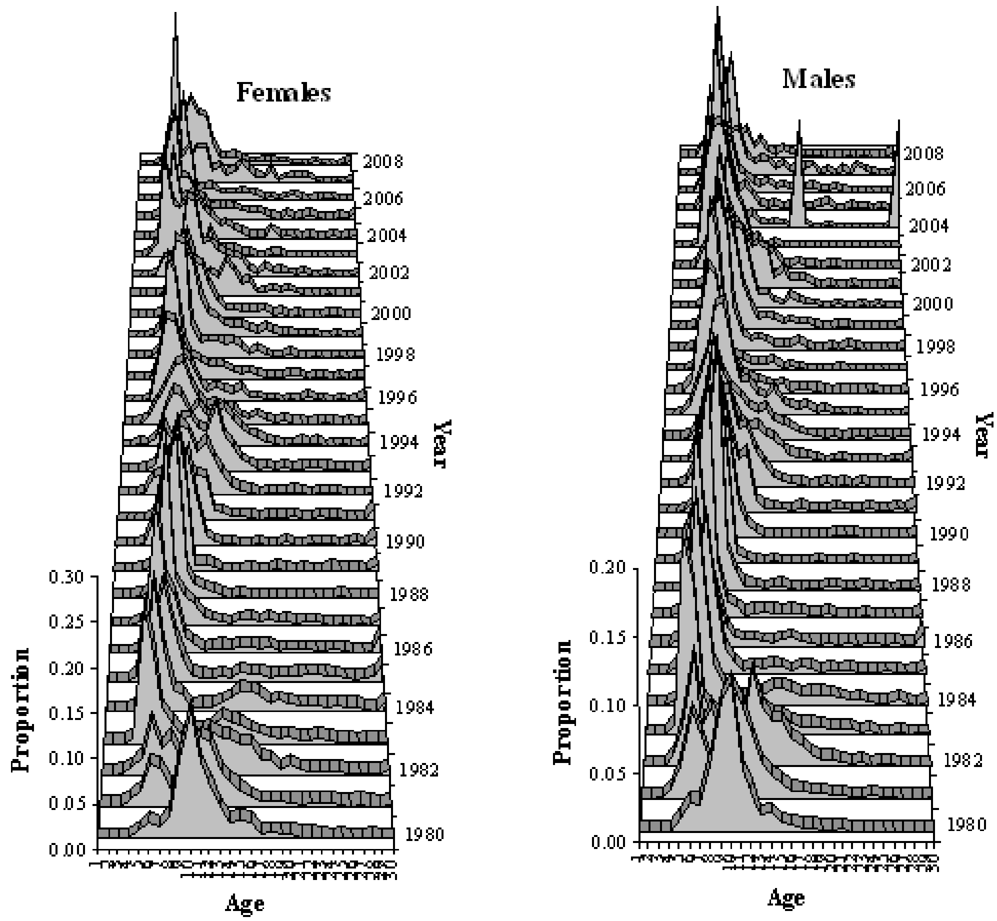

Figure 6. Age composition data from the Oregon mid-water trawl fishery from 1984 to 2008.

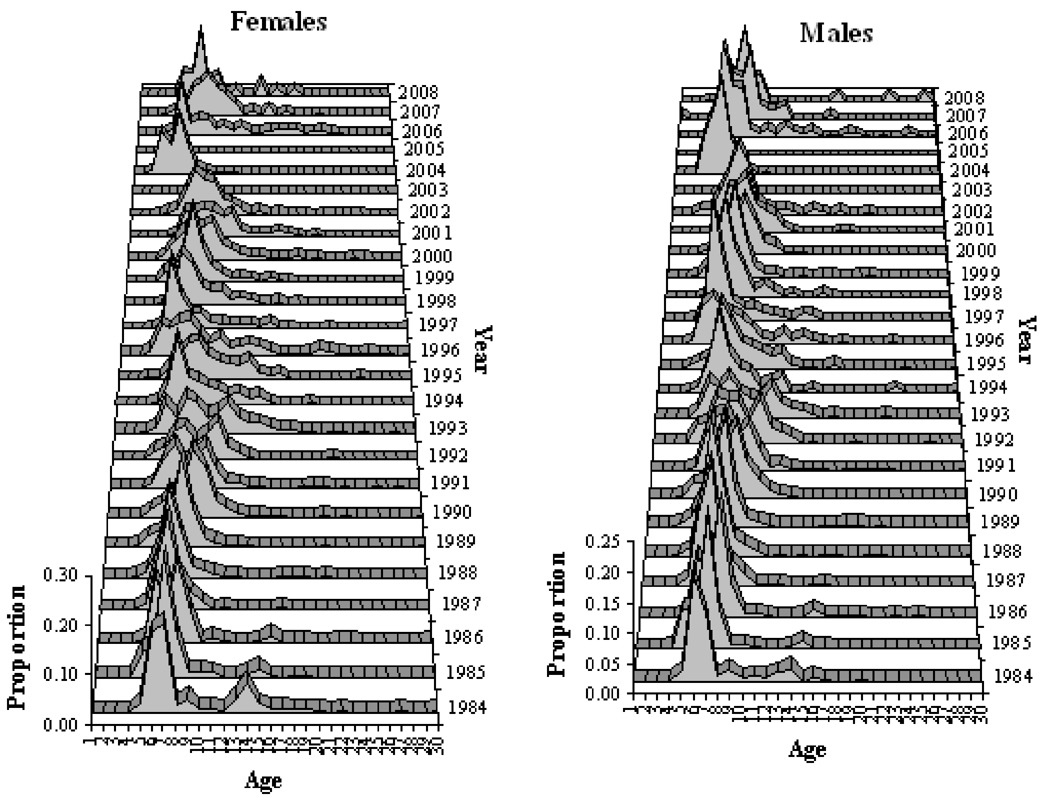

Figure 7. Female age composition data from the Oregon bottom trawl fishery from 1984 to 2008.

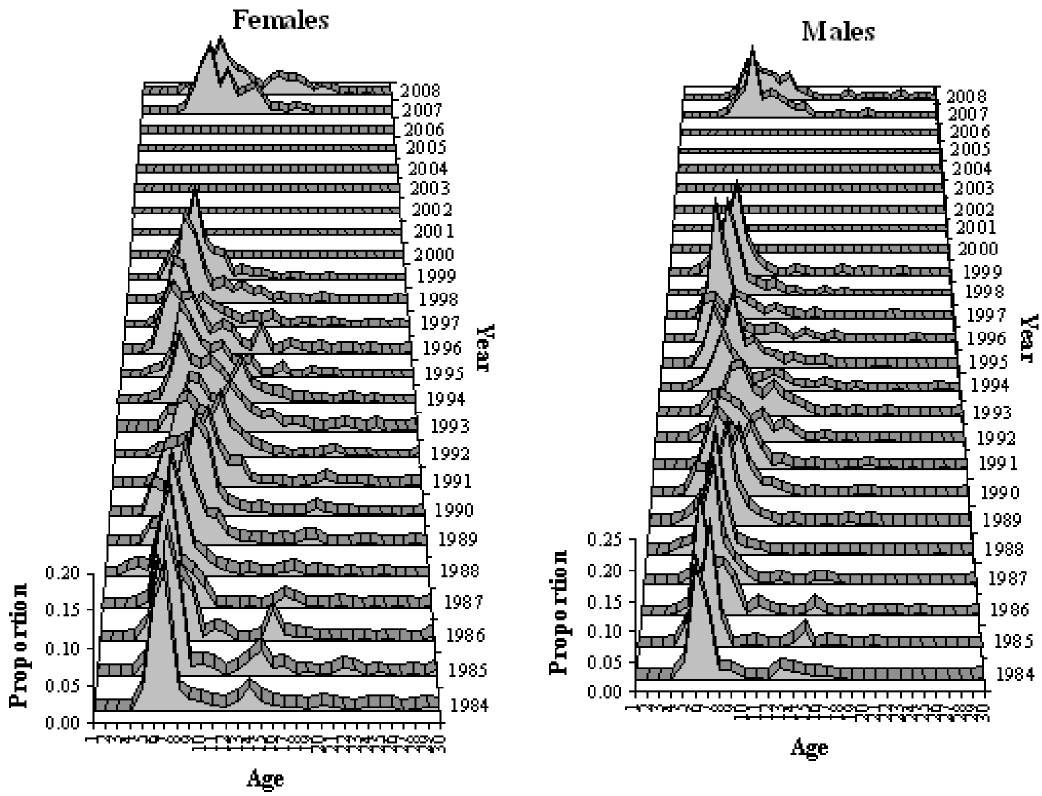

Figure 8. Age composition data from the Eureka-Conception fishery from 1978 to 2008.

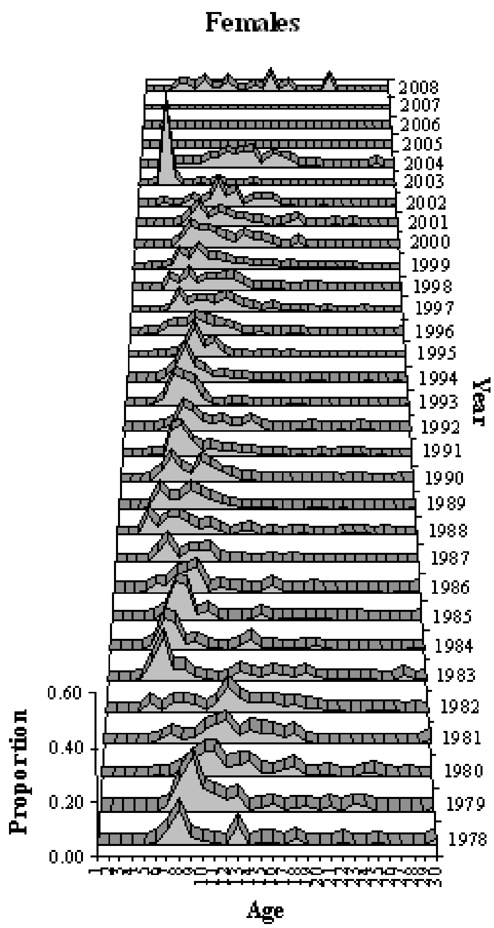

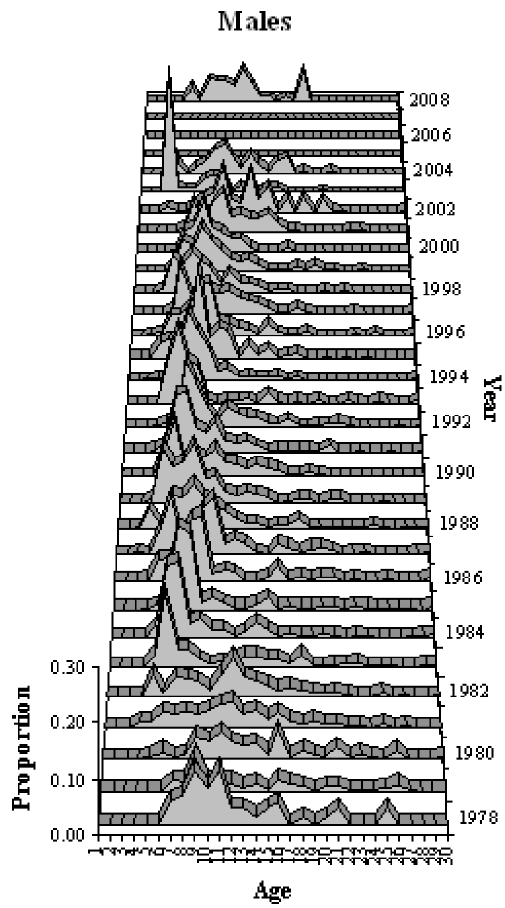

Figure 9. Length composition data from the northern area triennial suvery from 1980 to 2004.

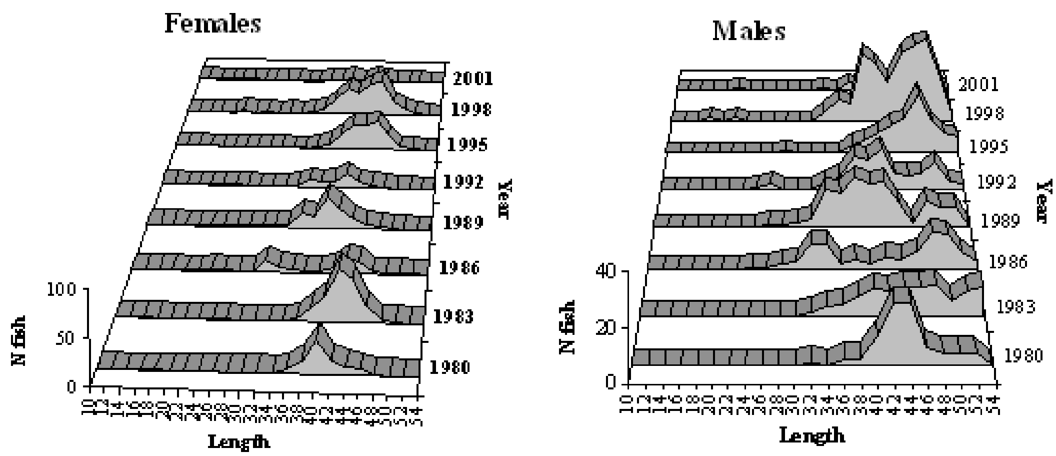

Figure 10. Length composition data for the southern area triennial survey from 1980 to 2004.

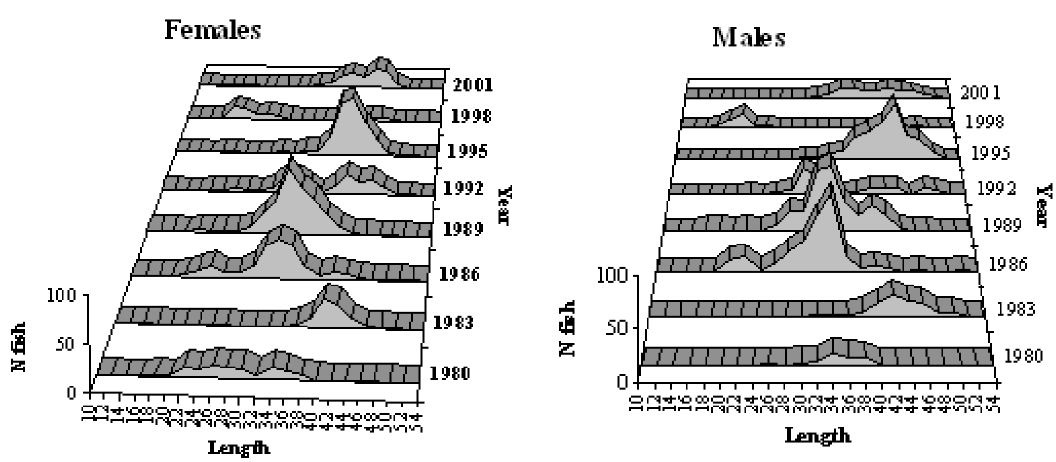

Figure 11. Age composition data from the NWFSC northern area survey from 2003 to 2008.

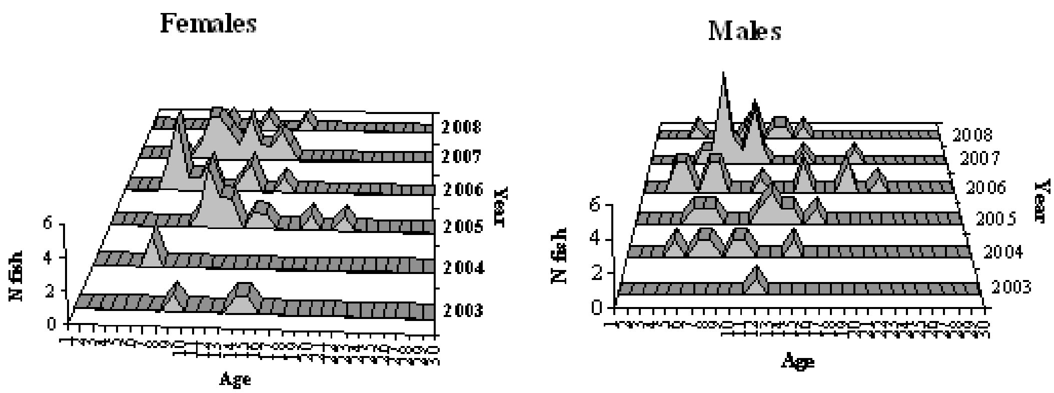

Figure 12. Age composition data from the NWFSC southern area survey from 2003 to 2008.

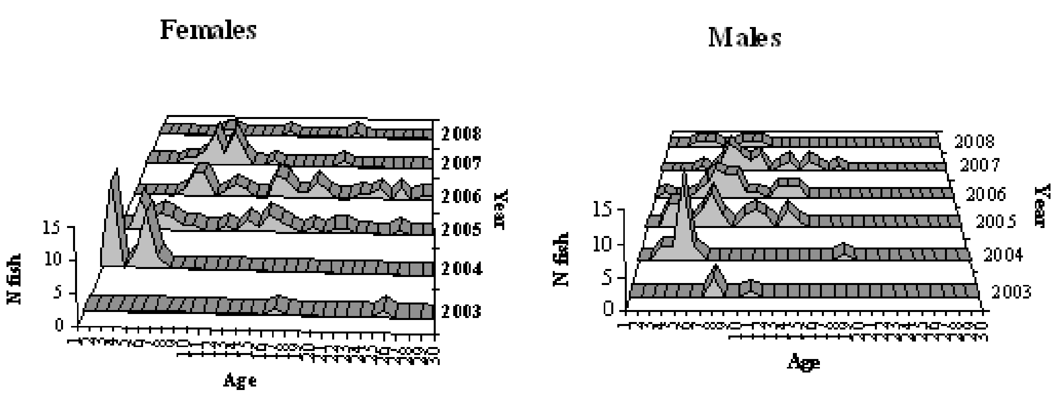

Figure 13. Length composition data from the NWFSC northern area survey from 2003 to 2008.

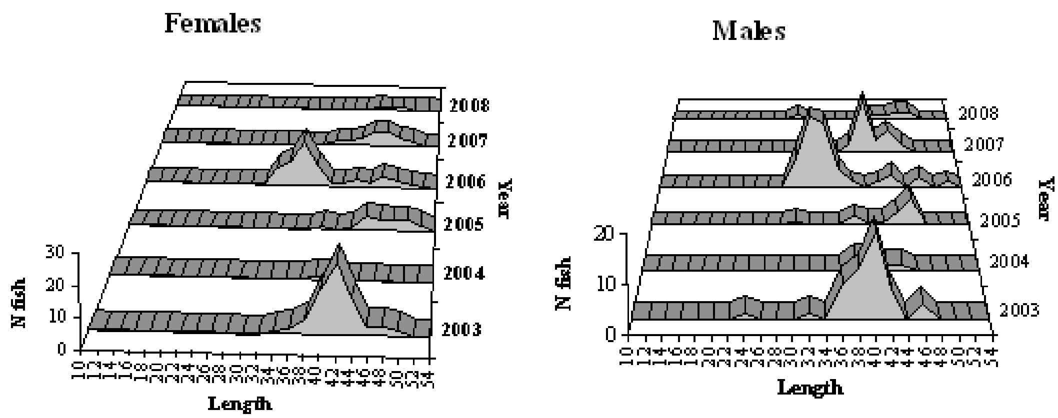

Figure 14. Length composition data from the NWFSC southern area survey from 2003 to 2008.

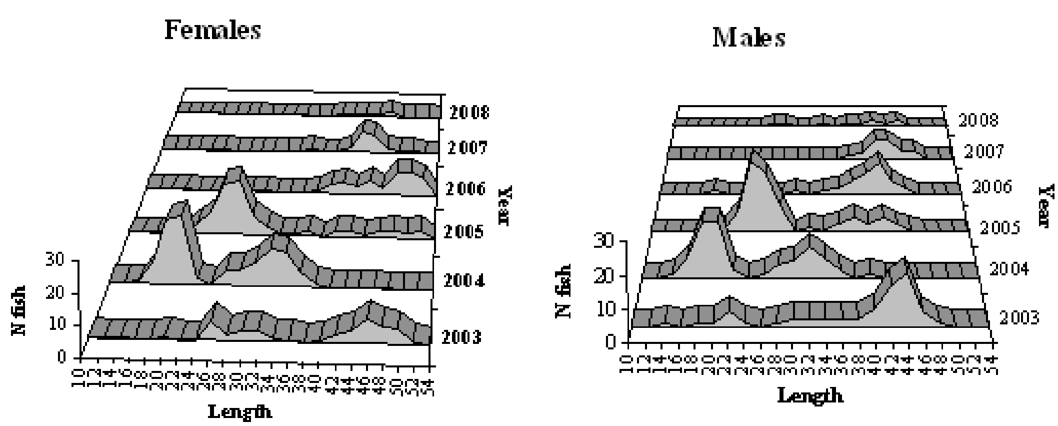

Figure 15. Fraction of landings in the north area, defined as the Vancouver-Columbia and Oregon trawl fisheries, with a 7-year moving average. Note that the fractions before 1977 were fixed at the value computed before the foreign landings (Rogers 2003) were added. This time series of fraction was used in the previous assessments as proportion recruits to the northern area.

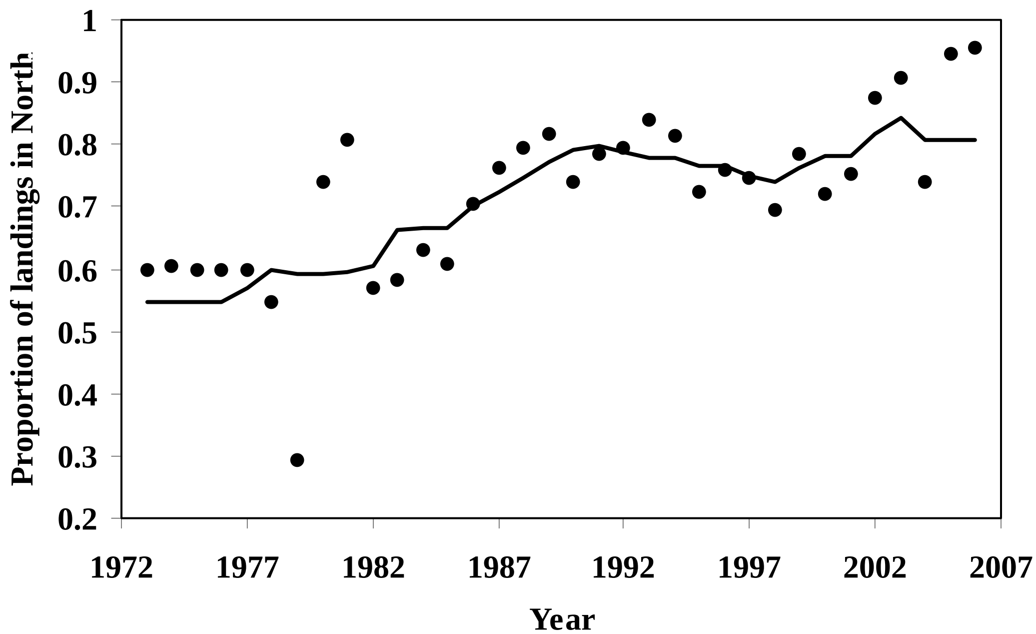

Figure 16. Time series of scaled abundance indicies of the Oregon bottom trawl logbook and triennial survey for the northern and southern areas.

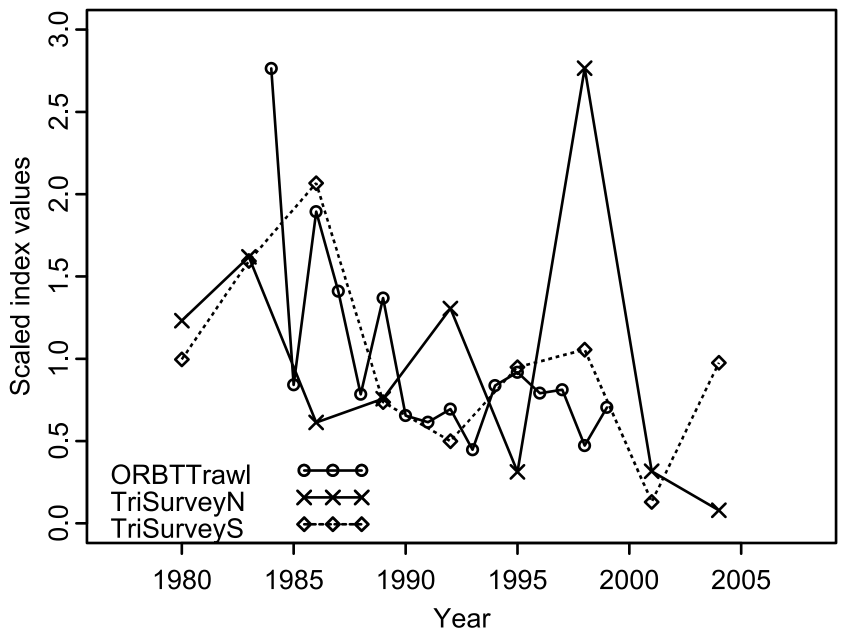

Figure 17. Time series of scaled abundance indicies of three whiting bycatch fisheries (foreign, joint venture, and domestic), and the NWFSC survey for the northern and southern areas.

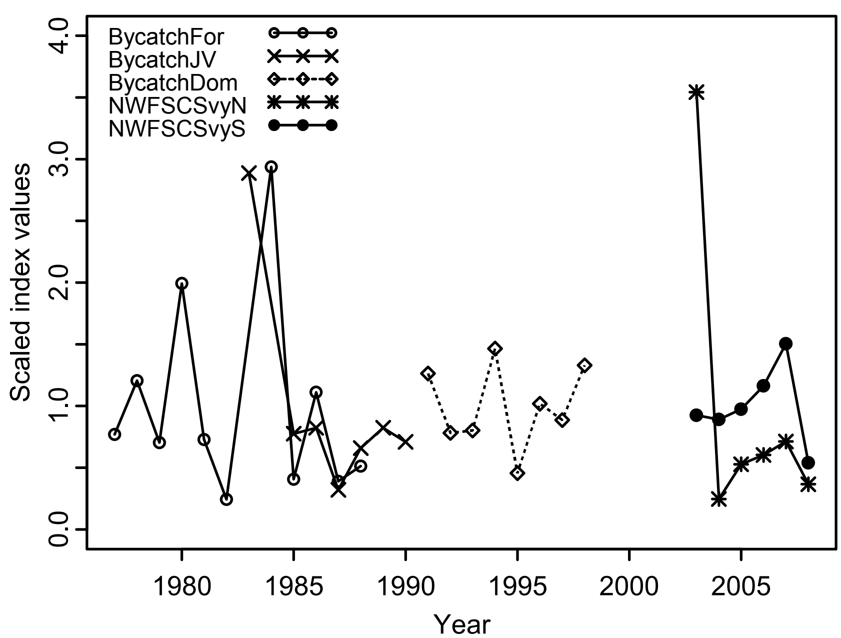

Figure 18. Comparisons of time series of spawning outputs between the reweighted post-STAR model (PostSTARRewet2), the final base model (PostSTARBase), and the pre-STAR base model (PreSTARBase).

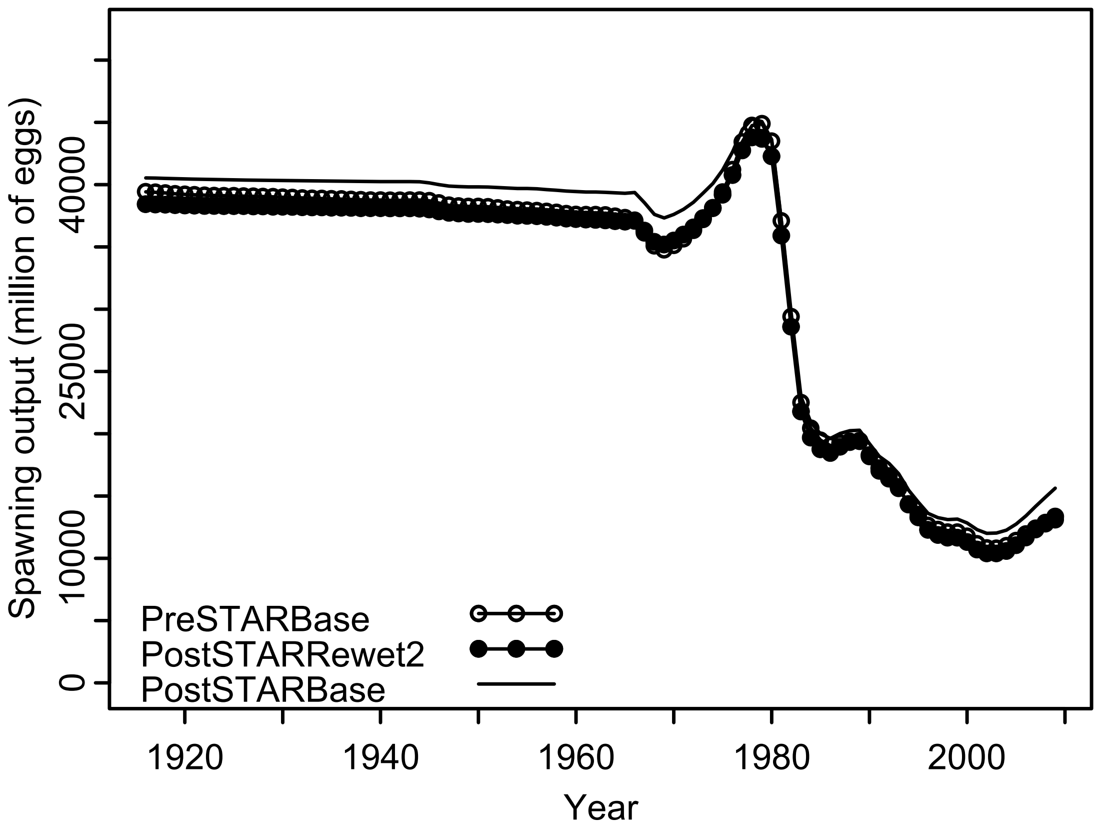

Figure 19. Comparisons of time series of recruitments between the reweighted post-STAR model (PostSTARRewet2), the final base model (PostSTARBase), and the pre-STAR base model (PreSTARBase).

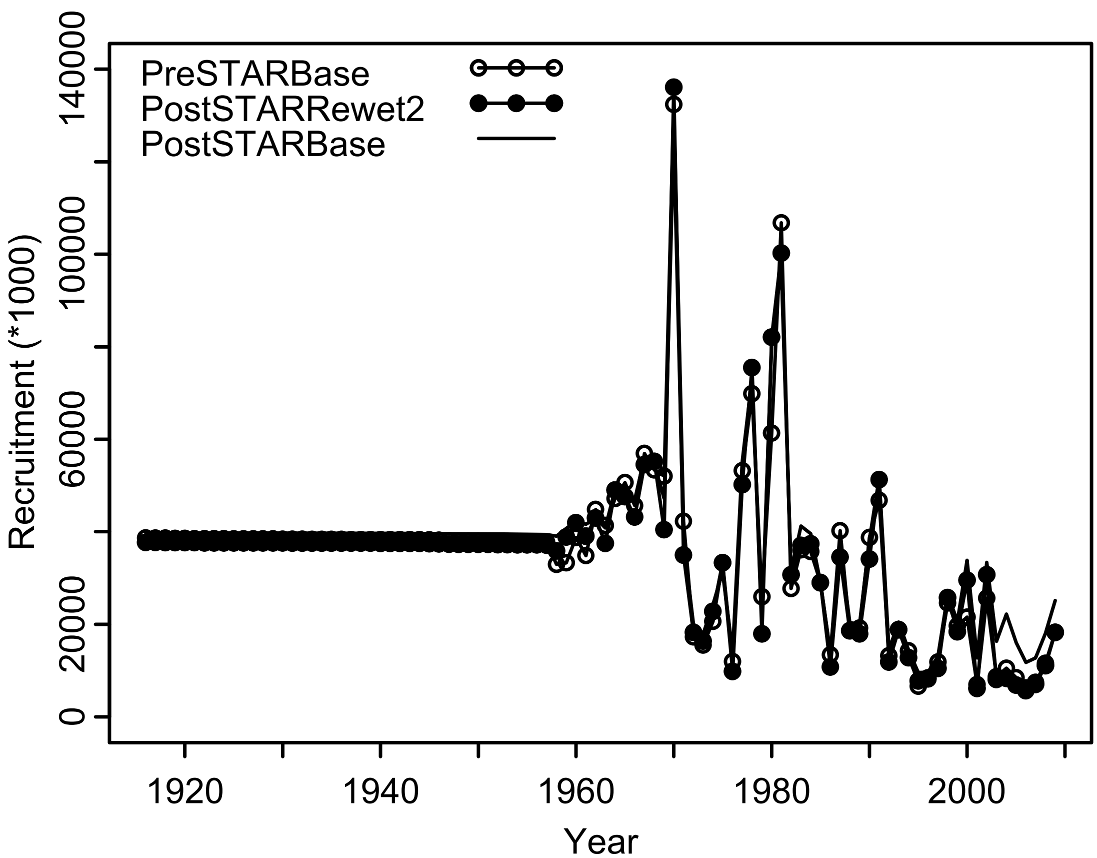

Figure 20. Time series of age spawning output from 1916 to 2009 estimated from the base model for two areas (area1 = northern area, area2 = southern area).

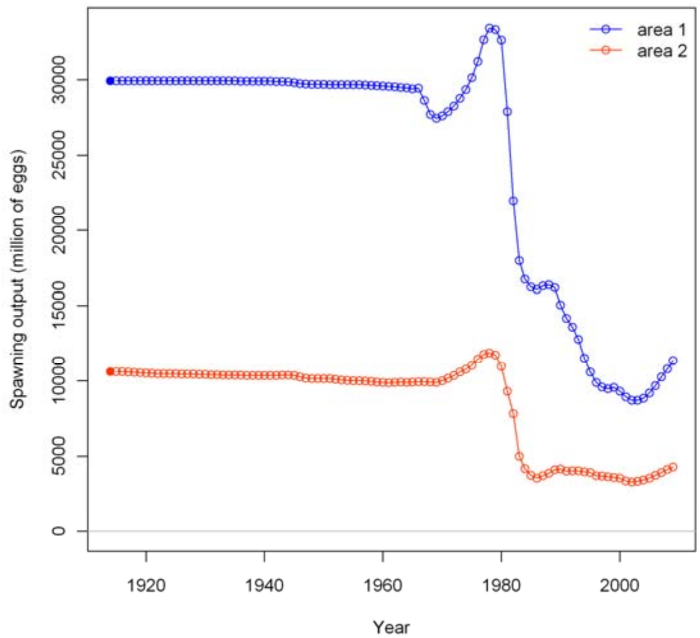

Figure 21. Time series of spawning outputs of the population from 1916 to 2009 with 95% asymptotic intervals estimated from the base model.

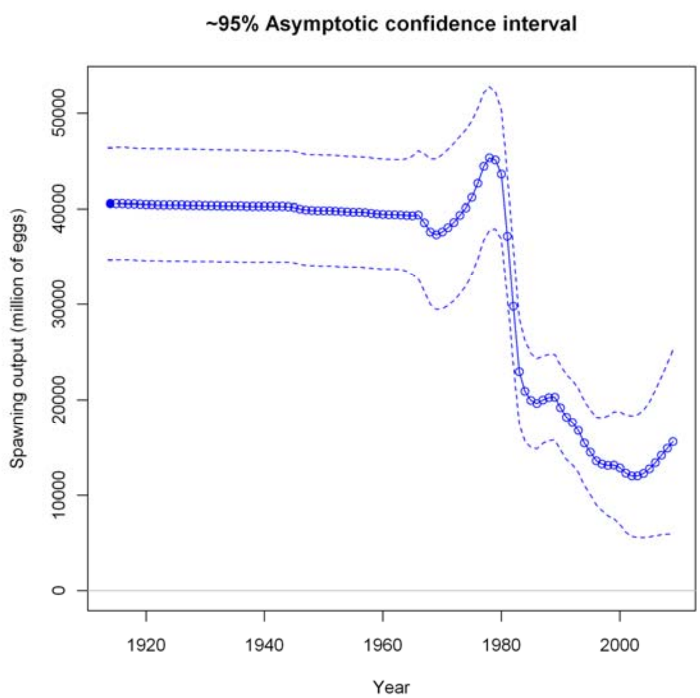

Figure 22. Time series of depletion from 1916 to 2009 with 95% asymptotic intervals estimated from the base model. Levels of management target and minimum stock size threshold are also shown.

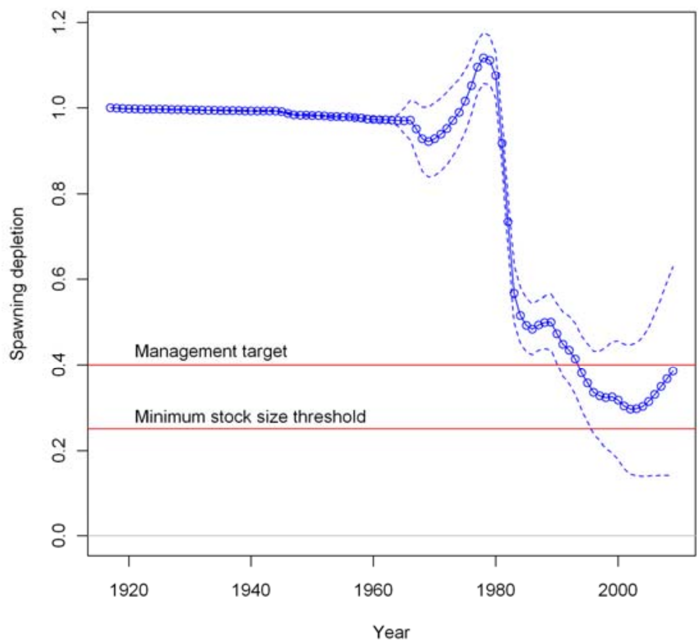

Figure 23. Estimated stock-recruit relationships from the base model (dark line). The expected recruits are bias-adjusted (green line). Open circles are actual recruitment.

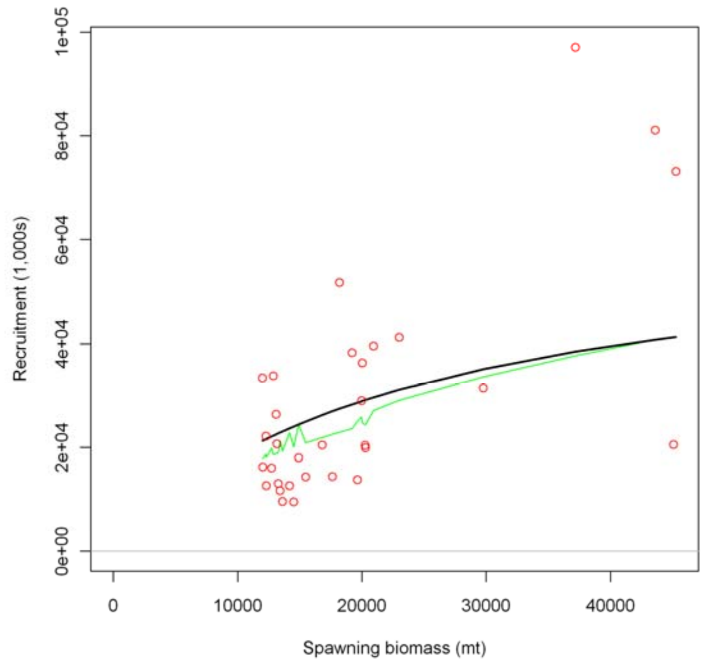

Figure 24. Estimated total recruitment and their 95% of asymptotic confidence intervals from 1916 to 2009 from the base model.

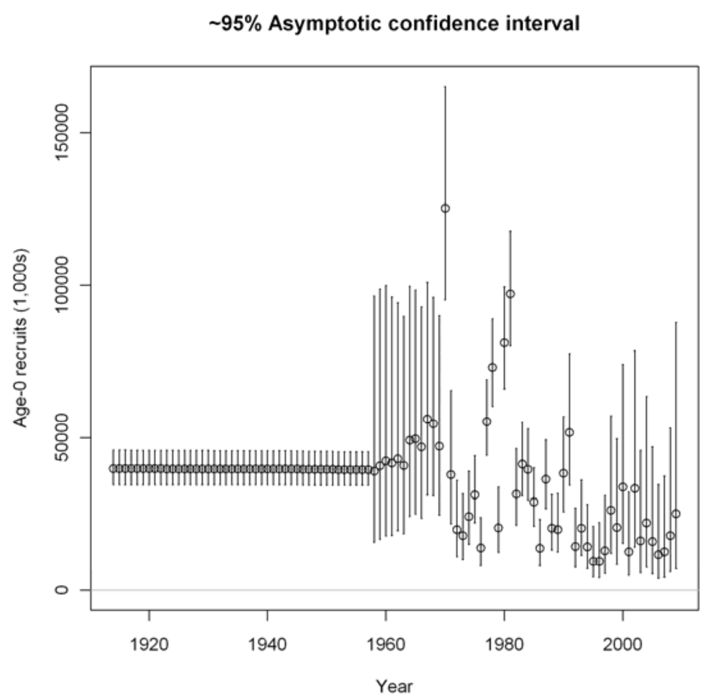

Figure 25. Time series of recruitment estimated from the base model from 1916 to 2009 along with virgin and initial recruitment and bias-adjusted values. Note that the y-axis is in log-scale.

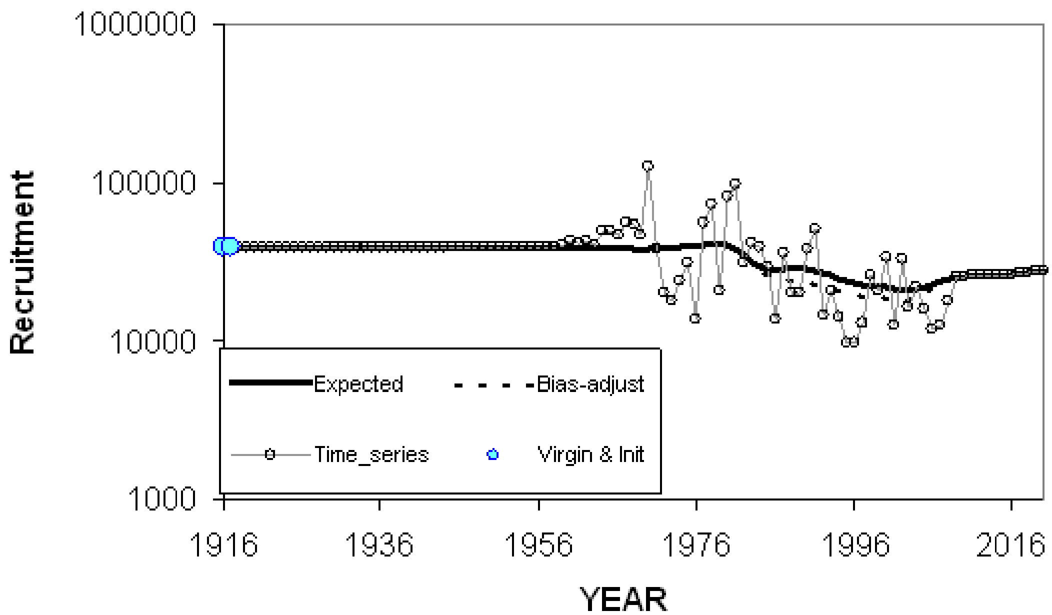

Figure 25. Time series of recruitment deviations estimated from the base model from 1958 to 2008.

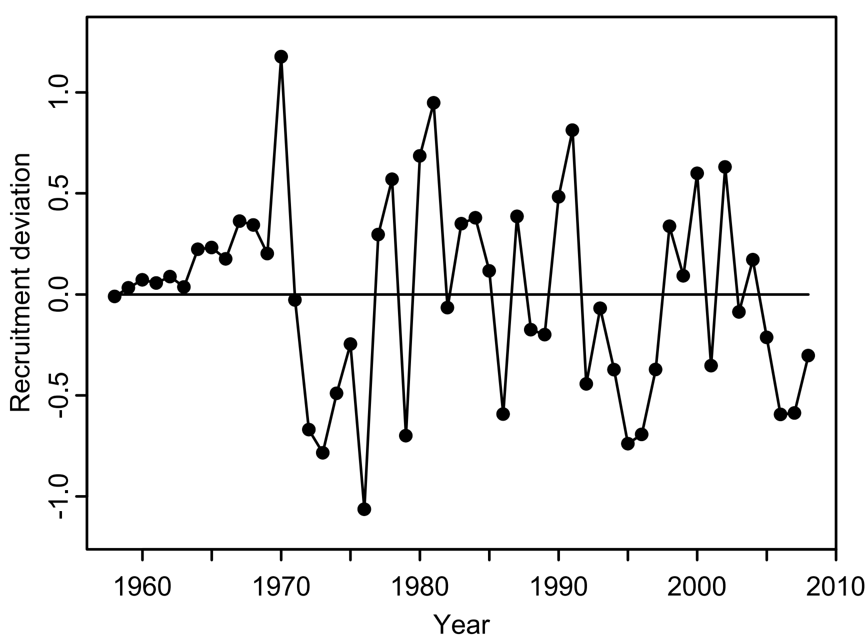

Figure 27. Time series of fishing mortalities for four fisheries in the northern area (top) and in the sourthern area (bottom) from 1916 to 2008.

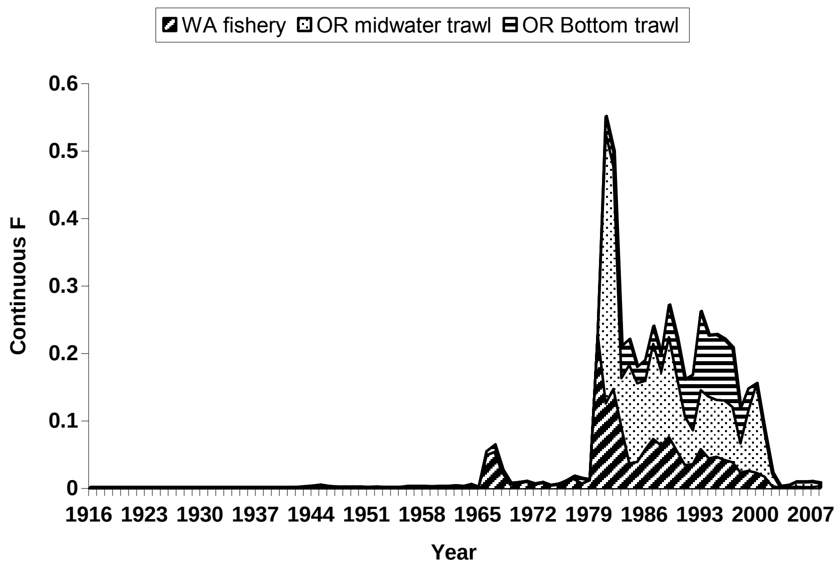

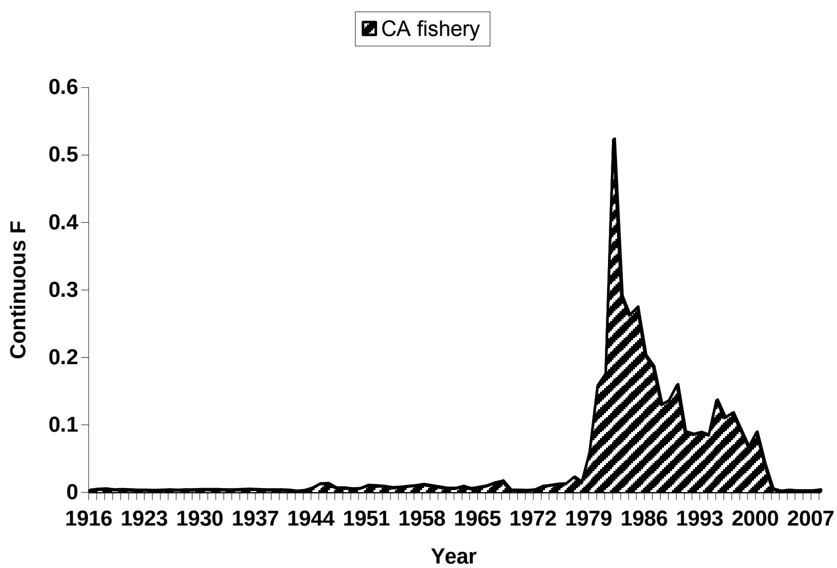

Figure 28. Model fit to the index of the juvenile fish survey from 2001 to 2008.

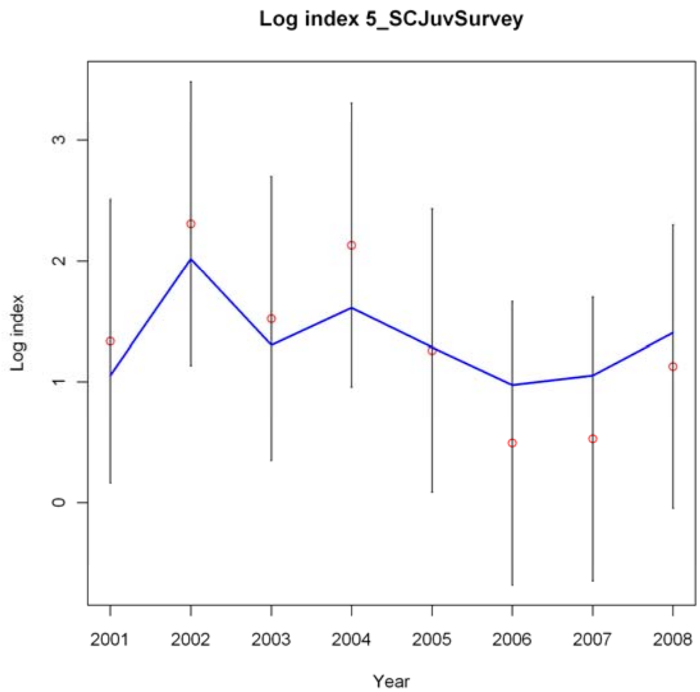

Figure 29. Model fits to the Oregon bottom trawl logbook index.

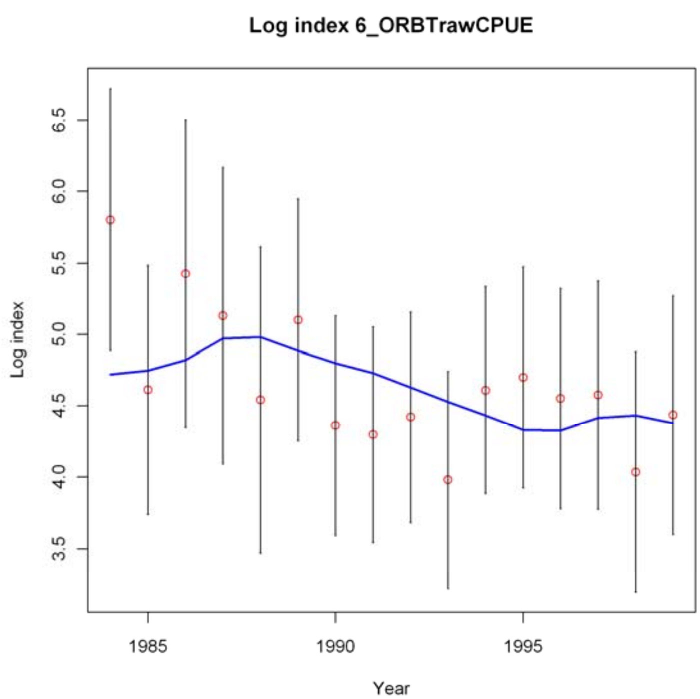

Figure 30. Model fits to the northern area triennial survey index

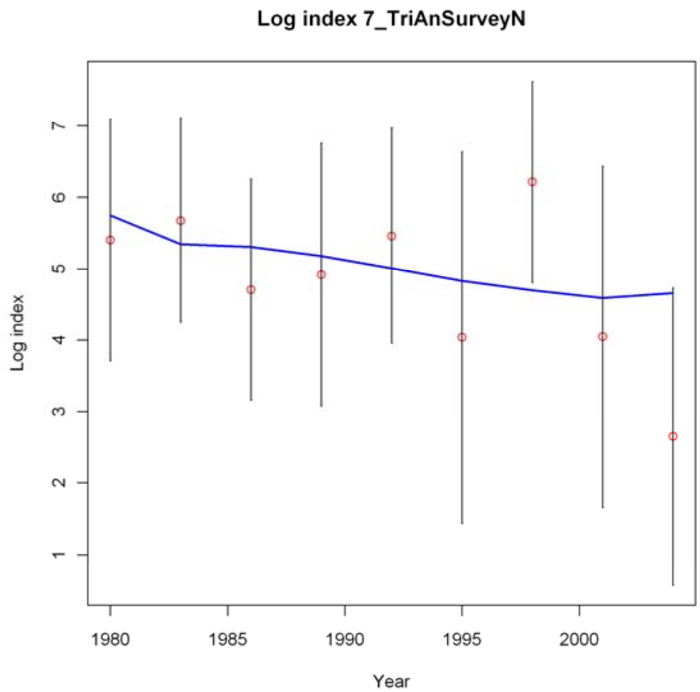

Figure 31. Model fits to the southern area triennial survey index.

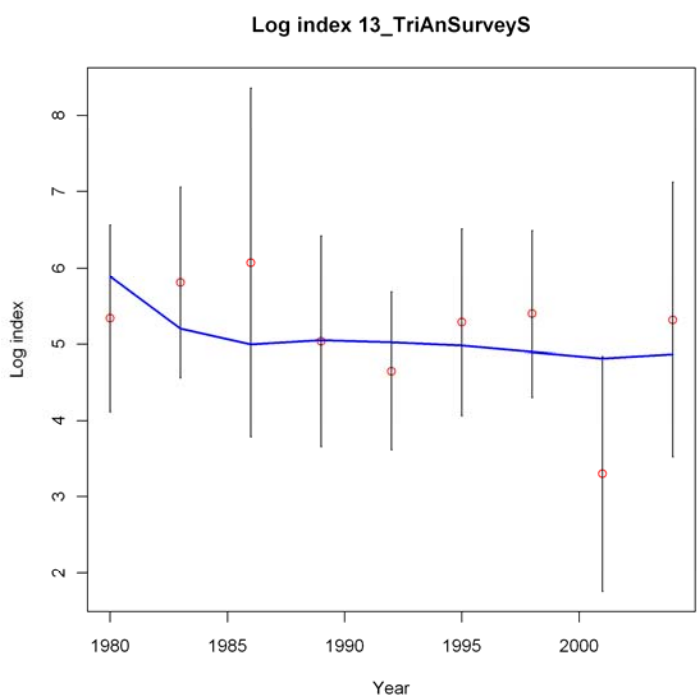

Figure 32. Model fits to the Pacific whiting foreign fishery bycatch index.

Figure 33. Model fits to the Pacific whiting joint venture fishery bycatch index.

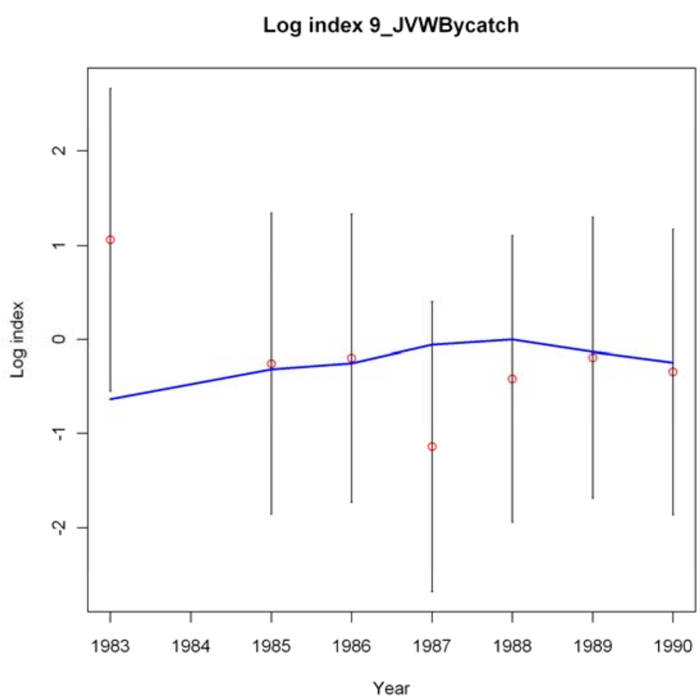

Figure 34. Model fits to the Pacific whiting domestic fishery bycatch index.

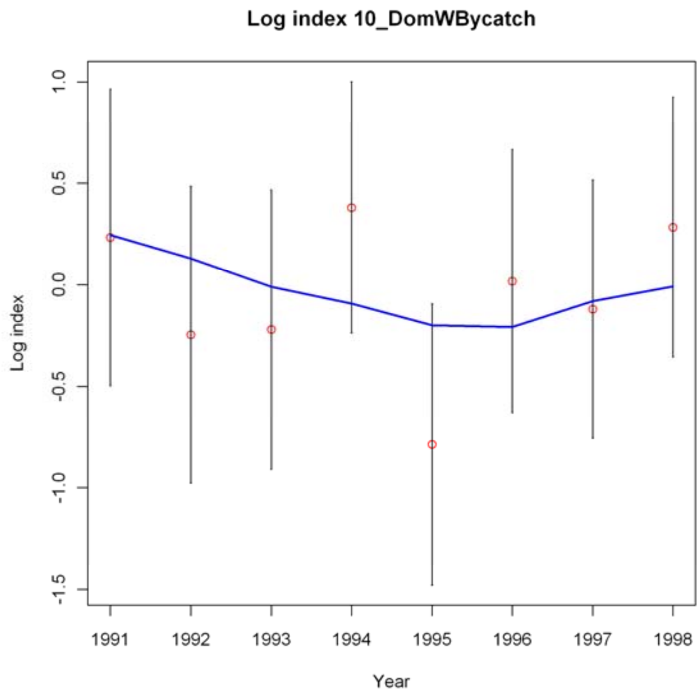

Figure 35. Model fits to the NWFSC northern area survey index.

Figure 36. Model fits to the NWFSC southern area survey index.

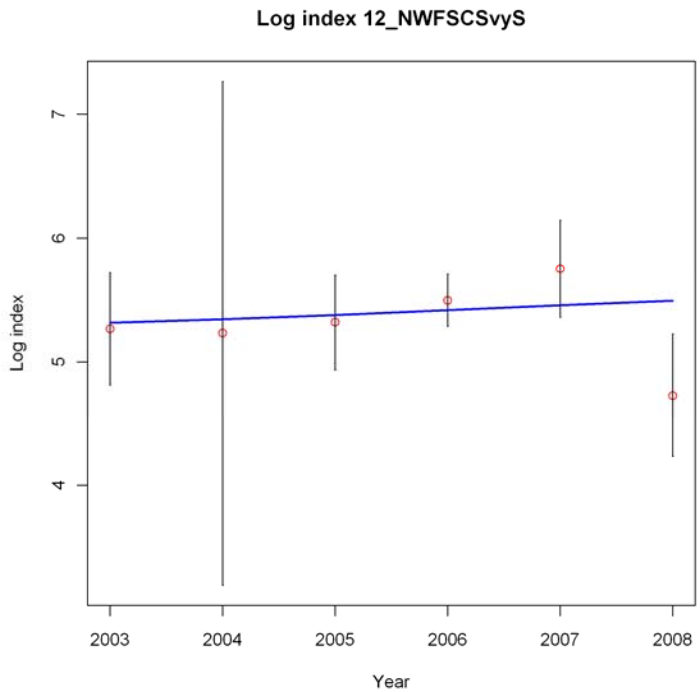

Figure 37. Estimated age selectivity curves for the Washington fishery for females (top) and males (bottom).

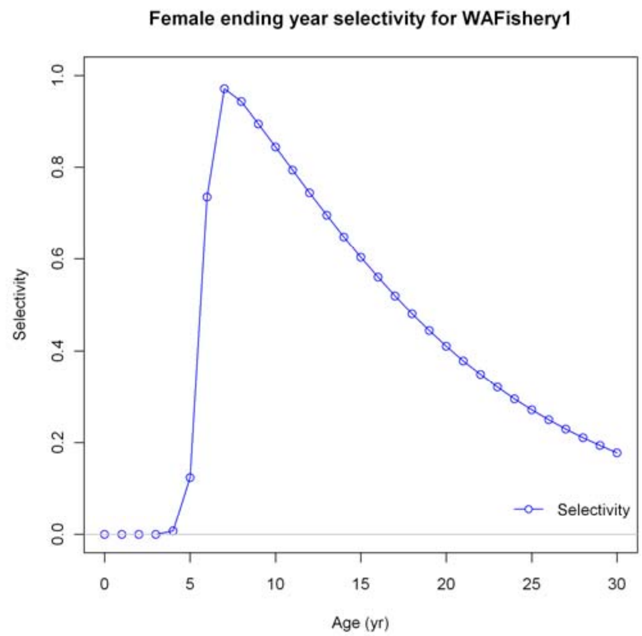

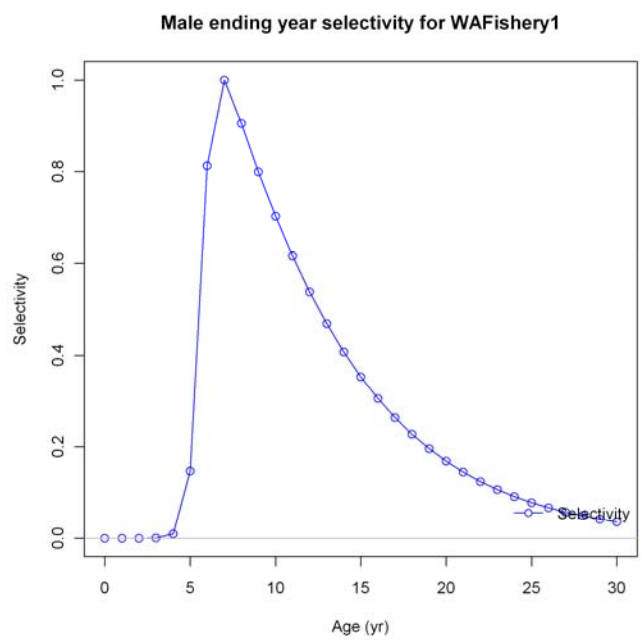

Figure 38. Estimated age selectivity curves for the Oregon mid-water trawl fisheries for females (top) and males (bottom).

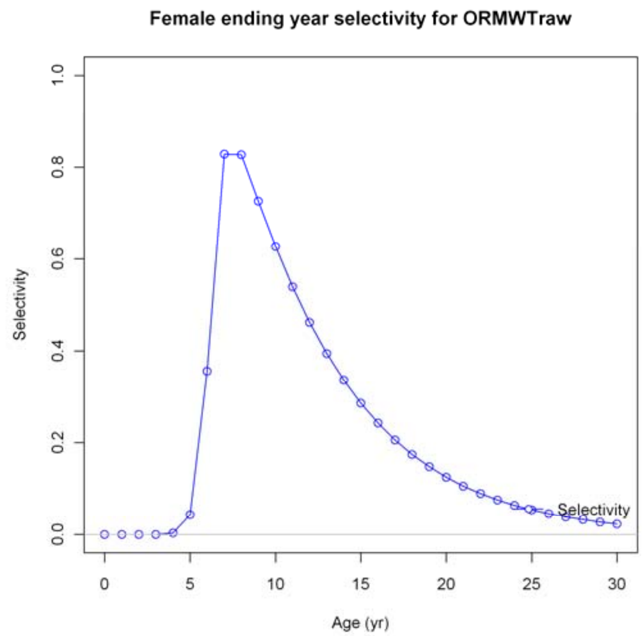

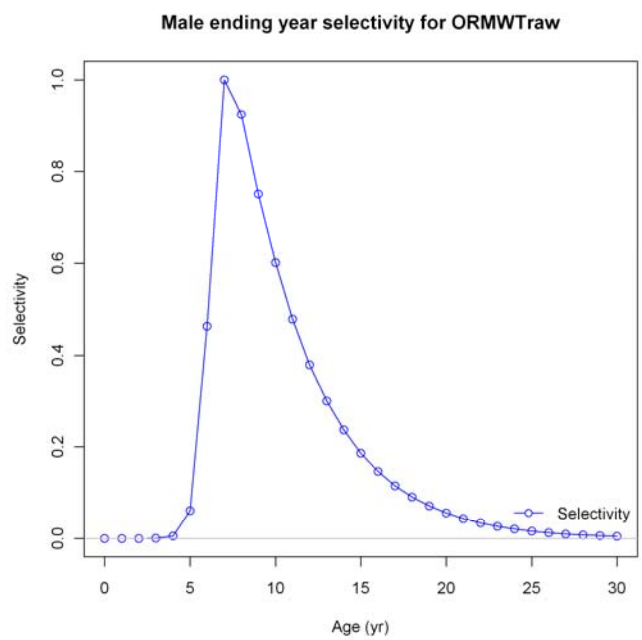

Figure 39. Estimated age selectivity curves for the Oregon bottom trawl fishery for females (top) and males (bottom).

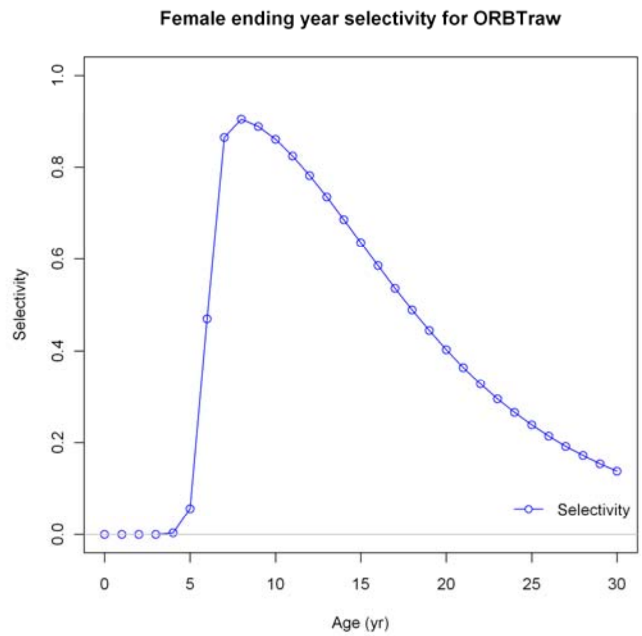

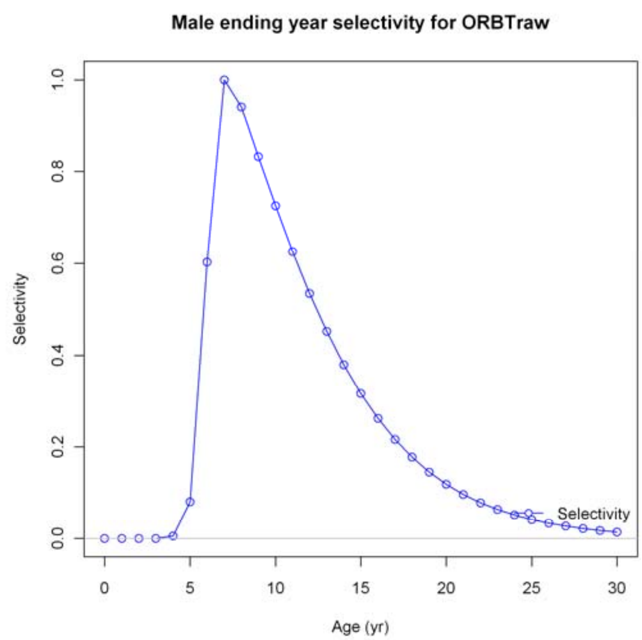

Figure 40. Estimated age selectivity curves for the Eureka-Conception fisheries for females (top) and males (bottom).

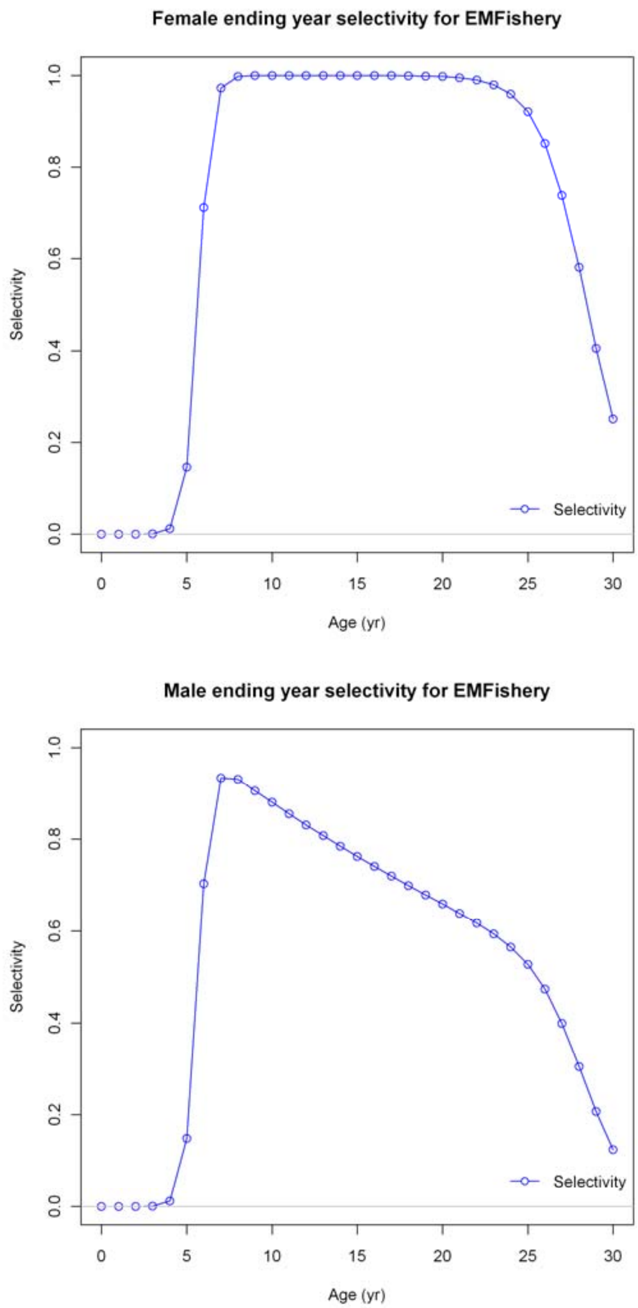

Figure 41. Estimated length selectivity curves for the triennial survey.

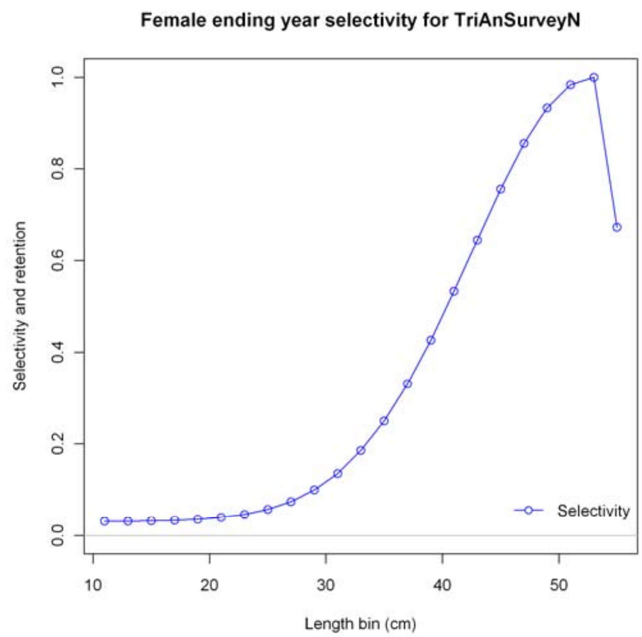

Figure 42. Estimated length selectivity curves for the NWFSC survey.

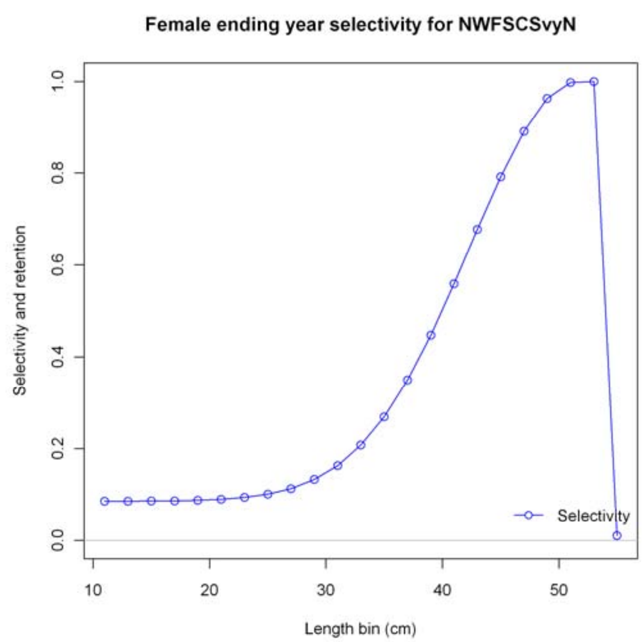

Figure 43. Age composition residuals of females (top) and male (bottom) for the Vancouver-Columbia fishery from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

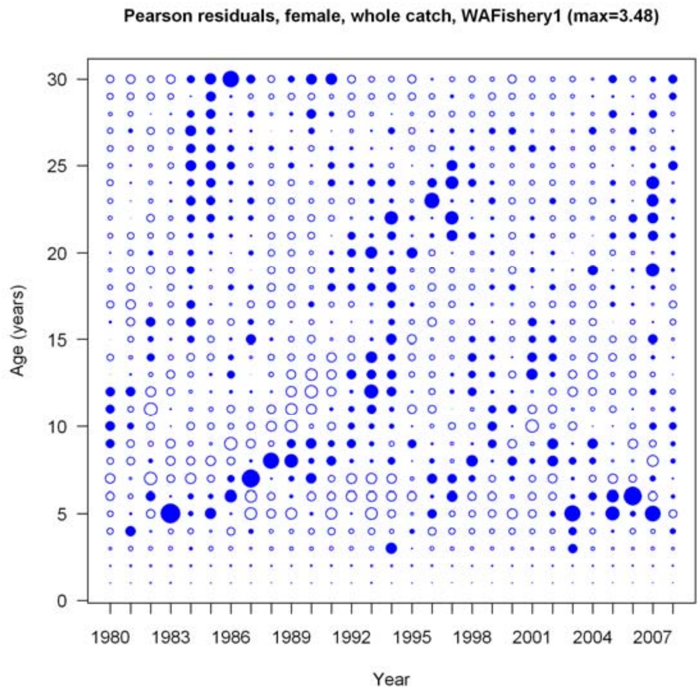

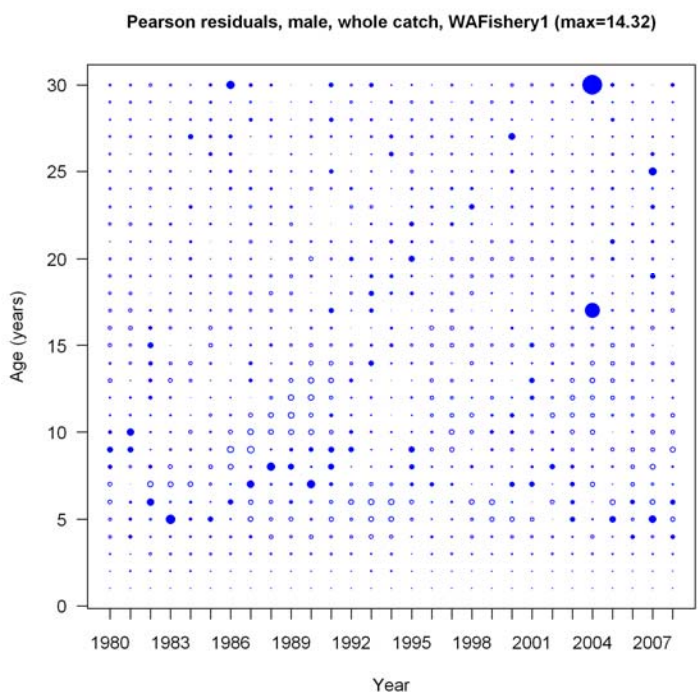

Figure 44. Age composition residuals of females (top) and male (bottom) for the Oregon mid-water trawl fishery from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

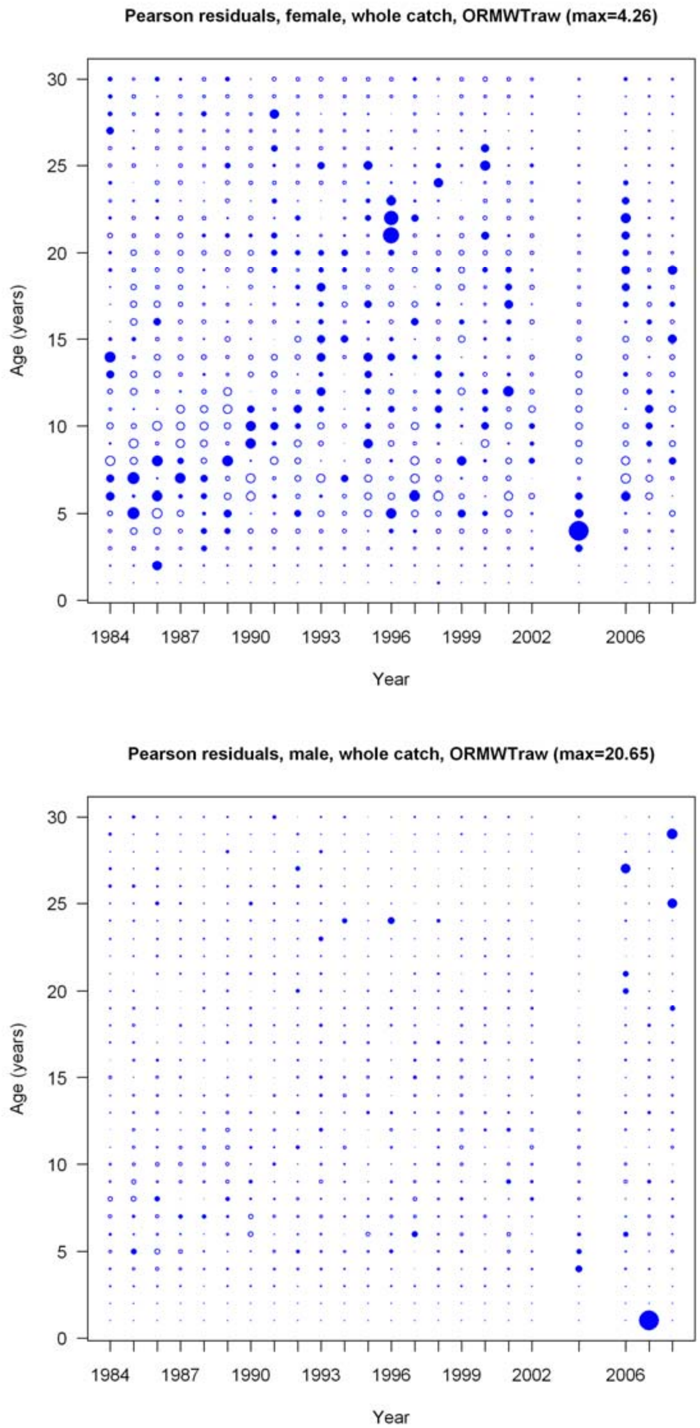

Figure 45. Age composition residuals of females (top) and males (bottom) for the Oregon bottom trawl fishery from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

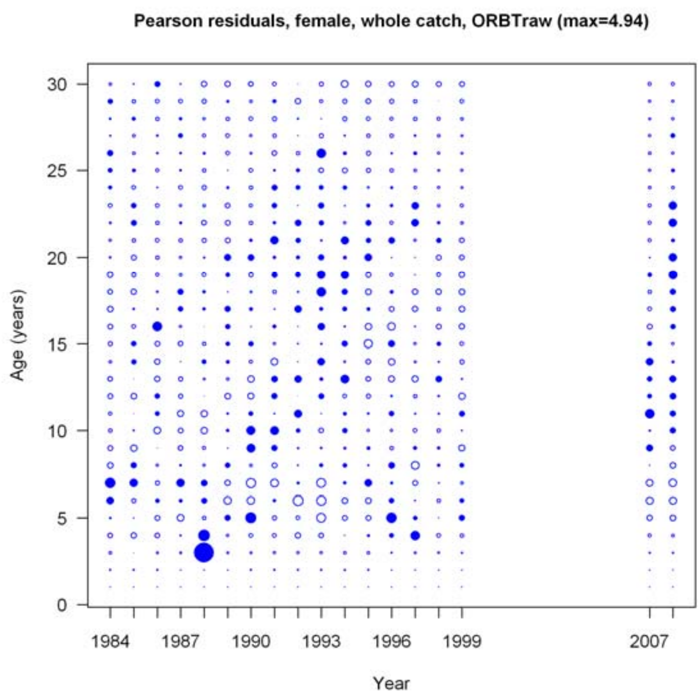

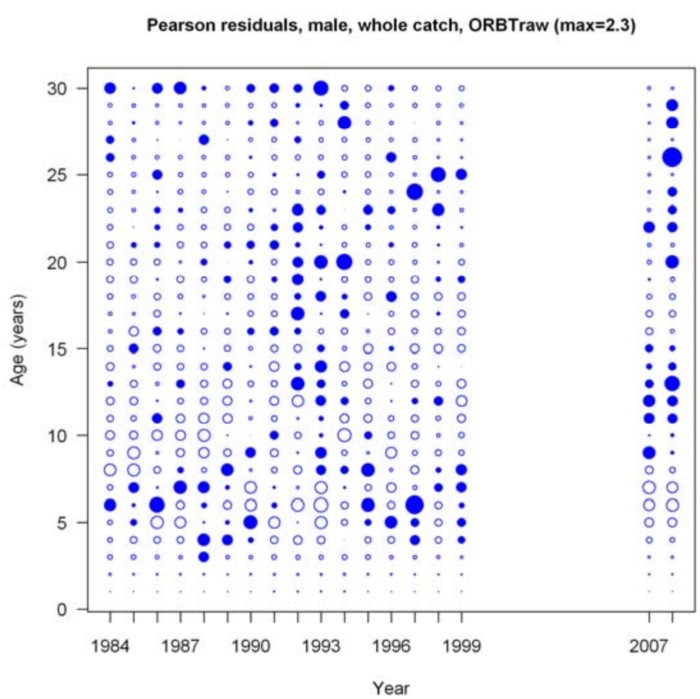

Figure 46. Age composition residuals of females (top) and males (bottom) for the Eureka-Conception fishery from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

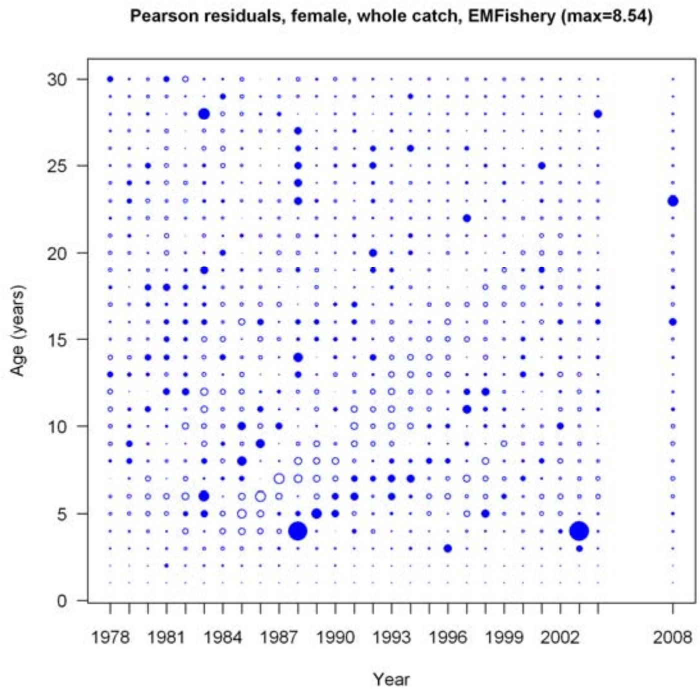

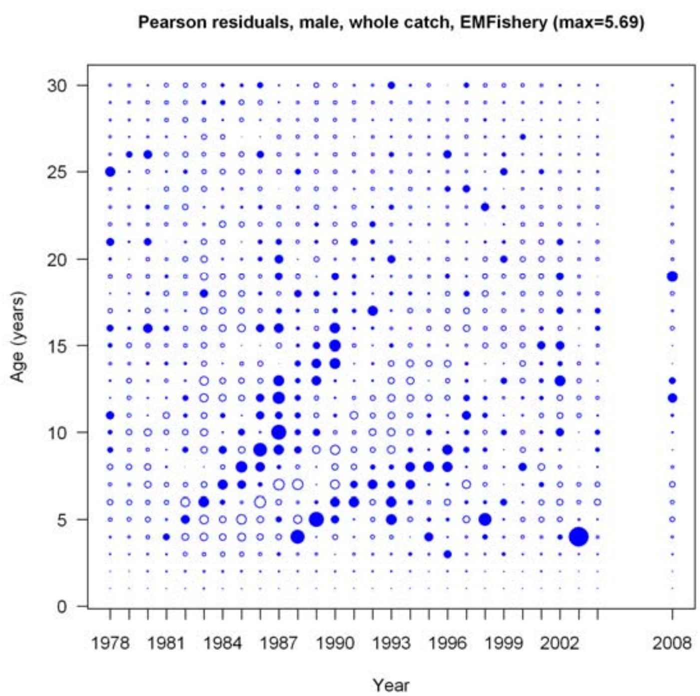

Figure 47. Age composition residuals of females (top) and males (bottom) for the NWFSC northern area survey from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

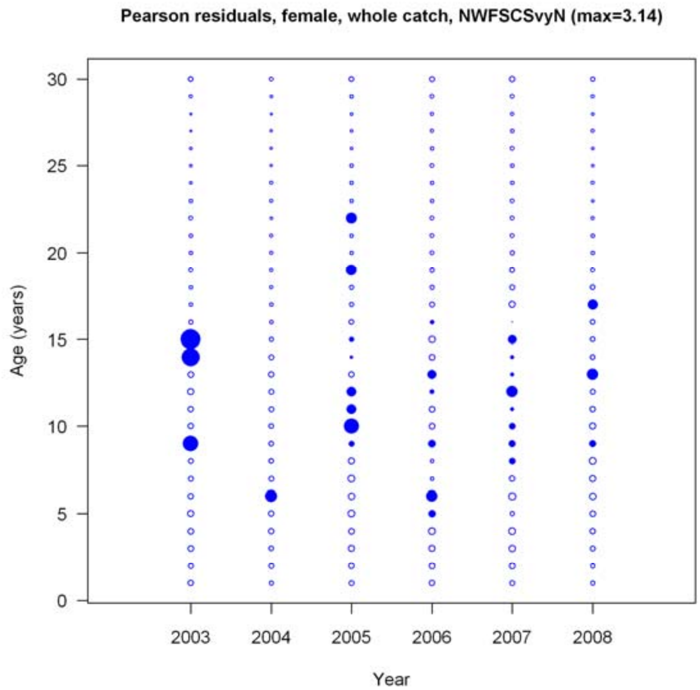

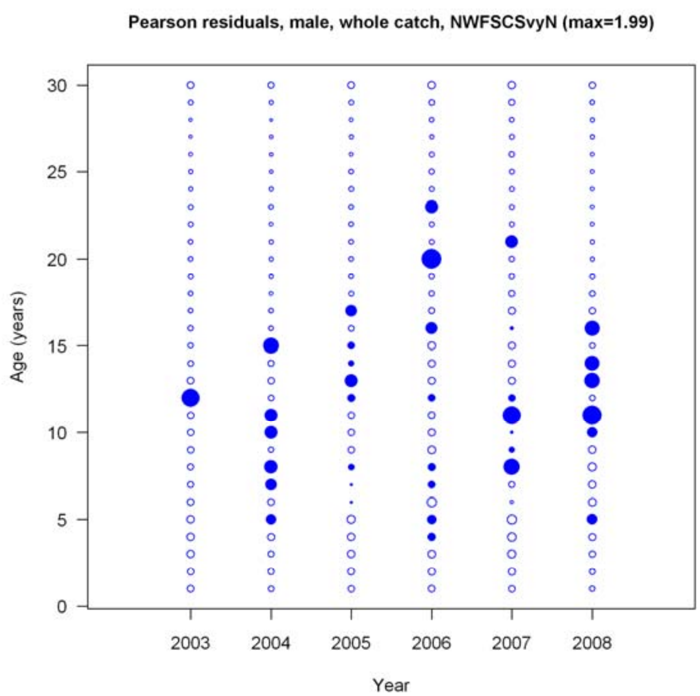

Figure 48. Age composition residuals of females (top) and males (bottom) for the NWFSC southern area survey from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

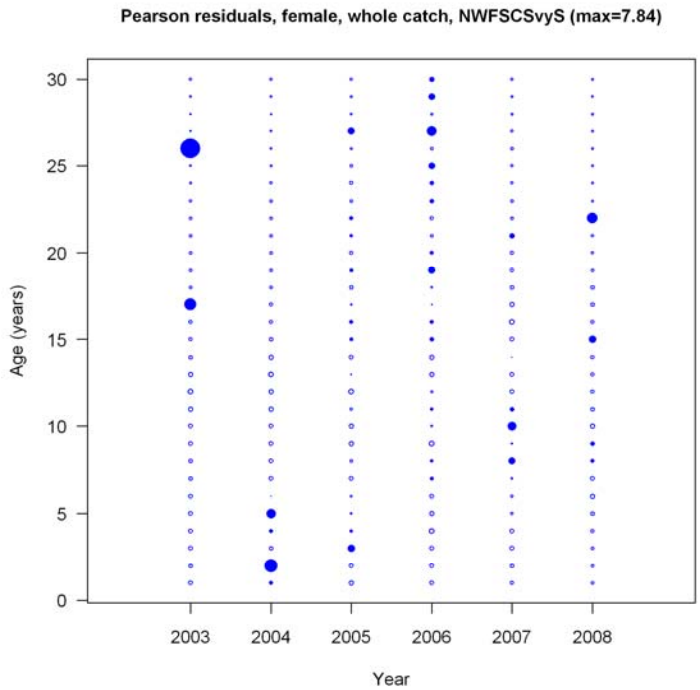

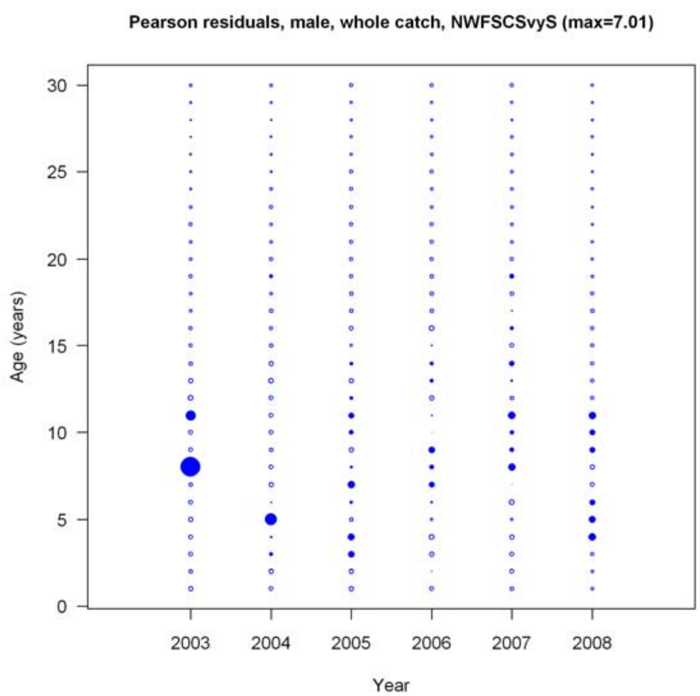

Figure 49. Length composition residuals of females (top) and males (bottom) for the northern area triennial survey from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

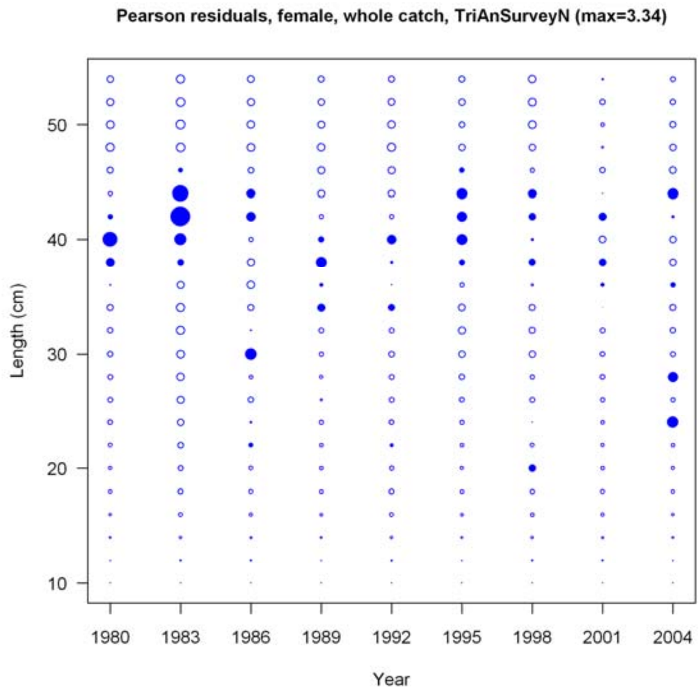

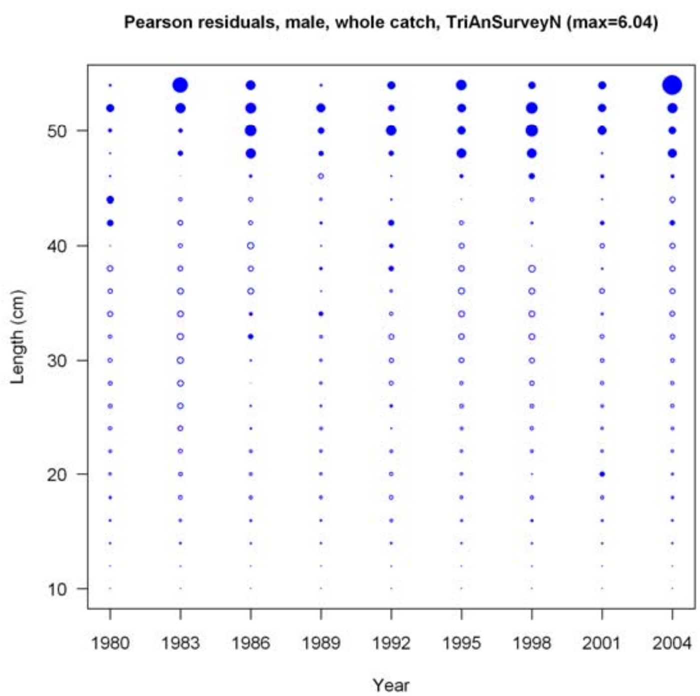

Figure 50. Length composition residuals of females (top) and males (bottom) for the southern area triennial survey from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

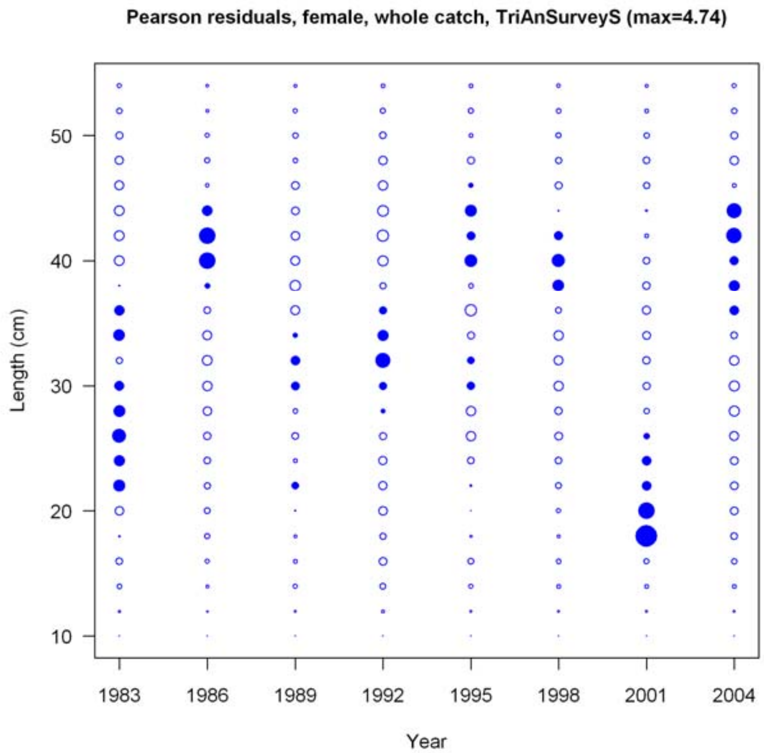

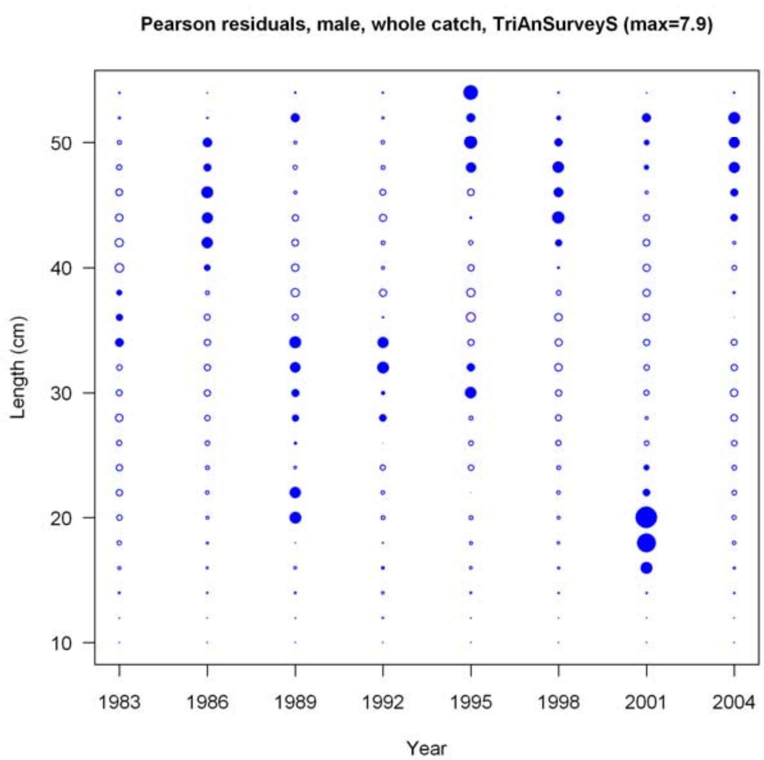

Figure 51. Length composition residuals of females (top) and males (bottom) for the NWFSC northern area survey from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

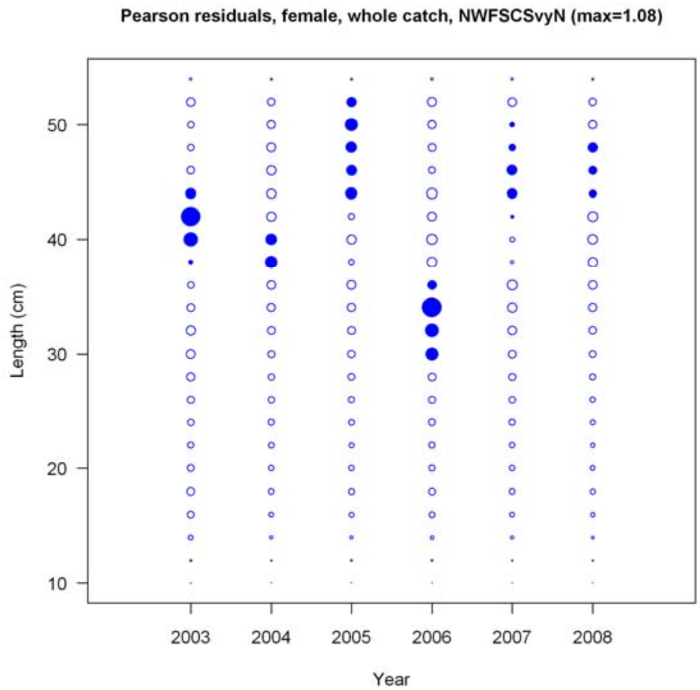

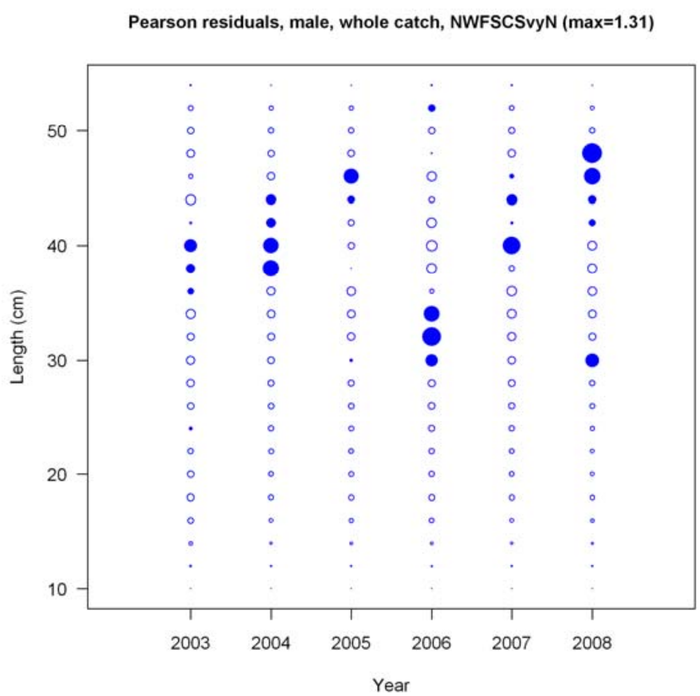

Figure 52. Length composition residuals of females (top)and males (bottom) for the NWFSC southern area survey from the base model. Residuals are standardized differences (observed – estimated). Dark circles are positive residuals and open circles are negative residuals.

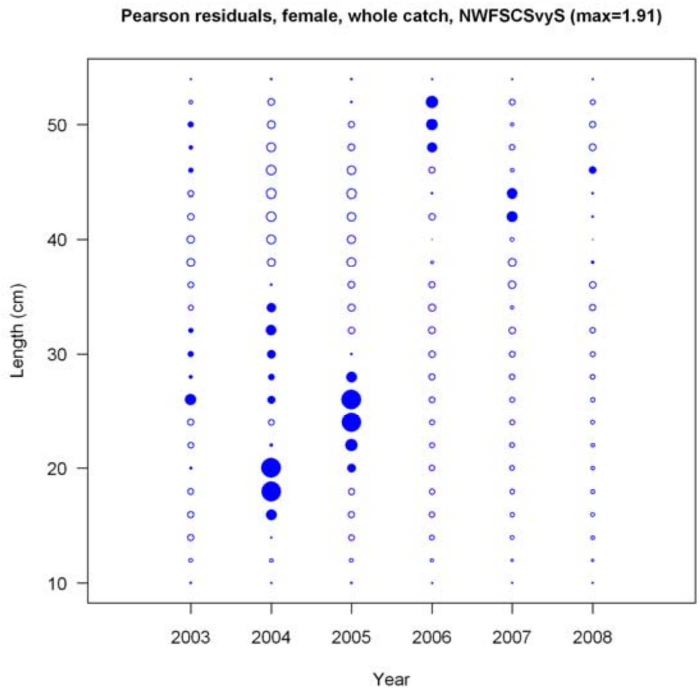

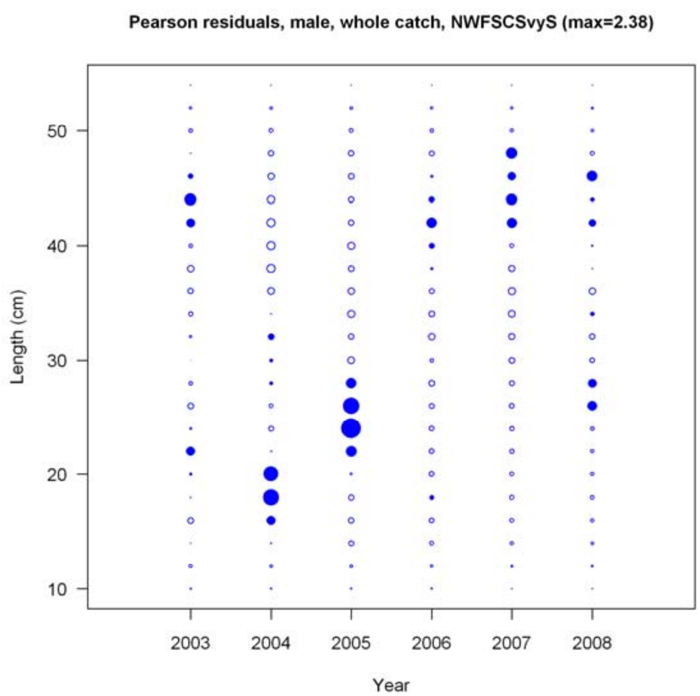

Figure 53. Comparisons of time series of spawning outputs between the base model and sensitivity runs.

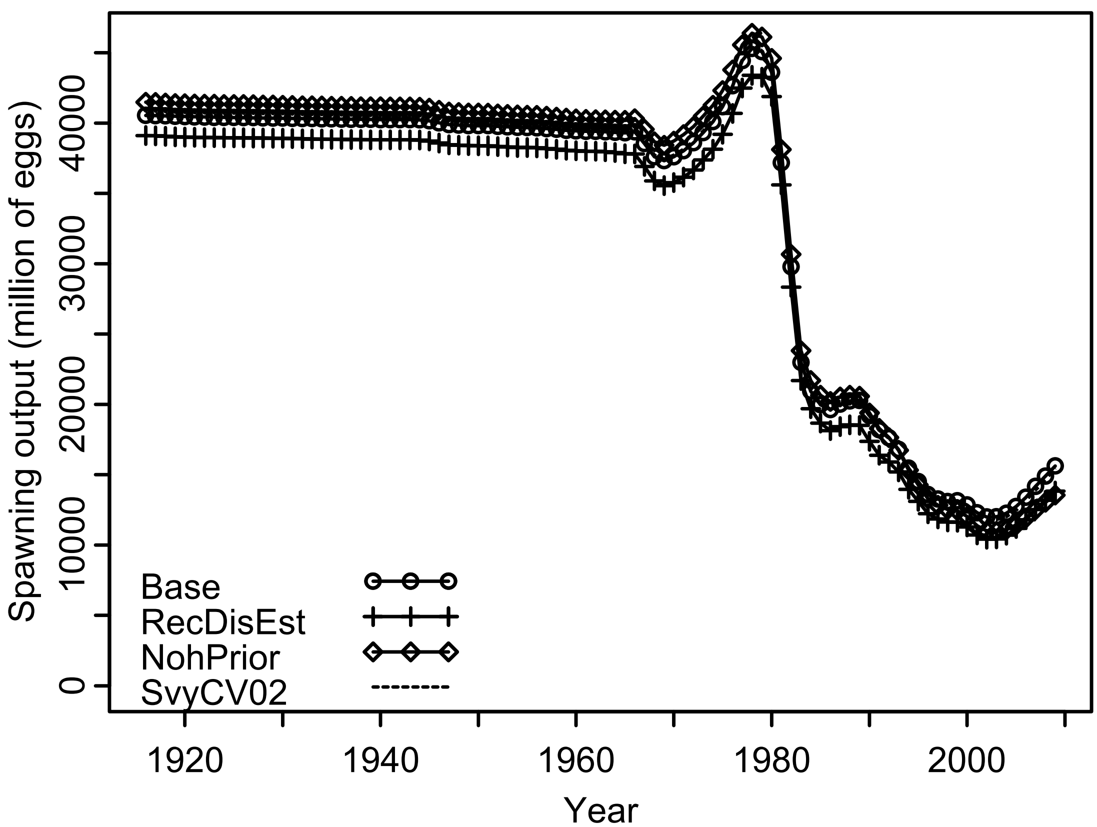

Figure 54. Comparisons of time series of recruitments between the base model and sensitivity runs.

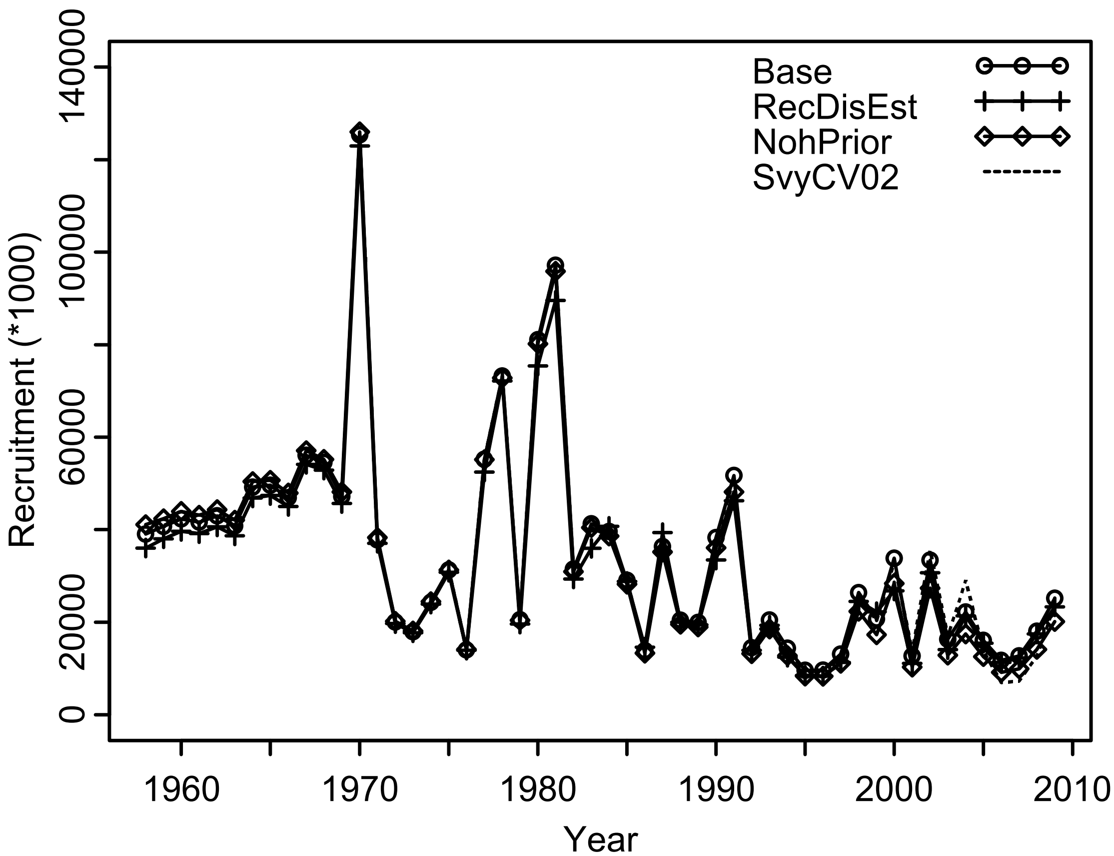

Figure 55. Comparisons of time series of spawning outputs between the base model and two fix proportions of recruitment to the northern area (0.6875 and 0.7500).

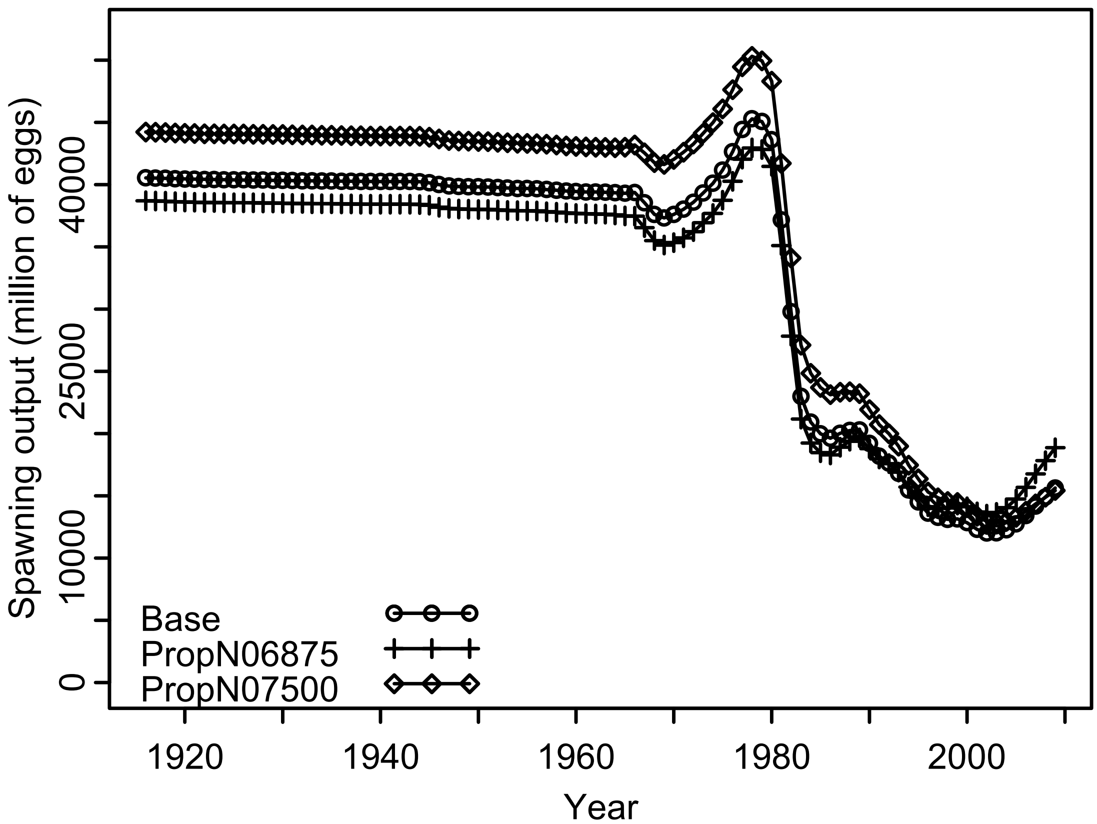

Figure 56. Comparisons of time series of recruitments between the base model and two fix proportions of recruitment to the northern area (0.6875 and 0.7500).

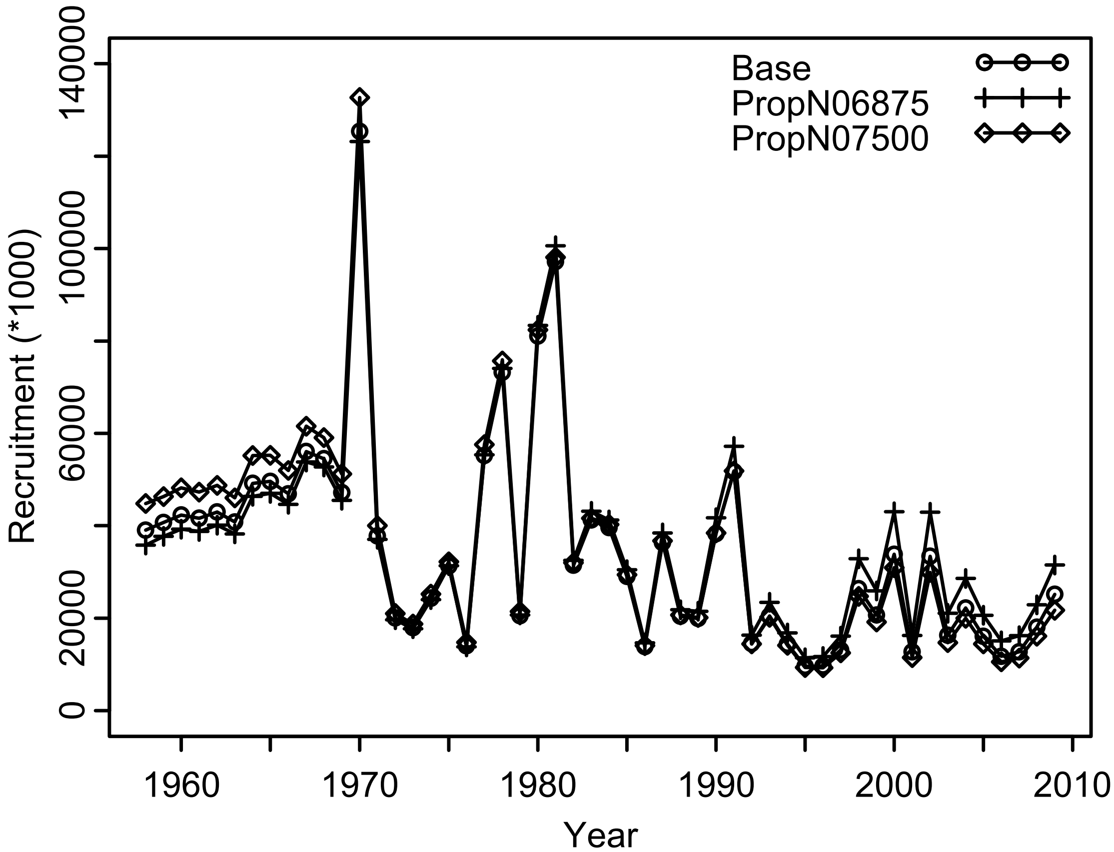

Figure 57. Comparisons of time series of spawning outputs between the base model and retrospective analysis runs.

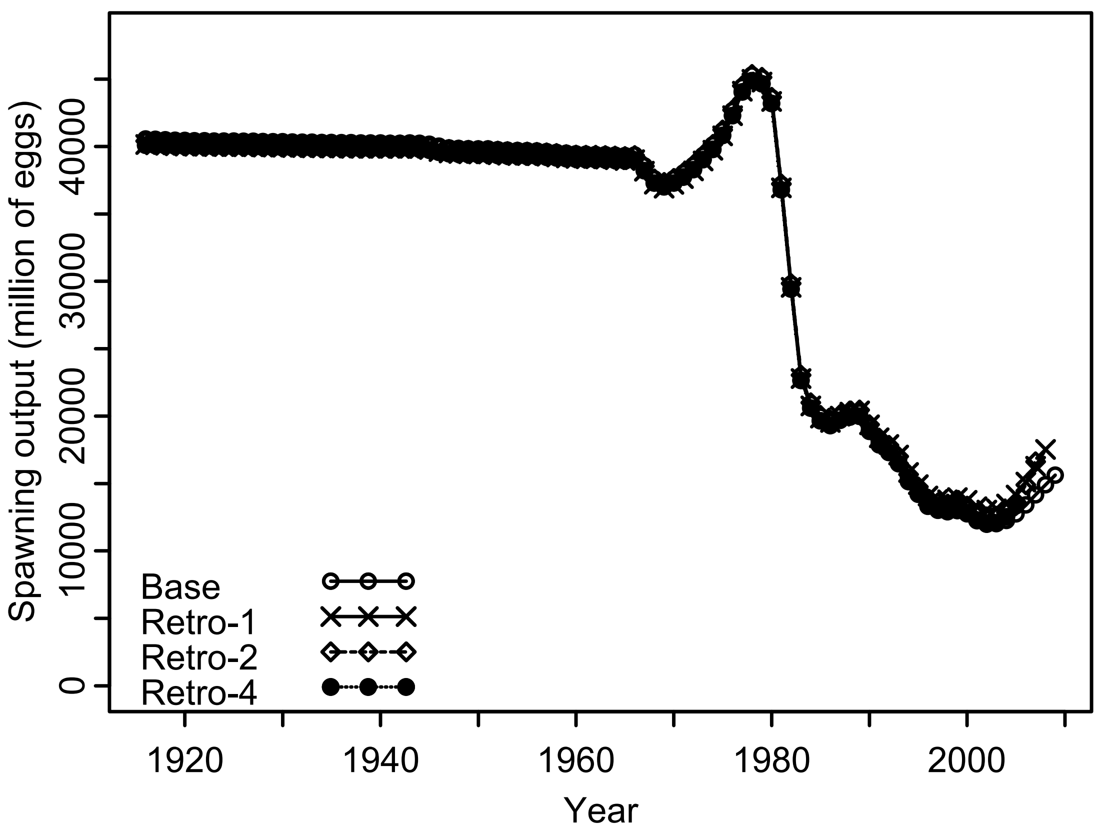

Figure 58. Comparisons of time series of recruitments between the base model and retrospective analysis runs.

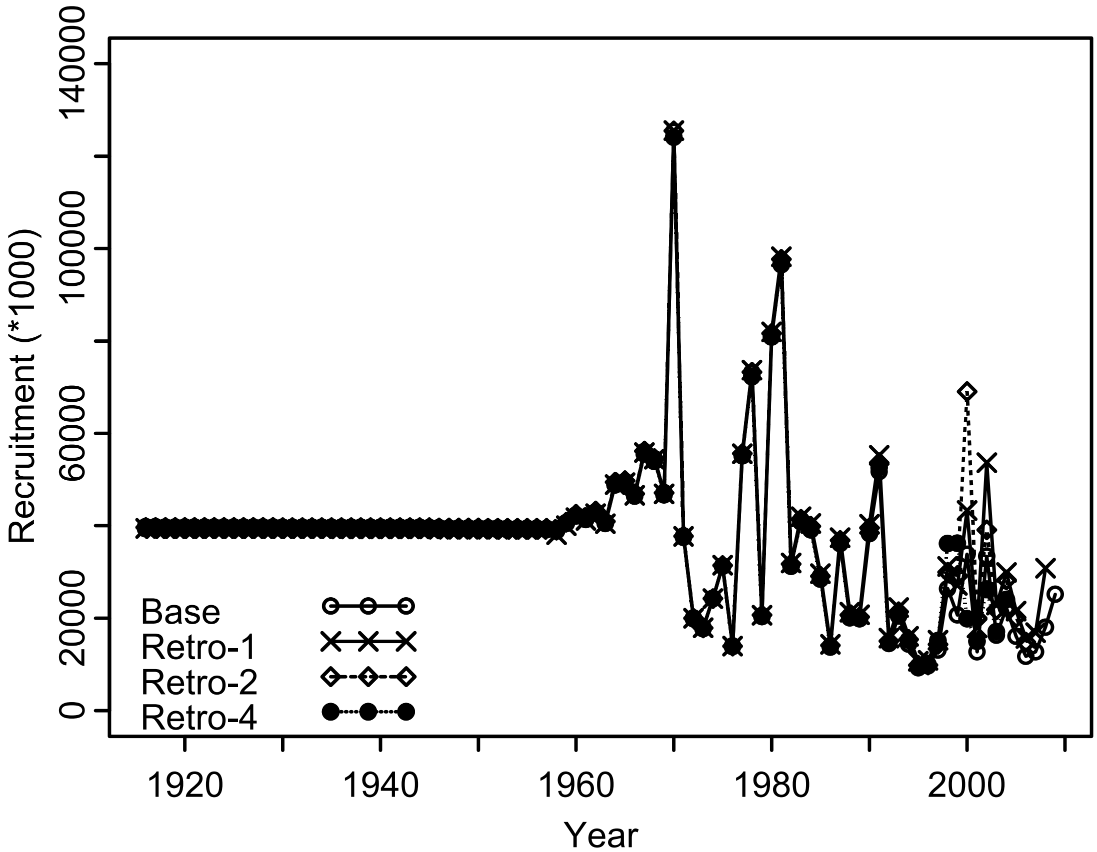

Figure 59. Likelihood profiles for the proportion of recruitment to northern area and associated depletion in 2009.

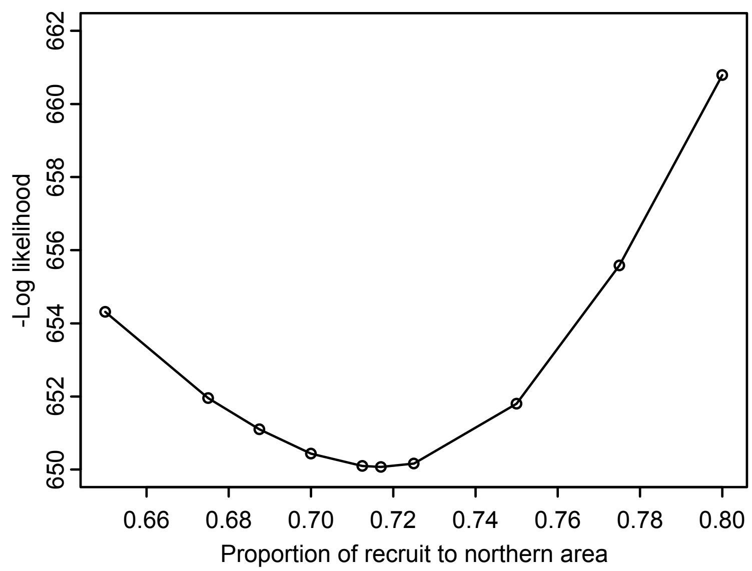

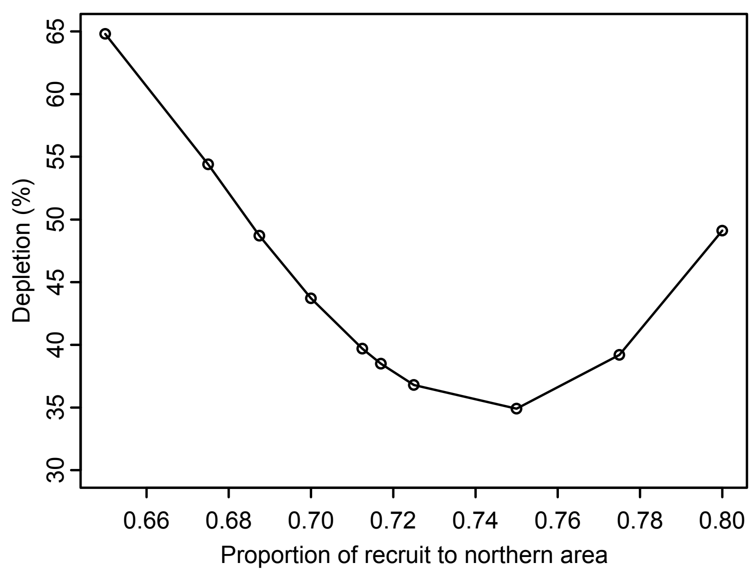

Figure 60. Likelihood profiles for steepness (*h*) and associated depletion in 2009.

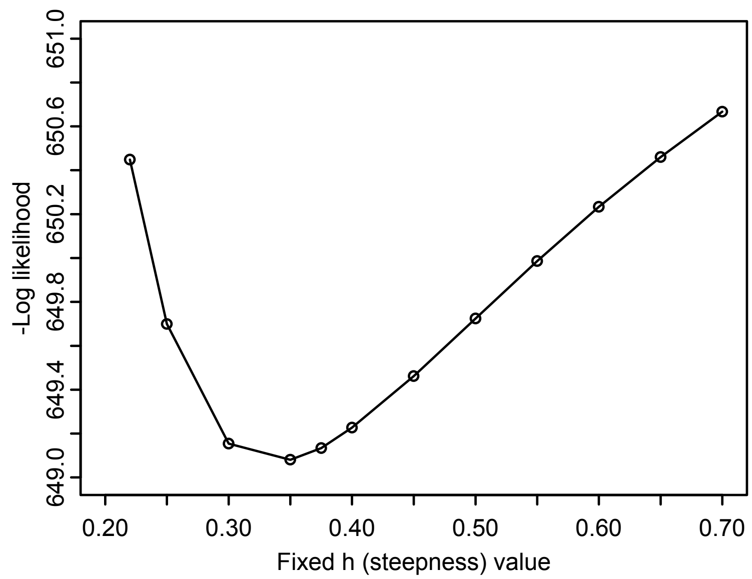

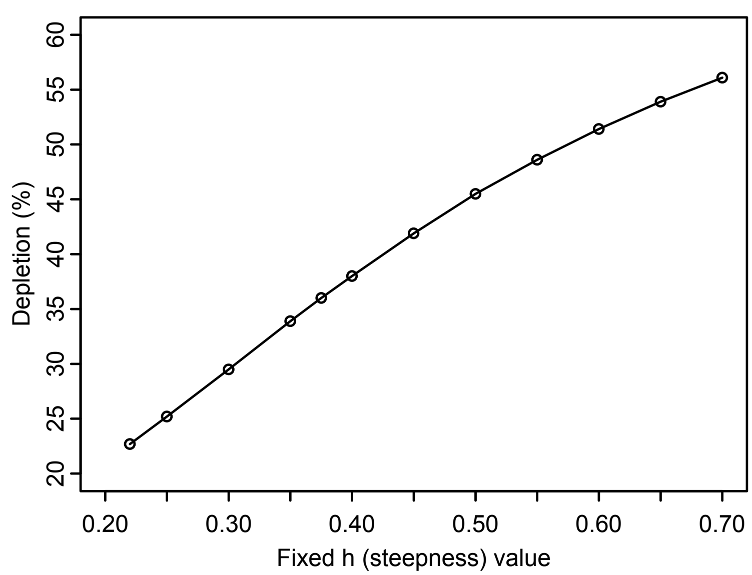

Figure 61. Likelihood profiles for natural mortality (*M*) and associated depletion in 2009.

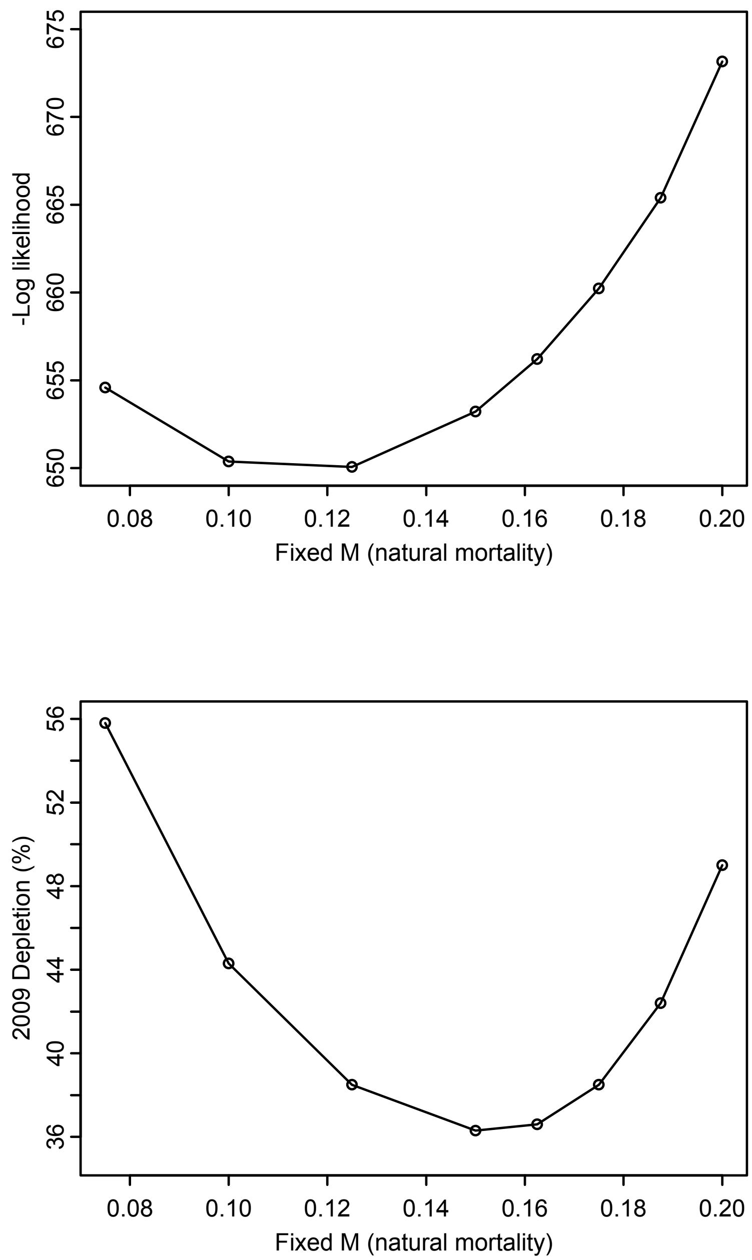

Figure 62. Comparisons of time series of spawning (*SO*) outputs between the 2009 base model and four previous assessments (2000, 2003, 2005, and 2007).

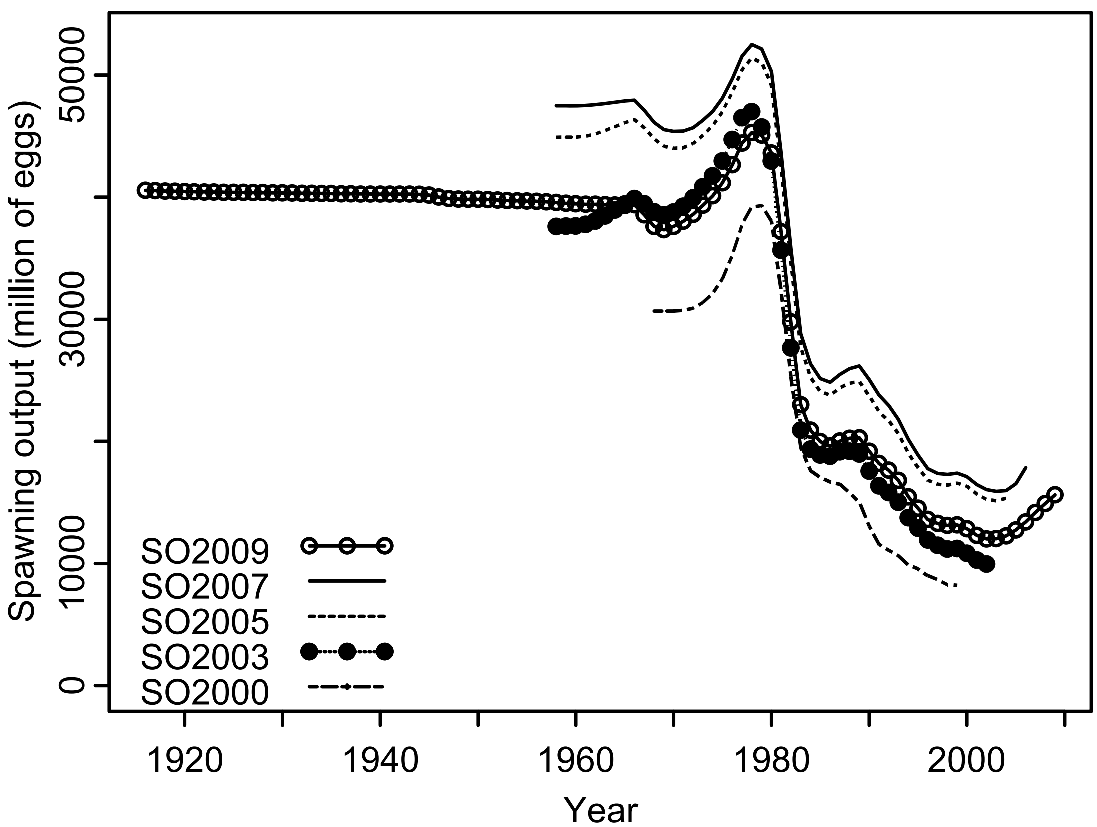

Figure 63. Comparisons of time series of recruitments between the 2009 base model and four previous assessments (2000, 2003, 2005, and 2007).

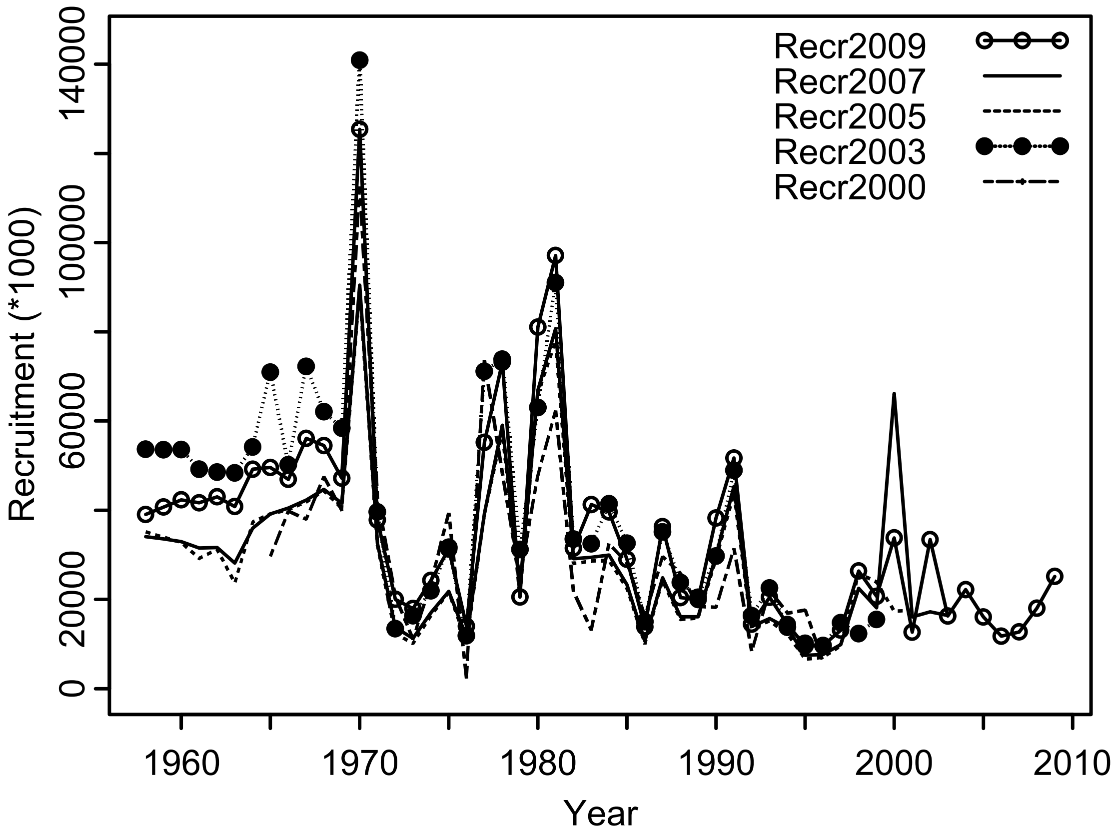

Figure 64. Estimated spawning potential ratio (SPR). The target SPR level of 0.4 (alternatively, the value could be 0.5) is also shown. Values below the target level indicates that overfishing occurred.

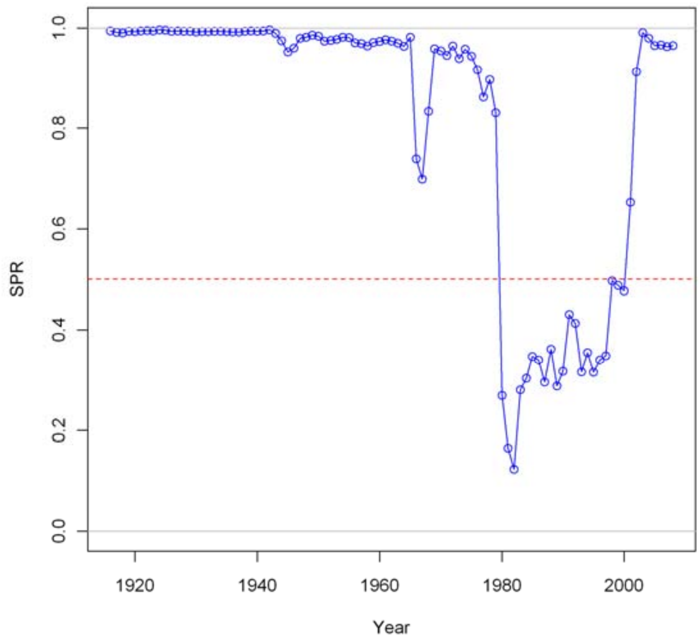

Figure 65. Phase plots of estimated spawning potential ratio to its target of 0.4 and estimated spawning output relative to its target of SB40%. The last point on the lower-left quarter corresponds to estimated value of 2009.

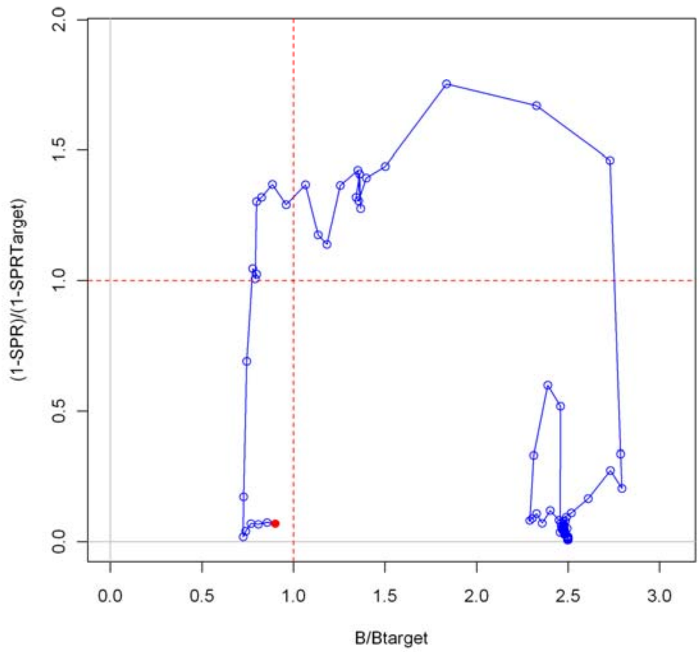

Figure 66. Equilibrium yield curve for the base model.

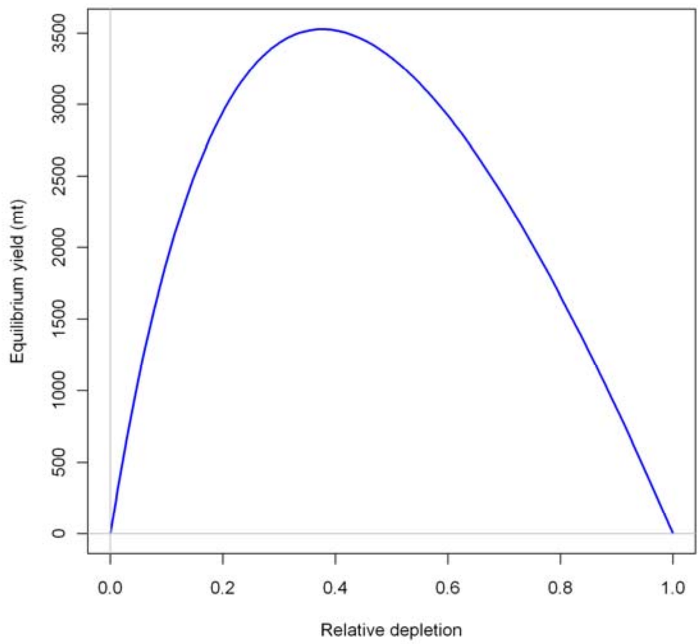

12 Appendix A. Chronology of the regulatory history of widow rockfish by the Pacific Fishery Management Council.

Date	Regulation
10/13/82	75,000 lb trip limit.
1/30/83	30,000 lb trip limit.
9/10/83	1,000 lb trip limit.
1/1/84	50,000 lb trip limit once per week.
5/6/84	40,000 lb trip limit once per week.
8/1/84	Closed fishery with 1,000 trip limit for incidental catch.
9/9/84	Closed fishery.
1/10/85	30,000 lb trip limit once a week or 60,000 lb trip limit once per two weeks, unlimited trips of less than 3,000 lbs.
4/28/85	Dropped 60,000 lb biweekly option.
7/21/85	3,000 lb trip limit, unlimited number of trips.
1/1/86	30,000 lb trip limit, only one weekly landing greater than 3,000 lbs.
9/28/86	3,000 lb trip limit, unlimited number of trips.
1/1/87	30,000 lb trip limit, only one weekly landing greater than 3000 lbs.
11/25/87	Closed fishery.
1/1/88	30,000 lb trip limit, only one weekly landing greater than 3000 lbs, unlimited number of trips less than 3,000 lbs.
9/21/88	3,000 lb trip limit, unlimited number of trips.
1/1/89	30,000 lb trip limit, only one weekly landing greater than 3,000 lbs.
4/26/89	10,000 lb trip limit once per week.
10/11/89	3,000 lb trip limit with unlimited number of trips.
1/1/90	15,000 lb trip limit once per week or 25,000 lb trip limit once per two weeks with only one landing greater than 3,000 lbs each week.
12/12/90	Closed fishery.
1/1/91	10,000 lb trip limit per week or 20,000 lb trip limit every two weeks with only one landing greater than 3,000 lbs per week.
9/25/91	3,000 lb trip limit with unlimited number of trips.
1/1/92	30,000 lbs cumulative landings every 4 weeks
5/9/92	Change from 3" mesh to 4.5" mesh in codend for roller gear north of Point Arena.
8/12/92	3,000 lb trip limit with unlimited number of trips.
12/2/92	30,000 lb cumulative trip limit per 4 weeks.
12/1/93	3,000 lb trip limit with unlimited number of trips.
1/1/94	30,000 lb cumulative limit per calendar month.
12/1/94	3,000 lb trip limit with unlimited number of trips.
1/1/95	30,000 lb cumulative limit per calendar month.

4/14/95	45,000 lb cumulative limit per calendar month.
9/8/95	4.5" mesh applies to entire net and bottom trawl.
1/1/96	70,000 lb cumulative limit per two months.
9/1/96	50,000 lb cumulative limit per two months.
11/1/96	25,000 lb cumulative limit per two months.
1/1/97	70,000 lb cumulative limit per two months.
5/1/97	60,000 lb cumulative limit per two months.
1/1/98	Limited entry: 25,000 lb cumulative per two month period.
	Open access: 12,500 lb cumulative per two month period.
5/1/98	Limited entry: 30,000 lb cumulative per two month period
7/1/98	Open access: 3,000 lb cumulative per month
10/1/98	Limited entry: 19,000 lb cumulative per month
1/1/99	Limited entry: cumulative limits: phase 1 - 70,000 lbs per period, phase 2 - 16,000 lbs per period, phase 3 - 30,000 lbs per period.
	Open access: 2,000 lbs per month.
5/1/99	Limited entry: decrease phase 2 and phase 3 limits to 11,000 lbs.
7/2/99	Open access: 8,000 lb cumulative limit per month.
10/1/99	Limited entry: vessels in Oregon and Washington using 30,000 lb cumulative monthly limit must have midwater trawl gear aboard or a state cumulative limit will be imposed.
1/1/00	Widow rockfish classified as a shelf species for regulatory purposes.
	Limited entry trawl: 30,000 lbs/2 months.
	Limited entry fixed gear: 3,000 lbs/month.
	Open access: 3,000 lbs/month.
1/1/01	Limited entry trawl: 20,000 lbs/2 months for months of Jan-Apr and Sep-Oct; otherwise 10,000 lbs/2 months for midwater trawls; 1,000 lbs/months for small footrope trawls.
	Limited entry fixed gear: 3,000 lbs/month.
	Open access: north - 3,000 lbs/month; south - 3,000 lbs per month with some monthly closures in some areas.
7/1/01	Limited entry midwater trawl in the north: 1,000 lbs/month.
10/1/01	Closed fishery for all except midwater, which may land 2,000 lbs/month in north for October, then 25,000 lbs/2 months.
1/1/02	Limited entry trawl in the north: closed through November to midwater trawl except for small bycatch in whiting fishery, in November 13,000 lbs/2 month with no more than 2 trips, small footrope trawl 1000 lbs/month through September, then closed Sept-Oct, then 500 lbs/month Nov-Dec.
	Limited entry trawl in the south: midwater closed year round except for a small bycatch in the whiting fishery; small footrope trawl 1,000 lbs/month through July, then closed.
1/1/03	Limited entry trawl RCA in the north: 75-200 fm during Jan-Aug, 50-200 fm during Sep-Oct, and shoreline to 200 fm (petrale areas open) during Nov-Dec.
	Limited entry trawl RCA in the south: between 34°27’ N. lat. and 40°10’ N. lat. - 60-

	200 fm during Jan-Oct, and shoreline to 200 fm (petrale areas open) during Nov-Dec; south of 34°27’ N. lat. - 100-200 fm during Jan-Oct, and shoreline to 200 fm (petrale areas open) during Nov-Dec.
	Limited entry and open access fixed gear RCA established as follows (seaward boundaries held static until Jan 2009; shoreward boundaries south of the OR-WA border vary): shoreline to 100 fm north of the OR-WA border (46°16' N. lat.) to the U.S.-Canada border; seaward boundary of 100 fm north of 40°10’ N. lat.; seaward boundary of 150 fm south of 40°10' N. lat.
	Limited entry trawl in the north: midwater trawl closed through November except for small amount of bycatch in whiting fishery, 12,000 lbs/2 months for Nov-Dec; small footrope trawl - 300 lbs/month Jan-Apr and Nov-Dec, 1000 lbs/month May-Oct.
	Limited entry fixed gear in the north: 200 lbs/month.
	Open access in the north: 200 lbs/month.
	Limited entry trawl in the south: same as north for midwater and small footrope trawl.
	Limited entry fixed gear in the south: closed Mar-Apr, then variable 100 lbs/2 months to 250 lbs/2 months.
	Open access in the south: same as limited entry fixed gear.
1/1/04	Limited entry trawl RCA in the north: 75-200 fm during Jan-Feb (petrale areas open), 60-200 fm during Mar-Apr, 60-150 fm during May-Jun, 75-150 fm during Jul-Sep, and shoreline to 250 fm during Oct-Dec.
	Limited entry trawl RCA in the south: 75-150 fm during Jan-Apr and Sep, and 100-150 fm May-Aug; between 38° N. lat. and 40°10’ N. lat. - shoreline to 250 fm during Oct-Dec; between 36° N. lat. and 38° N. lat. - shoreline to 200 fm during Oct-Dec; south of 36° N. lat. - shoreline to 150 fm during Oct-Dec.
	Limited entry trawl in the north: midwater trawl closed through November except for small amount of bycatch in whiting fishery (500 lbs/month during primary whiting season; combined widow and yellowtail trip limit of 500 lbs/trip with trips of at least 10,000 lbs of whiting), 12,000 lbs/2 months for Nov-Dec; small footrope trawl - 300 lbs/month Jan-Apr and Nov-Dec, 1000 lbs/month May-Oct.
	Limited entry fixed gear in the north: 200 lbs/month.
	Open access in the north: 200 lbs/month.
	Limited entry trawl in the south: closed.
	Limited entry fixed gear in the south: between 40°10’ and 34°27’ N lat. - 300 lbs/2 months Jan-Feb and Sep-Dec, closed Mar-Apr, 200 lbs/2 months May-Aug; south of 34°27’ N lat.: closed Jan-Feb, 2,000 lbs/2 months Mar-Dec.
	Open access in the south: between 40°10’ and 34°27’ N lat. - same as limited entry fixed gear; south of 34°27’ N lat. - closed Jan-Feb, 500 lbs/2 months Mar-Dec.
1/1/05 (regs. for 2005 and 2006)	Limited entry trawl RCA in the north: 75-200 fm during Jan-Feb and Nov-Dec (petrale areas open), and 100-200 fm during Mar-Oct.
	Selective flatfish trawls required shoreward of the RCA in the north (new permanent reg. implemented from 2005 to present).
	Limited entry trawl in the north: large and small footrope trawl- 300 lbs/2 months; midwater trawl- closed except for small amount of bycatch in whiting fishery (500

	lbs/month during primary whiting season; combined widow and yellowtail trip limit of 500 lbs/trip with trips of at least 10,000 lbs of whiting); selective flatfish trawl - 300 lbs/month Jan-Apr and Nov-Dec, 1,000 lbs/month May-Oct.
	Limited entry fixed gear in the north: 200 lbs/month.
	Open access in the north: 200 lbs/month.
	Limited entry trawl in the south: large footrope and midwater trawl- closed; small footrope trawl- 300 lbs/month.
	Limited entry fixed gear in the south: between 40°10' and 34°27' N lat. - 300 lbs/2 months Jan-Feb and Sep-Dec, closed Mar-Apr, 200 lbs/2 months May-Aug; south of 34°27' N lat.: 2,000 lbs/2 months Jan-Feb and May-Dec, closed Mar-Apr.
	Open access in the south: between 40°10' and 34°27' N lat. - same as limited entry fixed gear; south of 34°27' N lat. - 500 lbs/2 months Jan-Feb and May-Dec, closed Mar-Apr.
7/1/05	Limited entry fixed gear south of 34°27' N lat.: 3,000 lbs of shelf rockfish, shortbelly rockfish, and widow rockfish/2 months Jul-Dec.
	Open access south of 34°27' N lat.: 750 lbs of shelf rockfish, shortbelly rockfish, and widow rockfish /2 months Jul-Dec.
10/1/05	Limited entry trawl RCA north of 38° N lat. extended from shoreline to 250 fm; 36° N lat. to 38° N lat.: limited entry trawl RCA extended from shoreline to 200 fm; south of 36° N lat.: limited entry trawl RCA extended from 50 fm to 200 fm.
1/1/06	Limited entry fixed gear south of 34°27' N lat.: 3,000 lbs of shelf rockfish, shortbelly rockfish, and widow rockfish /2 months Jan-Feb.
	Open access south of 34°27' N lat.: 750 lbs of shelf rockfish, shortbelly rockfish, and widow rockfish /2 months Jan-Feb.
3/1/06	Limited entry fixed gear south of 34°27' N lat.: 3,000 lbs of shelf rockfish, shortbelly rockfish, and widow rockfish /2 months Mar.-Dec.
	Open access south of 34°27' N lat.: 750 lbs of shelf rockfish, shortbelly rockfish, and widow rockfish /2 months Mar.-Dec.
10/1/06	Widow bycatch cap in the non-tribal limited entry whiting trawl fishery increased from 200 mt to 220 mt.
1/1/07 (regs. for 2007 and 2008)	Widow bycatch cap of 200 mt adopted for the limited entry whiting trawl fishery.
	Limited entry trawl RCA: 75-250 fm in Jan-Apr and Nov-Dec; 75-200 fm in May-Jun and Sep-Oct; 100-200 fm in Jul-Aug.
	Limited entry trawl in the north: large and small footrope trawl- 300 lbs/2 months; midwater trawl- closed except for small amount of bycatch in whiting fishery (500 lbs/month during primary whiting season; combined widow and yellowtail trip limit of 500 lbs/trip with trips of at least 10,000 lbs of whiting; cumulative widow limit of 1,500 lbs/month); selective flatfish trawl - 300 lbs/month Jan-Apr and Nov-Dec, 1,000 lbs/month May-Oct.
	Limited entry fixed gear in the north: 200 lbs/month.
	Open access in the north: 200 lbs/month.
	Limited entry trawl in the south: large footrope and midwater trawl- closed; small footrope trawl- 300 lbs/month.
	Limited entry fixed gear in the south: between 40°10' and 34°27' N lat. - 300 lbs/2

	months Jan-Feb and Sep-Dec, closed Mar-Apr, 200 lbs/2 months May-Aug; south of 34°27’ N lat.: 3,000 lbs/2 months Jan-Feb and May-Dec, closed Mar-Apr.
	Open access in the south: between 40°10’ and 34°27’ N lat. - same as limited entry fixed gear; south of 34°27’ N lat. - 750 lbs/2 months Jan-Feb and May-Dec, closed Mar-Apr.
5/1/07	Widow bycatch cap in the limited entry whiting trawl fishery increased from 200 mt to 220 mt.
	Limited entry trawl in the north: RCA extended to the shore from Cape Alava (48°10’ N lat.) to U.S.-Canada border and from Cape Arago (43°20.83' N. lat.) to Humbug Mountain (42°40.50' N. lat.); the shoreward boundary of the trawl RCA is shifted shoreward to 60 fm from April 17 through October 31, 2007 between Leadbetter Point (46°38.17' N. lat.) and the Oregon/Washington border (46°16’ N. lat.); shoreward boundary of the trawl RCA shifted shoreward to 75 fm in all other areas through Dec.; the seaward boundary of the trawl RCA is shifted shoreward to 150 fm from the U.S.-Canada Border to Cascade Head (45°03.83’ N. lat.) from April 17 through August 31, 2007; the seaward boundary of the trawl RCA is shifted shoreward to 200 fm between Cascade Head (45°03.83’ N. lat.) and 40°10 N. lat. from April 17 through April 30, 2007.
7/26/07	Limited entry whiting trawl fishery closed due to attainment of 220 mt widow bycatch cap.
9/1/07	Limited entry fixed gear in the south between 40°10' N. lat. and 34°27' N. lat.: combined the trip limit for bocaccio and the trip limit for minor shelf rockfish, shortbelly rockfish, and widow rockfish into a single cumulative trip limit of 500 lb/2 months from Sep-Dec.
10/1/07	Limited entry trawl RCA north of Cape Alava (48°10’ N lat.) to U.S.-Canada border and from Cape Arago (43°20.83' N. lat.) to Humbug Mountain (42°40.50' N. lat.): shoreward boundary moved to the 75 fm line.
10/7/07	Limited entry whiting trawl fishery re-opened after widow bycatch cap is increased to 275 mt; shoreside whiting sector required to fish seaward of the 150 fm line; at-sea sectors voluntarily fish seaward of the 150 fm line.
1/1/08	Limited entry trawl RCA in the north: the seaward boundary north of 40□10’ N. lat. to the U.S.-Canada border is shifted to the modified petrale 200 fm line in Jan-Feb and Nov-Dec; the seaward boundary from the OR-WA border (46□16' N. lat.) to the U.S.-Canada border is shifted to 150 fm from May-Oct; all other areas and times will have a seaward boundary of 200 fm; the shoreward boundary is shifted to the shoreline from north of Cape Alava (48°10’ N lat.) to the U.S.-Canada border and from Cape Arago (43°20.83' N. lat.) to Humbug Mountain (42°40.50' N. lat.) for the entire year; the shoreward boundary from the OR-WA border (46□16' N. lat.) to Cape Alava shifted to 60 fm in Mar-Oct; all other times and areas will have a shoreward boundary of 75 fm for the year.
	Limited entry trawl RCA in the south: 100-150 fm for the year.
	Limited entry fixed gear in the south between 40°10' N. lat. and 34°27' N. lat.: modify the chilipepper rockfish limit of 2,000 lb/2 months by recombining it into a single combined cumulative limit with minor shelf rockfish, shortbelly, widow rockfish and bocaccio, and increase the trip limit from 500 lb/2 months to 2,500 lb/2 months of which no more than 500 lb/2 months may be any species other than chilipepper rockfish.
3/08	Widow bycatch cap of 275 mt adopted for the limited entry whiting trawl fishery.

5/1/08	Limited entry trawl RCA in the north: the seaward boundary is shifted to the 200 fm line from the OR-WA border (46°16' N. lat.) to Leadbetter Pt. (46°38.17' N. lat.) from May-Jun; the seaward boundary is shifted to the 150 fm line from Cape Falcon (45°46' N. lat.) to the OR-WA border from May-Aug; the shoreward boundary is shifted to the 60 fm line from north of Cape Alava (48°10' N lat.) to the U.S.-Canada border and from Cape Arago (43°20.83' N. lat.) to Humbug Mountain (42°40.50' N. lat.) from May-Oct; no other changes to the trawl RCA for all other times and areas.
	Darkblotched rockfish bycatch cap in the limited entry whiting trawl fishery increased to 40 mt to decrease impacts on widow rockfish.
8/19/08	Limited entry whiting trawl fishery closed due to attainment of 4.7 mt canary bycatch cap.
10/10/08	Limited entry trawl RCA in the north: the shoreward boundary of the is shifted from 60 fm to 75 fm, with the exception of the areas north of Cape Alava (48°10'N. lat.) and between Cape Arago (43°20.83' N. lat.) and Humbug Mountain (42°40.50'N. lat.).
10/12/08	Limited entry whiting trawl fishery reopened after the canary bycatch cap is increased from 4.7 mt to 6.4 mt and the widow bycatch cap is increased from 275 mt to 284 mt.
10/26/08	Canary bycatch cap in the limited entry whiting trawl fishery is increased from 6.4 mt to 6.7 mt.
11/1/08	Open access south of 34°27' N. lat.: shelf rockfish trip limit increased from 750 lb/2 months to 1,000 lb/2 months in period 6 (Nov-Dec).
1/1/09 (regs. for 2009 and 2010)	Sector-specific bycatch caps adopted for the limited entry whiting trawl fishery for canary, darkblotched, and widow rockfish distributed on a pro rata basis in relation to the sectors' whiting allocation. Additionally, NMFS has the authority to restrict fishing depths by sector of the limited entry whiting trawl fishery if a bycatch cap is attained inseason.
	Limited entry trawl RCA: north of Cape Alava (48°10'N. lat.) - shoreline to 200 fm during Jan-Mar (petrale areas open) and Sep-Dec (petrale areas open Nov-Dec), and shoreline to 150 fm during Apr-Aug; north of Cape Falcon (45°46' N. lat.) to Cape Alava - 75-200 fm during Jan-Apr (petrale areas open Jan-Mar) and Sep-Dec (petrale areas open Nov-Dec), and 75-150 fm during May-Aug; north of 40°10' N. lat. to Cape Falcon - 75-200 fm year-round (petrale areas open during Jan-Mar and Nov-Dec); south of 40°10' N. lat. - 100-150 fm year-round.
	Limited entry and open access fixed gear RCA: seaward boundary shifted from 100 fm to 125 fm between Cascade Head (45°03.83' N. lat.) and Cape Blanco (43° N. lat.), except on days when the directed fishery for Pacific halibut is open; otherwise, seaward boundary of 100 fm north of 40°10' N. lat. and 150 fm south of 40°10' N. lat.
	Limited entry trawl in the north (combined limits of widow, yelloweye, shortbelly, and minor shelf rockfish): large and small footrope trawl- 300 lbs/2 months; midwater trawl- closed except for small amount of bycatch in whiting fishery (500 lbs/month during primary whiting season; combined widow and yellowtail trip limit of 500 lbs/trip with trips of at least 10,000 lbs of whiting; cumulative widow limit of 1,500 lbs/month); selective flatfish trawl - 300 lbs/month Jan-Apr and Nov-Dec, 1,000 lbs/month of which no more than 200 lbs/month can be yelloweye during May-Oct.; multiple bottom trawl gear - 300 lbs/ month Jan-Apr and Nov-Dec, 300 lbs/2 months of which no more than

	200/lbs/month can be yelloweye during May-Oct.
	Limited entry trawl in the south: large footrope and midwater trawl - closed; small footrope trawl for minor shelf rockfish, shortbelly, widow, and yelloweye - 300 lbs/ month year-round.
	Limited entry and open access fixed gear in the north: 200 lbs/ month (combined limit for minor shelf rockfish, shortbelly, widow, and yellowtail) year-round.
	Limited entry fixed gear in the south: between 34□27’ N. lat. and 40□10’ N. lat. - 2,500 lbs/2 months (combined limit for minor shelf rockfish, shortbelly, widow, bocaccio, and chilipepper) of which no more than 500 lb/2 months may be any species but chilipepper; south of 34□27' N. lat. (combined limit for minor shelf rockfish, shortbelly, widow, and bocaccio) - 3,000 lbs/2 months during Jan-Feb and May-Dec, and closed during Mar-Apr.
	Open access in the south (combined limit for minor shelf rockfish, shortbelly, widow, and chilipepper):: between 34□27’ N. lat. and 40□10’ N. lat. - 300 lbs/2 months during Jan-Feb and Sep-Dec, closed during Mar-Apr, and 200 lbs/2 months during May-Aug; south of 34□27’ N. lat. - 750 lbs/2 months during Jan-Feb and May-Dec, and closed during Mar-Apr.
3/09	Widow bycatch caps for sectors of the limited entry whiting trawl fishery are adopted as follows: 105 mt to shoreside whiting, 85 mt to catcher-processors, and 60 mt to motherships.

13 Appendix B. Comparisons of widow rockfish stock assessment using direct ADMB code and SS2 interface software

Xi He and Richard Methot

November 2007

<u>**Important notice: Results shown in this report are solely for comparisons of widow rockfish assessments using ADMB software and Stock Synthesis (SS2) software. These results should NOT be used for management references or any other purposes.**</u>

Brief summary
This appendix compares the results of stock assessments for the widow rockfish population using two stock assessment programs. One uses programs written in ADMB code and another uses SS2 interface software. Both programs use the same data set. The results, including time series of spawning outputs and recruits as well as estimated key parameters, are very similar between two programs.

Introduction

The stock assessments for widow rockfish have been conducted using the ADMB software since 2000 (Williams et al. 2000, He et al. 2003, 2006, 2007). It is planned that for the next assessment for widow rockfish in 2009, the assessment will employ the stock synthesis program (SS2, developed by R. Methot, Methot 2007). This report compares the assessment results between these two programs. The same data set is used in both programs. A complete set of program codes and data used for both program are not printed on this report because they are too long (over 50 pages) to print but they are available upon request.

Models and methods

The ADMB program for the 2007 widow assessment was used in this exercise. To make it more comparable with SS2 software, one minor change was made in the ADMB program (wdw.tpl). In SS2, there is one parameter of fishing mortality each year for each fishery. In ADMB, there is an average fishing mortality for each fishery and then there is a deviation vector of fishing mortality for each fishery. The ADMB code was changed to have the same setup as in SS2. This change resulted in same numbers of estimated parameters in both programs, and had no effects on the ADMB outputs. The SS2 program version is 2.00j (dated August 25, 2007).

The same data set was in used in both programs. However, the data set was modified from the data set used in the 2007 widow assessment. The main reasons for this modification were that it simplified the SS2 program and it made possible for direct comparisons between two programs. The modifications of the data are listed below:

1. Change the widow assessment from two-area model to one-area model. That is, all widow are assumed to be in the northern area (Washington and Oregon). This is an easy change in the ADMB data by simply changing proportions of northern catches to 1.0.

Test runs showed that this change had very little effect (<2% of change in depletion rate) in the ADMB results.

2. Set both sexes to have the same length-weight relationship and the same growth function. This change makes conversions of growth in length and weigh by age much easier in the SS2 program because the SS2 program uses different methods in computing weight by age as in the ADMB program. The SS2 requires inputs of length bins, growth parameters, and length-weight relations to compute weight for each age, while the ADMB program directly computes weight for each age from given growth functions and length-weight relationships. Test run showed that this modification had very little effect (<1% of change in depletion rate) in the results.
3. No implicit priors were used in both programs. In the SS2 program, the lambda value for prior was set to zero. In the ADMB program, a prior function for the steepness parameter was removed. This modification had no effect on the results since the estimated steepness values in both program were much higher than those specified in the prior function used in the 2007 widow assessment.
4. Changes in ageing error inputs. In the ADMB, an ageing error matrix was used. In the SS2 program, a standard deviation is defined for each age group. To make it more comparable, it was assumed that there be no ageing error in the input data. The change in fact had the largest effects on the results. The depletion rate estimated by the ADMB program increased by about 5% as compared to the 2007 widow assessment. The main reason is that the assessment program estimates much stronger recruits in 2000 than those in the 2007 widow assessment.

All other estimation procedures for both programs were same, including uses of effective sample sizes for age samples and root mean square errors (RMSE) for each CPUE time series.

Results and discussions

Comparisons of main assessment results between two programs are presented in Table A1 and Figures A1 and A2. Plots of length at age and weight at age for both programs are presented in Figures A3 and A4.

Overall, the results are very similar between two programs. Time series of spawning outputs and recruits match each other very well. Both programs estimate a strong recruitment in 2000, which resulted in increasing trend of spawning outputs in recent years. The overall patterns of spawning output and recruitment are also very similar to those in the 2007 widow assessment (He et al. 2007). However, the depletion rates estimated by both programs are higher than that estimated in the 2007 widow assessment. As stated previously, this is mainly due to the assumption that there be no ageing errors in the current programs.

14 Appendix C. Multinomial sample sizes

Chris Francis
National Institute of Water and Atmospheric Research
301 Evams Bay Parade, Wellington 3, New Zealand
July 2009

This Appendix describes the method that was used to correct the multinomial sample sizes for compositional data in the Widow assessment, shows the results of its application to these data, and provides a brief rationale for the use of thes method. The description that follows concerns age data, but the approach is exactly the same for lengths. Also, for simplicity, the following description ignores sex, but the extension to include sex is straightforward.

Suppose $p_{ay,\mathrm{obs}}$ is the observed proportion at age a in year y in a set of age composition data that is assumed to have a multinomial error structure, and let $N_{\mathrm{init},y}$ denote the initial sample sizes. We run our assessment model using these sample sizes and obtain, from the modwl fit, estimates of the expected proportions at age, $p_{ay,\mathrm{exp}}$. Our aim is to use the $p_{ay,\mathrm{obs}}$, $p_{ay,\mathrm{exp}}$, and $N_{\mathrm{init},y}$ to calculate a correction factor f so that the size of the model residuals is consistent with the corrected sample sizes, $N_{\mathrm{corr},y} = fN_{\mathrm{init},y}$.

This aim is the same as for the method currently used in SS3 to correct multinomial sample sizes. Where the two methods differ is that the SS3 method is based on the residuals for individual proportions, $r_{ay} = p_{ay,\mathrm{obs}} - p_{ay,\mathrm{exp}}$, whereas the present method is based on residuals for mean age, $r_y = (m_{y,\mathrm{obs}} - m_{y,\mathrm{exp}})$, where $m_{y,\mathrm{obs}} = \Sigma_a(a\ p_{ay,\mathrm{obs}})$, and $m_{y,\mathrm{exp}} = \Sigma_a(a\ p_{ay,\mathrm{exp}})$. The reason for using mean-age residuals is discussed below.

For the multinomial distribution, the expected variance of the mean age, $m_{y,\mathrm{obs}}$, and thus of the residual r_y, is $v_y/(fN_{\mathrm{init},y})$ [i.e., $v_y/N_{\mathrm{corr},y}$], where v_y is the variance of the age frequency in year y, given by $v_y = \Sigma_a(a^2\ p_{ay,\mathrm{obs}}) - m_{y,\mathrm{obs}}^2$. Therefore, the expected variance of $r_y(N_{\mathrm{init},y}/v_y)^{0.5}$ is $1/f$, and we estimate f as $1/\mathrm{Var}(r_y(N_{\mathrm{init},y}/v_y)^{0.5})$.

Figure 1 shows the application of this method to the Widow age and length composition data. In this application, the sample sizes, $N_{\mathrm{init},y}$, were those obtained after correction (or tuning) using the SS3 method. That is to say, the residuals for individual proportions, r_{ay}, should be consistent with the size expected given these sample sizes. What Figure 1 shows is that the mean-age residuals are still too large (note that many of the confidence intervals for the observed values do not overlap the expected values). Thus, according to the present method, the sample sizes are too large, and so the estimated f is less than 1 for all data sets (range 0.04 to 0.45).

The reason the mean-age residuals, r_y, can be too large, while the individual proportion residuals, r_{ay}, are not, is that there is substantial correlation between the individual residuals. This is shown in Figure 2, in which the observed age frequency flips from one side of the expected frequency to the other from one year to the next. Sideways movement of this magnitude would not be possible if the individual residuals were uncorrelated. This correlation could be caused by either observation or process error (or a combination of both). One explanation of how this could occur derives from the fact that size (and thus age) distribution of fish often varies spatially. We would get between-year sideways movements of age frequencies if the spatial distribution of fishing changed substantially from year to year. In a model like that for Widow, in which selectivities are assumed to be time-invariant, this would movement would add process error to the observations. If the spatial distribution of catch sampling varied from year to year, in a way that did not reflect the movement of fishing activity, this would produce observation error, with a correlation between individual proportions. More information on the generation of correlations in composition data are given by Hrafnkelsson & Stefánsson (2004) and section 3 of Francis (2006).

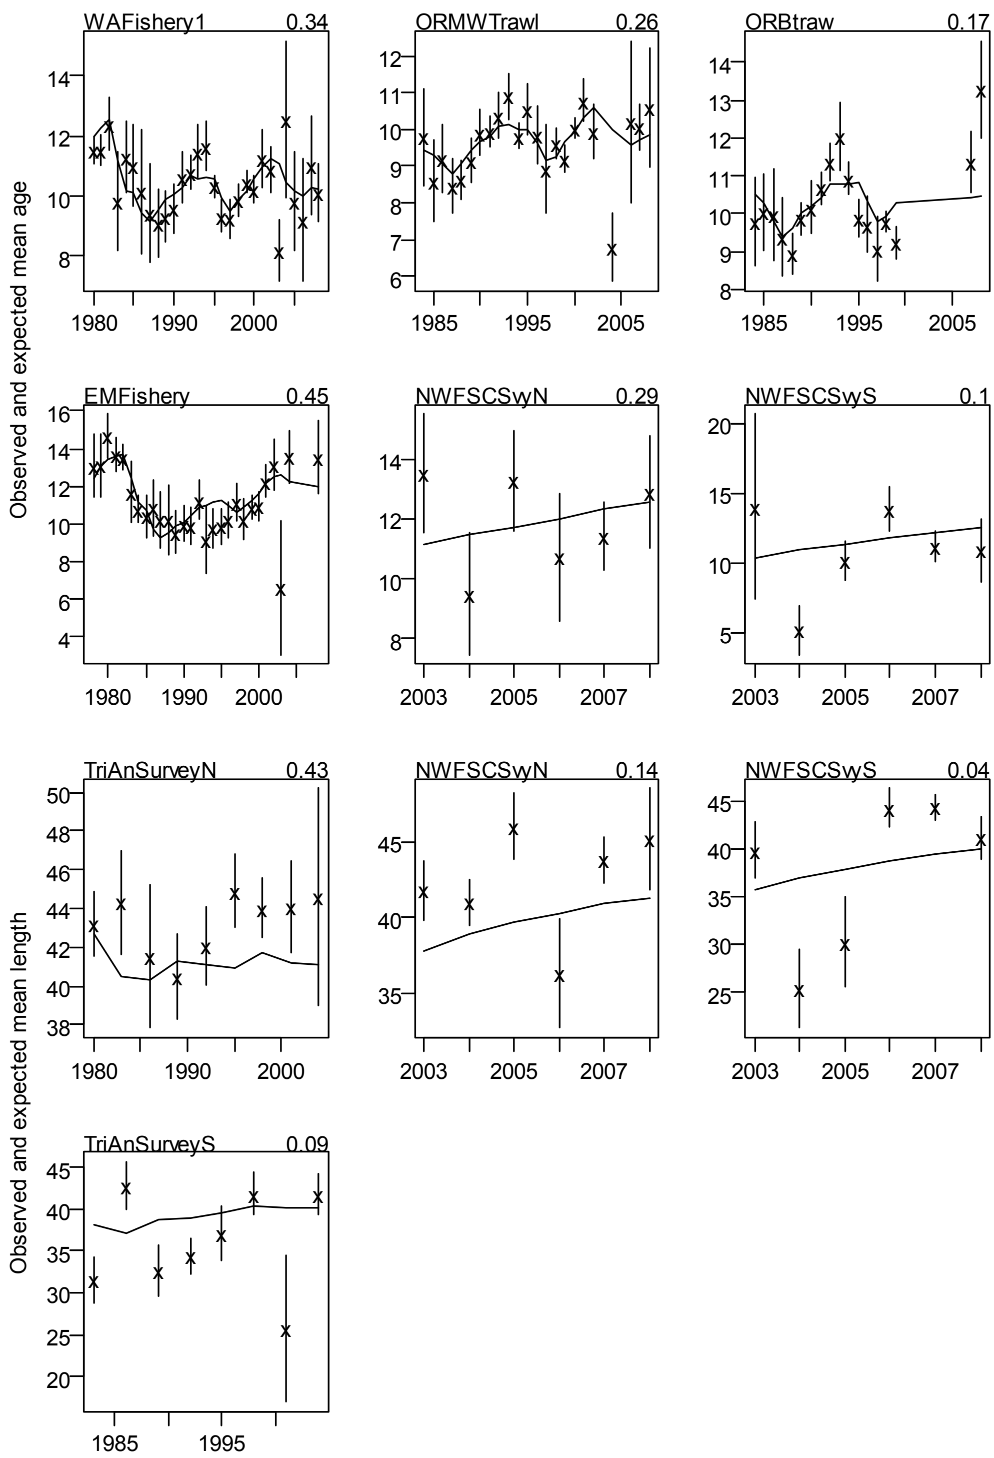

Figure 1: Observed & expected mean ages (upper panels) and lengths (lower panel) for the Widow comps in the (former) base case model. Vertical bars are approximate 95% confidence intervals based on the multinomial sample sizes used in that model. The number printed above each panel is the correction factor *f*, calculated as described above.

Note that there is no intention to suggest that mean age (or length) is a quantity of particular interest in stock assessments. The only reason mean age (or length) is used in calculating the correction factor is that it is sensitive to the sort of correlations shown in Figures 1 and 2. Because of these correlations the composition data are less informative than is suggested by the multinomial sample size correction method used in SS3 (which assumes no correlation). Ideally, we should include these correlations in the likelihood function for composition data. However, that is not straightforward to do. The method proposed here is a simpler pragmatic alternative approach which adjusts sample sizes to compensate for the correlations.

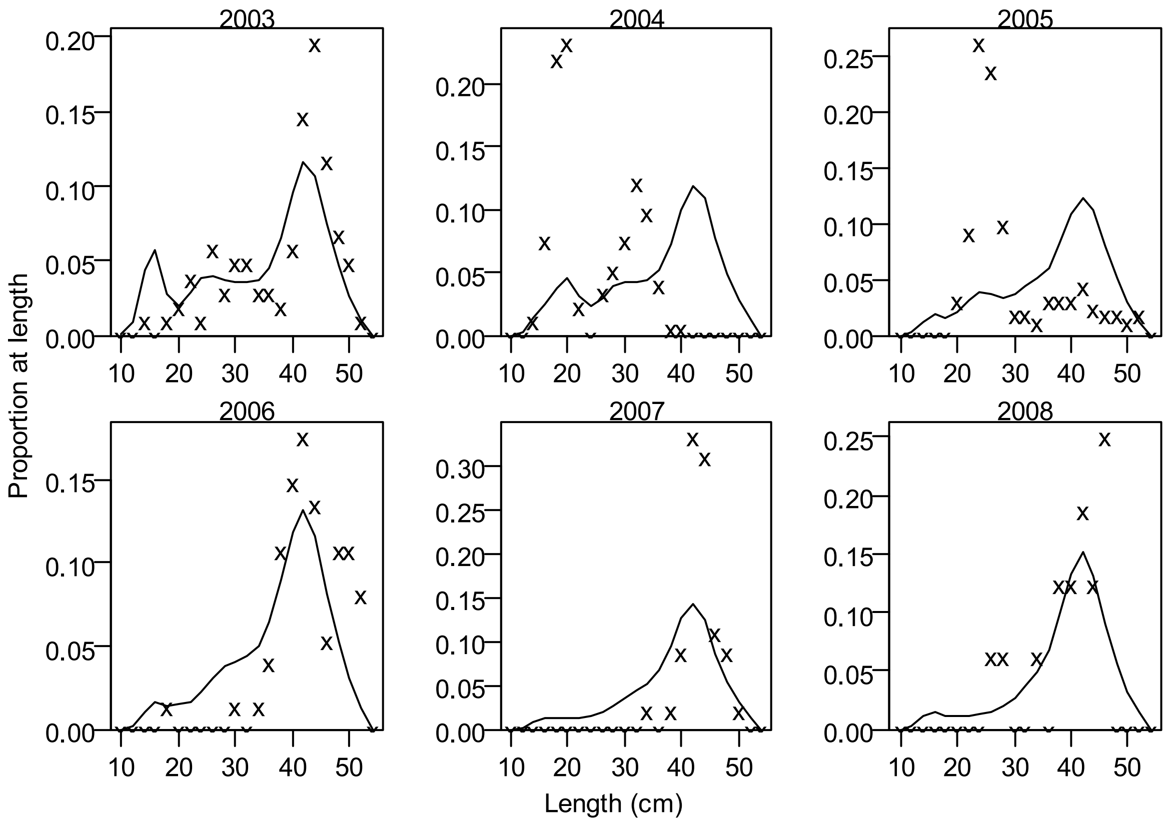

Figure 2: Observed ('x') and expected (line) proportions at length (sexes combined) for data set NWFSCSvyS.

20 Appendix I. Spatial distribution of widow rockfish catch by the West Coast Groundfish Observer program. These figures were provided by Marlene Bellman of the NWFSC.

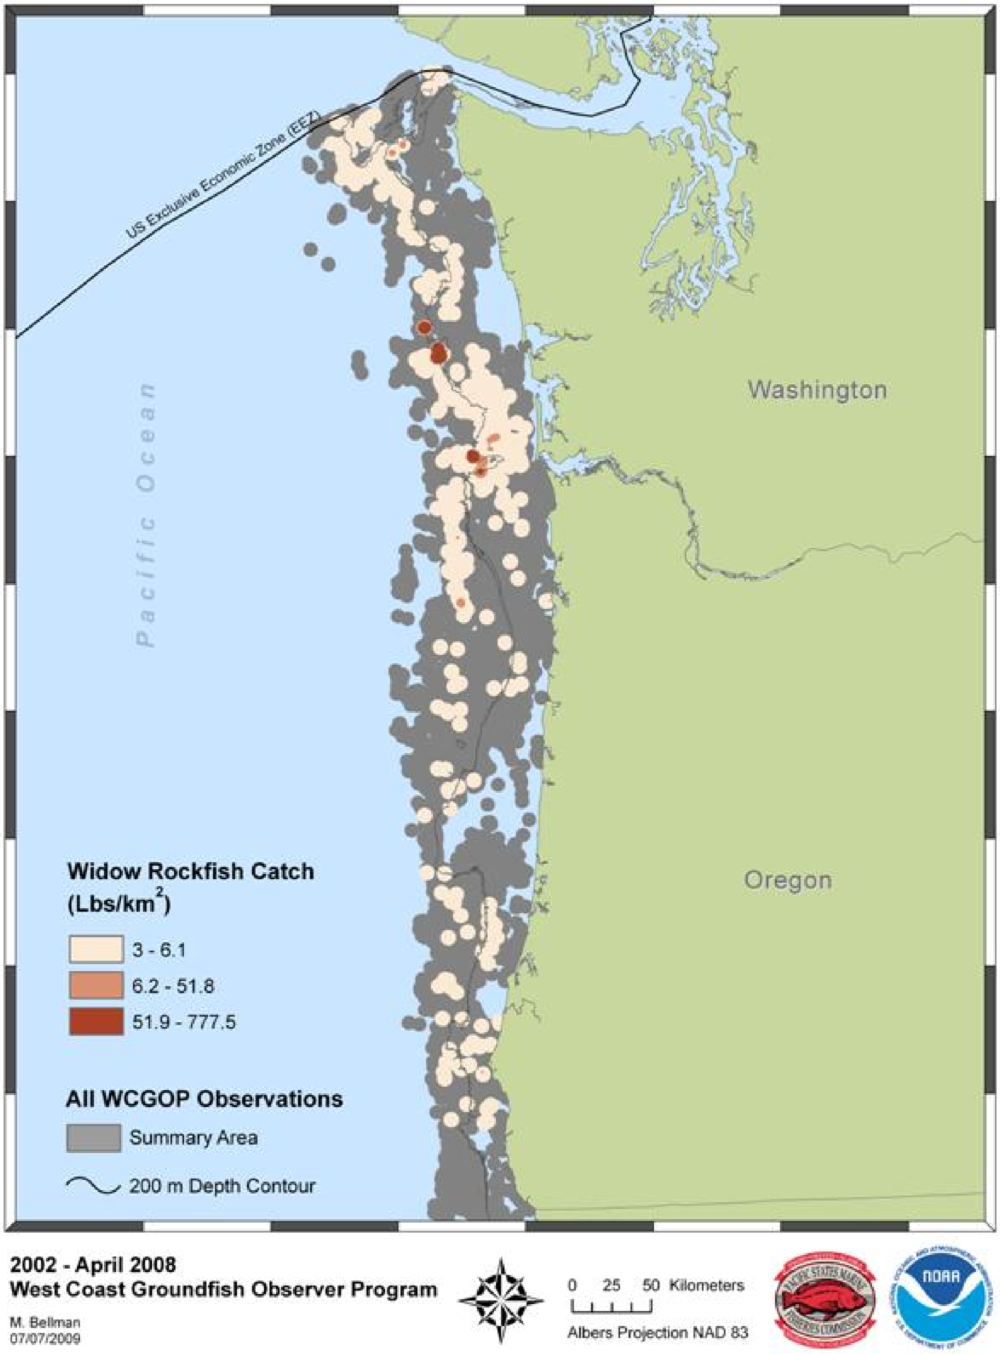

Figure I1. Spatial distribution of widow rockfish catch (lbs/km^2) observed by the West Coast Groundfish Observer Program from 2002 to April 2008 and the summary area of all observed fishing events off of Washington and Oregon. Note that this figure does not include midwater trawls from the at-sea whiting fishery.

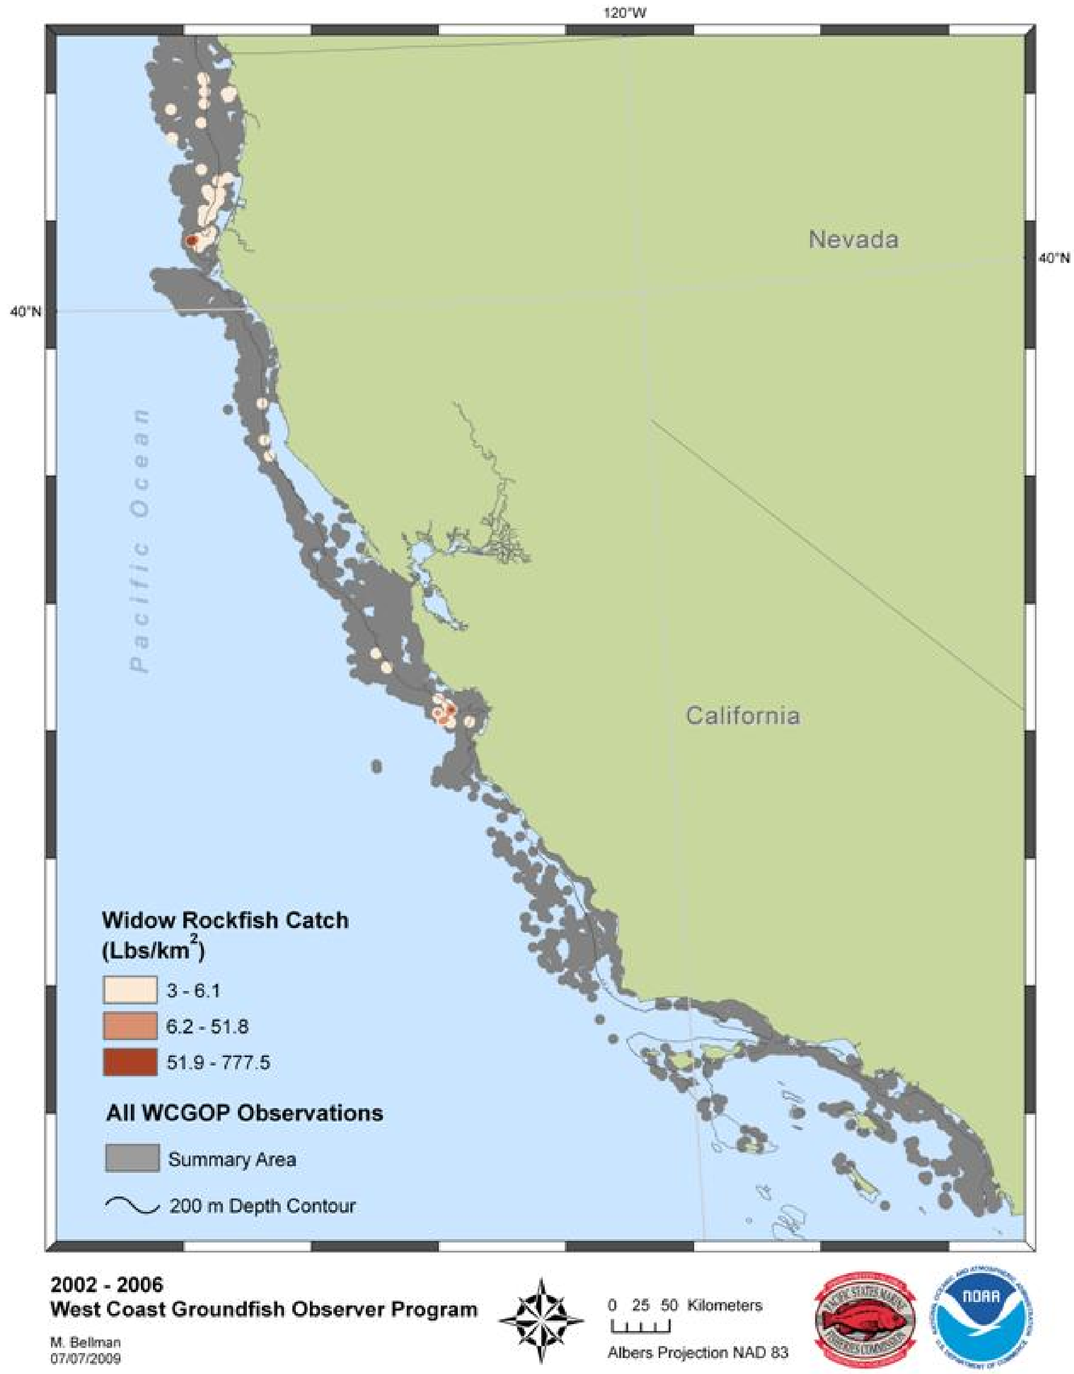

Figure I2. Spatial distribution of widow rockfish catch (lbs/km^2) observed by the West Coast Groundfish Observer Program from 2002 to April 2008 and the summary area of all observed fishing events off California. Note that this figure does not include midwater trawls from the at-sea whiting fishery.

WIDOW ROCKFISH

STAR Panel Report

July 13-17, 2009

Southwest Fisheries Science Center
110 Shaffer Road, Santa Cruz, CA 95060

Panel Reviewers

Martin Dorn	Panel Chair, Scientific and Statistical Committee (SSC) Representative
Chris Francis	Center for Independent Experts (CIE)
Vladlena Gertseva	NMFS, Northwest Fisheries Science Center (NWFSC)
J. J. Maguire	Center for Independent Experts (CIE)

Panel Advisors

John DeVore	Pacific Fishery Management Council
Gerry Richter	Groundfish Advisory Subpanel (GAP) Representative
John Budrick	Groundfish Management Team (GMT) Representative

Stock Assessment (STAT) Team members present

Xi He	NMFS, Southwest Fisheries Science Center (SWFSC)
Alec MacCall	NMFS, Southwest Fisheries Science Center (SWFSC)
Stephen Ralston	NMFS, Southwest Fisheries Science Center (SWFSC)
John Field	NMFS, Southwest Fisheries Science Center (SWFSC)
E. J. Dick	NMFS, Southwest Fisheries Science Center (SWFSC)

Overview

A draft assessment of widow rockfish (*Sebastes entomelas*) off the United States West Coast was reviewed by the STAR panel during July 13-17, 2009. The assessment assumes a single coastwide stock given that there is currently no biological or genetic information to suggest the presence of multiple stocks. Northern and southern areas are modeled with different growth in each area. Recruits are produced from a common pool of spawners, and are assigned to each area according to year-invariant proportion (estimated by the model). No mixing is assumed to occur post recruitment.

This assessment uses the Stock Synthesis platform (version 3.03a) and incorporates a variety of data sources into the base model. Catch and age-frequency data from four fisheries are used in the assessment, including Washington and California fisheries (all gears combined), and Oregon midwater and bottom trawl fisheries. A fishery-dependent relative abundance (CPUE) index calculated from Oregon trawl fishery data was used in the model, and three bycatch indices were estimated from foreign, joint-venture and domestic Pacific whiting fisheries. Fishery-independent data included the midwater trawl pelagic juvenile survey, the triennial trawl survey and the NWFSC shelf-slope survey. In addition to survey indices, length-frequency data were available from the triennial and NWFSC shelf-slope surveys, and age data from the NWFSC shelf-slope survey.

The last full assessment of widow rockfish was conducted in 2005, and it was subsequently updated in 2007. Major changes made in this assessment, compared with the previous assessment include:

- Use of SS3 modeling framework instead of previously employed direct ADMB code;
- Extension of period modeled from 1958 to 1916;
- Use of revised catch history based on Lynde (1986), Tagart (1985) and Ralston et al. (2009);
- Addition of NWFSC shelf-slope trawl survey (referred to as NWFSC combo survey in the assessment report);
- Use of revised triennial survey estimates using a GLMM approach (instead of area-swept approach previously used);

The STAR panel concluded that the widow rockfish assessment constitutes the best available scientific information on the status of widow rockfish off the U.S. west coast and recommends that it be used for status determination and management in the Council process. The base model developed during the Panel meeting is considered reasonably well investigated. However further model evaluation and exploration of alternative model configurations is a priority for widow rockfish. There was insufficient time to accomplish this during the STAR Panel meeting because of difficulties in developing a suitable base model. The STAR panel thanks the STAT team members for their hard work and willingness to respond to panel requests.

Analyses requested by the STAR panel

A total of 14 requests were made by the STAR panel. While data and modeling requests were fulfilled in an order different than that in which they were made, data requests are discussed first in the list below, followed by modelling requests. The requests have been grouped and re-ordered for readability.

Data requests

1. **Split Oregon catches for midwater and bottom trawl fisheries prior to 1983 out of the Washington fishery.**
   Rationale: The draft assessment models four fisheries: a) Vancouver – Columbia, b) Oregon midwater trawl, c) Oregon bottom trawl, d) Eureka, Monterey and Conception. Because there was no age composition data prior to 1983, catches for the OR MWT and BT for 1983 and prior years, when widow catches were substantial, were lumped with the Vancouver – Columbia (Washington) catches. This is inaccurate in terms of fishery history and could result in model misspecification. Information is available for years prior to 1983 to partition Oregon catches into bottom trawl and midwater trawl and the panel requested that it be done.
   Response: Available information was used to parse OR MWT and BT out of the Vancouver-Columbia fishery, into OR MWT and BT, with little effects on the modeling results.
2. **Provide new estimates for catches in Vancouver – Columbia for 1916 to 1976.**
   Rationale: Some catches are known to have occurred prior to the late 1970s, but as there were no estimates, the draft assessment assumed that catches in Vancouver – Columbia for 1916 to 1976 were the same as in the Eureka, Monterey and Conception commercial fisheries for the same years. This seemed highly unlikely and the panel requested that real data be used or that catches in those years without information be assumed to be zero.
   Response: Widow rockfish catches were estimated from a spreadsheet prepared by Tagart (1985), total rockfish catches by state from 1938 to 1955 published in the Bulletin of Commercial Fisheries (red books), an Alaska Fisheries Science Center report on catch reconstruction (Lynde 1986) for 1956 to 1980, and on the percent widow rockfish in the total rockfish category. This should be seen as provisional reconstruction that should be re-evaluated in the next assessment. These new landings were assigned to the OR bottom trawl fishery for modeling as opposed to the Vancouver – Columbia fishery. This was not expected to make a large difference, but was felt to correspond more to reality.
3. **Provide discard rates by State and gears from the West Coast observer program for 2002-2008. Review Pikitch data to see if there is information on discard rates by gear (bottom vs midwater trawl). If the discard rates are different, total removals**

should be adjusted accordingly. For foreign fleets, remove the discards as discards are not believed to have occurred. Report what discard rates had been applied to what fishery in what year.

Rationale: It was unclear what discard rates had been used in the draft assessment. The panel asked that what had actually been done be documented and potentially revised using sources of information that might not have been used.

Response: No discard was applied to the foreign fishery, since Rogers (2003) indicates that the large capacity foreign vessels did not discard fish based on either size or species. For all domestic fisheries, discards were assumed to be 6% until 1981, and 19% from 1982-2001 (Pikitch study did not show significant differences in discard rates between bottom and midwater trawl fisheries for widow rockfish). Between 2002 and 2007, total catches (landings plus discard) were reconstructed from West Coast Groundfish Observer Program total mortality estimates and at-sea whiting fishery bycatch estimates, provided by the Northwest Fisheries Science Center. The only 2008 discard information for widow rockfish available at the time of STAR Panel was the discard estimate from the PacFIN quota-species monitoring report, and this value was minimal, therefore for 2008 landing data from PacFIN and the widow bycatch estimate in the at-sea whiting fishery were used, and no discard was added.

4. **Provide a graph of the abundance indices scaled to their own average for a common time period so that they are on a similar scale.**

   Rationale: A close examination of the abundance indices should be standard practice into assessments before any modeling takes place to identify what story the indices are telling if any.

   Response: As this request was not seen as high priority, there was insufficient time during the panel meeting to provide this graph. Such a graph should be included in the final assessment report.

Modeling requests

5. **Reset all effective Ns using Stewart's method with number of trips and number of fish for fisheries; for the surveys, use Stewart's method with the number of positive hauls. Do the re-tuning with effective N multipliers for the composition data sets, rather than adjusting each individual year.**

   Rationale: The draft assessment appears to have tuned each individual year of each data source rather than use a single weight by source of data. This is not appropriate, and single weight per series should be used rather than individual weights for each data point of each data series.

   Response: This was done, but the multipliers were used as new weights rather than as multipliers for the original weights. A new run was requested where the multipliers are used to modify the original weights rather than used as new estimates for the weights. This resulted in more stable model with a higher Bcurrent to B0 ratio (depletion).

6. **Provide a run with one asymptotic length-based selectivity for all surveys, genders and areas combined. Also provide a run with separate asymptotic length-based selectivity curves for each survey, but combining genders and areas.**
   Rationale: The draft assessment estimated selectivities by gender for each of the survey (2), genders (2) and areas (2) for a total of 8 selectivities. The resulting estimates showed strange patterns and were based on few observations.
   Response: Estimating a single selectivity for the 2 surveys, the 2 genders and the 2 areas deteriorated the fit and resulted in unreasonable selectivities. It seemed more sensible to estimate one selectivity per survey with genders combined. This improved the fit, but the results were counterintuitive in that the two survey curves shifted substantially to the left of the combined survey selectivity seen earlier. This indicates the survey selectivities are not well estimated, which is not surprising given the sparseness of the survey length composition data. There could also be issues associated with forcing the survey selectivities to be asymptotic.
   The Panel thought that taking two steps to change these selectivities should have been done one at a time. The panel requested two survey selectivity curves and allowing these curves to be dome-shaped using a double-normal function. These curves were more reasonable and the panel considered this configuration to be suitable for the base case model.
7. **Provide a run with the abundance index for juveniles up-weighted and the age and length compositions down-weighted.**
   Rationale: As a result of management measures, age and length compositions have become increasingly sparse since the early 2000s. In addition, length and age compositions provide only indirect evidence on the size of year-classes while the juvenile index does provide direct evidence.
   Response: As expected, a closer fit to the juvenile abundance index was obtained, and this model appeared to be more stable in comparison to other model configurations.
8. **Provide a new base case using the Francis multipliers applied to the N-multipliers from the last re-weighted run (Reweight 2). For the age compositions, four Francis weights will be used: 1) average WA and EM fisheries = 0.4 , 2) average for the ORM and ORB trawl fisheries = 0.22, and 3) average for north and south NWFSC survey = 0.20. For the length compositions, use 0.25 for the triennial survey and 0.10 for the NWFSC survey.**
   Rationale: The panel considered that the weights given to age and length compositions is too high because of autocorrelation in the compositions. A method was proposed to estimate appropriate weights (see Appendix) and a subjective judgement, based on the results, was made for the weights to be applied to each age and length composition data source.

Response: The panel considered this model to be an improvement given concerns about overweighting age and length composition data. The STAR panel and the STAT team agreed that this model was appropriate as a base case.

9. **For the new base case with the Francis weights, use h=0.30 and h=0.50 to bracket uncertainties. If these provide too narrow a range to bracket the uncertainties, use h=0.25 and h=0.55.**
   Rationale: Steepness is poorly known and changes in steepness results in substantial changes in depletion and recent population trends.
   Response: Runs with the four steepness were provided and the panel concluded that those with steepness of 0.25 and 0.55 were bracketing the uncertainties in this assessment.
10. **Provide spawning output trends for proportion of recruits in northern area at 0.68 and 0.80 and a table of the key parameters. Provide a graph of spawning output as depletion for the two areas to better see what is happening in the two areas for all three scenarios, including base case.**
    Rationale: The panel questioned the estimate of the proportion of recruitment in the north (0.72). The estimated coastwide depletion varies substantially as that proportion of northern recruitment varies, and the depletion was the greatest when the proportion was at the estimated value. The panel requested sensitivity analyses where the recruitment proportion in the north is fixed at lower (0.68) and higher (0.80) values.
    Response: When profiling on proportion of recruits in the north with the final base case (estimated propN = 0.717), steepness was near one when the proportion north was 0.65. The panel asked that the final assessment report provide runs with the proportion north of 0.6875, 0.717 and 0.75 with the requested graphs and key parameters.
11. **Provide a likelihood profile on steepness to be completed after the meeting.**
    Rationale: Steepness has considerable influence on the assessment results, particularly on recruitment and depletion estimates. It is important to know if the steepness used in the assessment is optimal in terms of likelihood.
    Response: Because of the time required to sort out the landings and discard data, and the time devoted to finding an acceptable model configuration, there was insufficient time during the panel meeting to complete this request. This request should be addressed in the final assessment report.
12. **Examine the contribution of age 1 male of OR MWT in 2007 to the total likelihood.**
    Rationale: This observation had a large residual and the panel was concerned that it could have a large influence on the total likelihood.
    Response: Because of the time required to sort out the landings and discard data, and the time devoted to finding an acceptable model configuration, there was insufficient time during the panel meeting to complete this request. This request should be addressed in the final assessment report.

13. **Slide 26 of the original widow rockfish presentation on July 14 shows stacked fishing mortalities by area. Provide different graphs for northern and southern areas.**
    Rationale: These data were from a two area model and the fishing mortality in the two areas are not additive.
    Response: Because of the time required to sort out the landings and discard data, and the time devoted to finding an acceptable model configuration, there was insufficient time during the panel meeting to complete this request. This request should be addressed in the final assessment report.
14. **Provide a run with single area model, re-combining the Triennial and NWFSC surveys into one series each with corresponding age composition data. If results are significantly different, try to explain the differences.**
    Rationale: The draft assessment used two-areas mostly because of difference in growth. As the assessment is largely age-based, difference in growth are less important than the reduction in sample size of stock size indices and composition information caused by having to break the series in two areas.
    Response: Because of the time required to sort out the landings and discard data, and the time devoted to finding an acceptable model configuration, there was insufficient time during the panel meeting to complete this request. This request should be addressed in the next assessment.

Description of base case model and alternative models to bracket uncertainty

Start year of the model =1916; two area model with time-invariant proportion of recruits assigned to each area; discard incorporated into total catches;
M fixed at 0.125yr^{-1} for both females and males; h estimated (but with Dorn's prior); $\sigma_R = 0.6$;
Von Bertalanffy growth parameters - all fixed for females and males.

Fisheries

- Washington fishery (all gears combined)
- Oregon midwater trawl fishery
- Oregon bottom trawl fishery
- California fishery (all gears combined)

Abundance indices:

- Oregon trawl CPUE (1984-1999)
- Foreign Pacific whiting fishery bycatch CPUE (1977-1988)
- Joint-venture Pacific whiting fishery bycatch CPUE (1983-1990)
- Domestic Pacific whiting fishery bycatch CPUE (1991-1998)
- Midwater trawl pelagic juvenile survey (2001-2008)
- Triennial trawl survey south of 43^o N (1980-2004)
- Triennial trawl survey north of 43^o N (1980-2004)

NWFSC shelf-slope trawl survey south of 43° N (2003-2008)
NWFSC shelf-slope trawl survey north of 43° N (2003-2008)

Age frequencies:

Washington fishery (all gears combined) (1980-2008)
Oregon midwater trawl fishery (1984-2008)
Oregon bottom trawl fishery (1984-2008)
California fishery (all gears combined) (1978-2008)
NWFSC shelf-slope trawl survey north of 43° N (2003-2008)
NWFSC shelf-slope trawl survey south of 43° N (2003-2008)

Length frequencies:

Triennial trawl survey index north of 43° N (1980-2004)
Triennial trawl survey index south of 43° N (1983-2004)
NWFSC shelf-slope trawl survey north of 43° N (2003-2008)
NWFSC shelf-slope trawl survey south of 43° N (2003-2008)

Uncertainty was bracketed by fixing steepness at 0.25 (low biomass) and at 0.55 (high biomass) to contrast with the base model where steepness was estimated to be 0.4.

Technical merits of the assessment

There were problems with the data and structure of the model in the draft document. Through fruitful interchanges between the STAT and the STAR Panel, considerable improvements in both model structure and data were achieved. The base case available at the end of the Panel meeting is considered reasonably well investigated and a substantial improvement on the original base case. There remain problems, however, particularly with the sharply-peaked selectivity patterns. Because the panel spent time trying to reconstruct catch history and because an inappropriate tuning algorithm had been used, there was insufficient time to fully examine models fits and model results. Because of these concerns, the Panel recommends that the next widow rockfish assessment be a full assessment rather than an update.

Explanation of areas of disagreement regarding STAR panel recommendations

A. Among STAR panel members (including concerns raised by the GAP and GMT representatives

There were no areas of disagreement among STAR panel members.

B. Between the STAR panel and the STAT team

There were no areas of disagreement between the STAR panel and the STAT team.

Unresolved problems and major sources of uncertainty

Whether it is preferable to do a single area stock assessment or a two area assessment remains one of the major unresolved problems for the widow rockfish assessment. There also remain problems with age determination and the reliability of age readings which needs to be better evaluated. As a result of substantially lower allowable catch due to fisheries management measures, the widow rockfish assessment has moved from being relatively data rich to being data poor because low allowable catches have resulted in sparse age and length compositions, and have rendered useless fishery-dependent stock size indices that were used in previous assessments. Furthermore, there is no reliable fishery independent monitoring.

Management, data, or fishery issues raised by the GAP and the GMT representatives

GAP and the GMT representatives (as well as representatives of fishing industry attending the meeting) provided assistance in identifying appropriate discard rates to apply to different fisheries in different time periods.

Prioritized recommendations for future research and data collection

- For the next assessment of widow rockfish, reconsider the overall structure of the model including the definition of fisheries, assignment of catches, age or size based selectivities, one or two area model. Development of a one area model (at least for comparative purposes) should be a priority. Estimates of growth, maturity, and fecundity used in a one area model should be representative of widow rockfish throughout its range off the West Coast.

- Do an interagency aging comparison to more reliably estimate the aging error matrix for widow rockfish, possibly using the Punt et al. (2008) aging error program.

- Do a comparative analysis of break and burn and surface age reading of otoliths to evaluate the reliability of ages in the early years of the assessment. If the comparative analysis indicates that age composition estimates can be improved, re-read the otoliths using the best available method.

- Low allowable catches have resulted in sparse age and length compositions in recent years. Sampling protocols for widow rockfish should be re-evaluated to ensure that adequate samples are obtained.

- There is currently no effective monitoring program for this stock. There is a need for the development of alternative survey methods for widow rockfish.

- Investigate the usefulness of blocking time periods into presumptive environmental regimes as indicated by the PDO (Pacific Decadal Oscillation) to reflect possible climate effect.

- Bias adjustment of stock recruitment relationship in SS3 seems to have been widely implemented with little or no peer review. Simulation testing is needed to confirm that bias adjustment is justified in all cases, and guidelines are needed on how to configure bias adjustment settings to reflect the information available and the biological characteristics of the stock.

- Develop methods to incorporate uncertainty in natural mortality and/or steepness in model configurations in which these parameters are fixed. The delta method for propagating uncertainty (McCall in prep.) is promising approach that warrants further evaluation.

Acknowledgements

The Panel thanks staff at the SWFSC Santa Cruz laboratory their exceptional support and provisioning during the STAR meeting.

Appendix: Multinomial sample sizes

This Appendix describes the method that was used to correct the multinomial sample sizes for compositional data in the widow rockfish assessment, shows the results of its application to these data, and provides a brief rationale for the use of this method. The description that follows concerns age data, but the approach is exactly the same for length data. Also, for simplicity, the following description ignores sex, but the extension to include sex is straightforward.

Suppose $p_{ay,\mathrm{obs}}$ is the observed proportion at age a in year y in a set of age composition data that is assumed to have a multinomial error structure, and let $N_{\mathrm{init},y}$ denote the initial sample sizes. We run our assessment model using these sample sizes and obtain, from the model fit, estimates of the expected proportions at age, $p_{ay,\mathrm{exp}}$. Our aim is to use the $p_{ay,\mathrm{obs}}$, $p_{ay,\mathrm{exp}}$, and $N_{\mathrm{init},y}$ to calculate a correction factor f so that the size of the model residuals is consistent with the corrected sample sizes, $N_{\mathrm{corr},y} = fN_{\mathrm{init},y}$.

This aim is the same as for the method currently used in SS3 to correct multinomial sample sizes. Where the two methods differ is that the SS3 method is based on the residuals for individual proportions, $r_{ay} = p_{ay,\mathrm{obs}} - p_{ay,\mathrm{exp}}$, whereas the present method is based on residuals for mean age, $r_y = (m_{y,\mathrm{obs}} - m_{y,\mathrm{exp}})$, where $m_{y,\mathrm{obs}} = \Sigma_a(a\, p_{ay,\mathrm{obs}})$, and $m_{y,\mathrm{exp}} = \Sigma_a(a\, p_{ay,\mathrm{exp}})$. The reason for using mean-age residuals is discussed below.

For the multinomial distribution, the expected variance of the mean age, $m_{y,\mathrm{obs}}$, and thus of the residual r_y, is $v_y/(fN_{\mathrm{init},y})$ [i.e., $v_y/N_{\mathrm{corr},y}$], where v_y is the variance of the age frequency in year y, given by $v_y = \Sigma_a(a^2\, p_{ay,\mathrm{obs}}) - m_{y,\mathrm{obs}}^2$. Therefore, the expected variance of $r_y(N_{\mathrm{init},y}/v_y)^{0.5}$ is $1/f$, and we estimate f as $1/\mathrm{Var}(r_y(N_{\mathrm{init},y}/v_y)^{0.5})$.

Figure 1 shows the application of this method to the widow rockfish age and length composition data. In this application, the sample sizes, $N_{\mathrm{init},y}$, were those obtained after correction (or tuning) using the SS3 method. That is to say, the residuals for individual proportions, r_{ay}, should be consistent with the size expected given these sample sizes. What Figure 1 shows is that the mean-age residuals are still too large (note that many of the confidence intervals for the observed values do not overlap the expected values). Thus, according to the present method, the sample sizes are too large, and so the estimated f is less than 1 for all data sets (range 0.04 to 0.45).

The reason the mean-age residuals, r_y, can be too large, while the individual proportion residuals, r_{ay}, are not, is that there is substantial correlation between the individual residuals. This is shown in Figure 2, in which the observed age frequency flips from one side of the expected frequency to the other from one year to the next. Lateral shifts of this magnitude would not be possible if the individual residuals were uncorrelated. This correlation could be caused by either observation or process error (or a combination of both). One explanation of how this could occur derives from the fact that size (and thus age) distribution of fish often varies spatially. Between-year lateral shifts in age frequencies could occur if the spatial distribution of fishing changes substantially from year to year. In a model like that for widow rockfish, in which selectivities are assumed to be time-invariant, changes in the spatial pattern of fishing would add process error to the observations. If the spatial distribution of catch sampling varied from year to year, in a way that did not reflect the movement of fishing activity, this would produce observation error, with a correlation between individual proportions. More information on the generation of correlations in composition data are given by Hrafnkelsson & Stefánsson (2004) and section 3 of Francis (2006).

Note that there is no intention to suggest that mean age (or length) is a quantity of particular interest in stock assessments. The only reason mean age (or length) is used in calculating the correction factor is that it is sensitive to the sort of correlations shown in Figures 1 and 2. Because of these correlations the composition data are less informative than is suggested by the multinomial sample size correction method used in SS3 (which assumes no correlation). Ideally, we should include these correlations in the likelihood function for composition data. However, that is not straightforward to do. The method proposed here is a simpler pragmatic alternative approach which adjusts sample sizes to compensate for the correlations.

Status and Future Prospects for Lingcod in Waters off Washington, Oregon, and California as Assessed in 2009

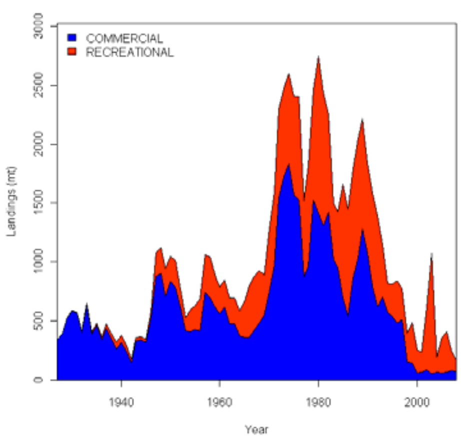
This assessment applies to lingcod (*Ophiodon elongatus*) off the West Coast of the United States, and is conducted as two separate assessments of (1) Lingcod off of Washington and Oregon (the North stock), and lingcod off of California (the South stock).

For each stock, two fisheries are modeled: the commercial fishery and the recreational fishery. Landings are included from 1928-2008, with equilibrium landings estimated for the commercial fisheries prior to 1928. Since the fishery off of California developed earlier, the equilibrium catches are an order of magnitude higher there (341 metric tons (mt) in California vs. 36 mt for Washington/Oregon).

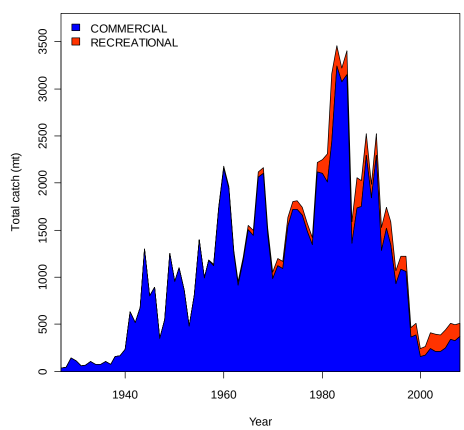
The largest landings off California were 2749 mt in 1980 (nearly equally divided between the commercial and recreational fleets). For Washington/Oregon, the largest landings were 3443 mt in 1983 (with over 90% of the landings coming from the commercial fleet). Landings exceeded 1400 mt for the years 1971-1991 in the South and the years 1973-1994 in the North. Landings have declined significantly over the past two decades, with the average landings over the past 10 years being 298 mt in the North and 405 mt in the South.

Landings history from 1928-2008

South



North



Year	S. Commercial	S. Recreational	N. Commercial	N. Recreational	Total
1999	142	342	216	125	825
2000	56	199	90	80	425
2001	63	170	93	92	418
2002	81	534	124	166	905
2003	51	1,021	107	189	1,368
2004	63	130	115	171	479
2005	61	299	140	190	690
2006	62	348	197	174	781
2007	79	174	190	168	611
2008	69	102	216	134	521

Landings (MT) for the last 10 years.

Catch (total mortality) is similar to landings for most of the time series. However, discard rates and therefore estimates of mortality due to discard for the commercial fishery have been quite high relative to landed catch in recent years due to regulations.

This assessment used the Stock Synthesis (SS) model, version 3.03a. Lingcod has been modeled using various age-structured forward-projection models since the mid-1990s. The previous assessment was conducted in 2005 in SS2 (Jagielo et al. 1995). Data used in the base models for the current assessment include the following: Commercial and Recreational landings data from 1928-2008, with information on prior catch informing the "equilibrium" landings level; Commercial discard rates from 2002-2007; Triennial survey indices for the years 1980-2004 (every 3rd year); NWFSC survey indices for the years 2003-2008; commercial logbook CPUE indices for the years 1976-1997 (North) or 1978-1997 (South); PSMFC Dockside (recreational) boat survey index 1980-1989, 1993-1997 (South); Commercial length composition data for 1965-2008 (North) or 1978-2008 (South); Commercial discard length composition data for 2003-2007 (North) and 2004-2007 (South); Recreational length composition data for 1993-2008 (North) or 1987-2008 (South); Triennial length composition data for 1986-2004 (North) or 1989-2004 (South); NWFSC length composition data for 2003-2008.

Age data were available and used in sensitivities but not in the base models due to issues with outliers and possible aging bias. The data used in sensitivities include: Commercial conditional age-at-length data for 1980-2008 (North) and 1987-2008 (South); Recreational conditional age-at-length data for1999-2008 (North); Triennial conditional age-at-length data for 1992-2004 (North) or 1995-2004 (South); NWFSC survey conditional age-at-length data for 2003-2008.

A number of sources of uncertainty were explicitly included in this assessment. There were also other sources of uncertainty that were not included in the current model, including the degree of connection between the two lingcod stocks and also between the northern stock and the stock off British Columbia; the effect of the PDO, ENSO and other climatic variables on recruitment, growth and survival of lingcod.

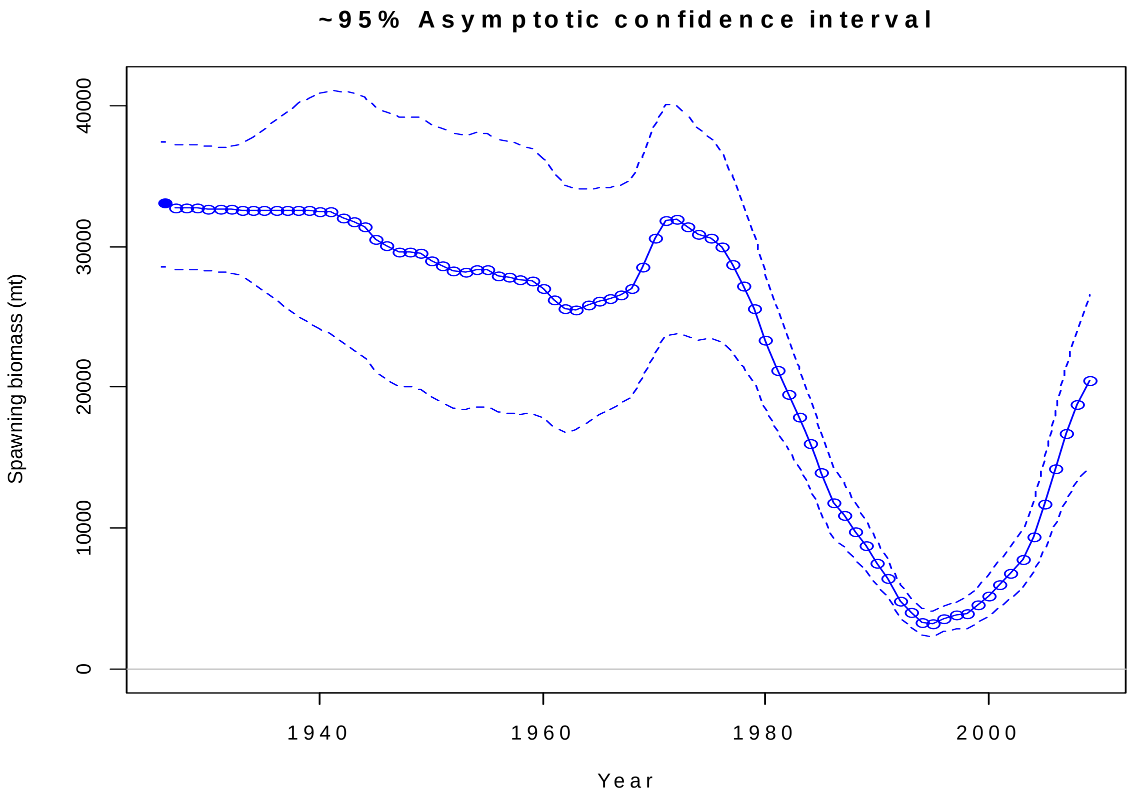
A reference case was selected based on extensive model testing and an attempt was made to balance the sources of uncertainty. In addition, an attempt was made to make the North and South models as equivalent as possible. In this regard, fixed and estimated parameters are largely the same for the two assessments. Natural mortality (M) is fixed at 0.18 for females and 0.32 for males in both assessments, while stock-recruitment steepness (h) is fixed at 0.8. Size at age 1 is estimated along with all other growth parameters except size at age 20. In the North, male and female size at age 20 is estimated within a model which includes conditional age-at-length data and then fixed in the base model. In the South, estimating Lmax resulted in unrealistically large values (possibly due to bias in ageing); therefore size at age 20 was fixed at the values used in the 2005 assessment. In both models there is a single block for commercial selectivity and retention changes, occurring in 1998 (to present) reflecting the increased regulation and areal limitations which have come into place over that period. That same block is used to model changes in recreational selectivity, reflecting changes in minimum size limits. In the North, male and female selectivities are estimated separately for the recreational fishery, whereas data to do so is lacking in the South.

Combined models:

The point estimate for the depletion of the spawning output (= spawning biomass) at the start of 2009 is 61.9% for the North, 73.7% for the South, and 67.0% coastwide. For West Coast groundfish, a stock is considered overfished when it is below 25% of virgin spawning biomass, and recovered when it reaches 40% of virgin spawning biomass. The current assessment indicates that coastwide; the stock is recovered, as are both stocks, off of Washington and Oregon and off of California. Overfishing is considered to be occurring when catch exceeds the ABC specified for a particular year. Overfishing last occurred in 2003, although there is some dispute about the magnitude of recreational fishery catch off of California for that year.

North Model:

The base model indicates that the lingcod female spawning biomass off of Washington and Oregon declined rapidly in the 1980s and early 1990's, hitting a low of 3,217 mt in 1995, and has subsequently recovered to 21,264 mt, which is over 60% of the virgin level. The 95% confidence interval in the current depletion for the North ranges from 48-76%.



Year	Total biomass (mt)	Age 2+ biomass (mt)	Female spawning biomass (mt)	~95% confidence interval	Estimated depletion	~95% confidence interval
1999	8,743	8,508	4,610	3,362-5,859	13.9%	11-17%
2000	9,824	9,176	5,244	3,805-6,682	15.9%	12-19%
2001	11,776	11,023	6,030	4,388-7,672	18.2%	14-22%
2002	14,364	13,635	6,840	4,980-8,699	20.7%	16-25%
2003	17,283	16,655	7,837	5,694-9,980	23.7%	19-29%
2004	20,215	19,903	9,437	6,859-12,015	28.5%	23-35%
2005	23,078	22,498	11,689	8,489-14,888	35.3%	28-43%
2006	25,551	25,198	14,271	10,321-18,220	43.1%	34-52%
2007	27,979	27,093	16,710	11,993-21,426	50.5%	40-61%
2008	30,235	29,813	18,774	13,360-24,187	56.8%	44-69%

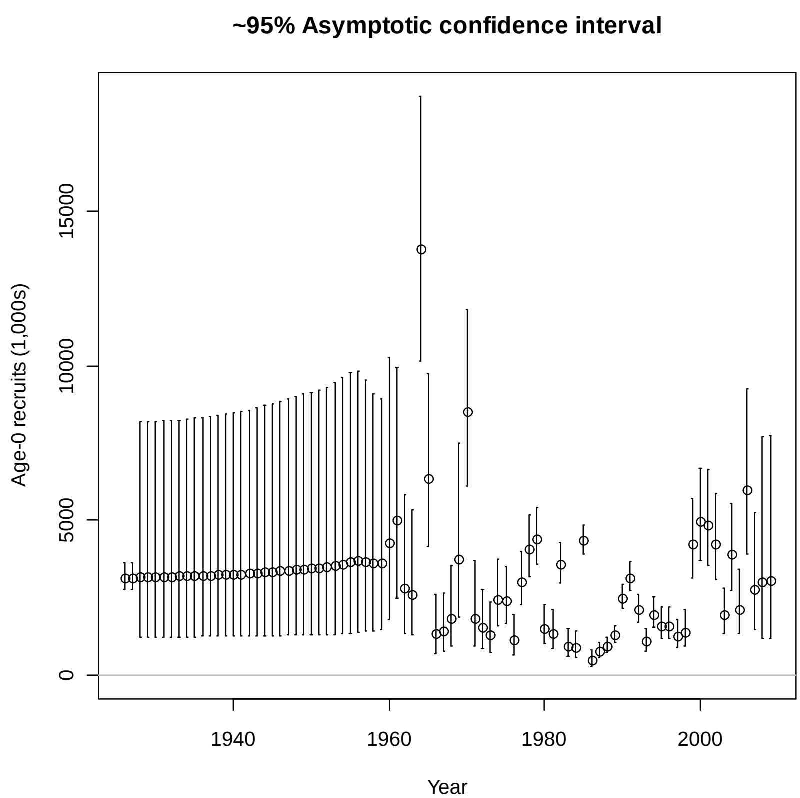
Recruitment

Recruitments in the North were estimated from 1928-2007, with bias correction ramping in from 1950 to 1964 as data becomes informative. The base model indicates a very strong recruitment event in 1964, a secondary event in 1970, and recent relatively strong recruitments in 1999-2002, with fairly high recruitment in 2006 as well. Recruitments subsequent to 2007 are drawn exclusively from the stock-recruit curve, with correspondingly high levels of uncertainty.

Recent estimated trend in lingcod recruitment in the North.

Year	Estimated recruitment	~95% confidence interval
1999	4,235	2,955-5,514
2000	4,972	3,490-6,454
2001	4,836	3,304-6,368
2002	4,256	2,883-5,628
2003	1,960	1,237-2,683
2004	3,908	2,520-5,296
2005	2,138	1,114-3,162
2006	6,004	3,379-8,629
2007	2,771	937-4,605
2008	3,018	28-6,008



Reference points

For the North, lingcod unfished spawning biomass (SBzero) is estimated to have been 33,075 mt (~95% confidence interval: 28,661-37,489 mt) with an expected mean recruitment of 3.162 million age-0 recruits (~95% confidence interval: 2.728-3.595).

The spawning potential ratio (SPR) for lingcod in the North has been above the proxy target of 45% (indicating fishing mortality rates below the target) since 1998, and in recent years has been far above that level. The full exploitation history in terms of both biomass and relative SPR ((1-SPR)/(1-$SPR_{45\%}$)) is portrayed graphically via a phase plot below.

Recent trend in relative spawning potential ratio (1-SPR/1-$SPR_{Target=0.45}$)

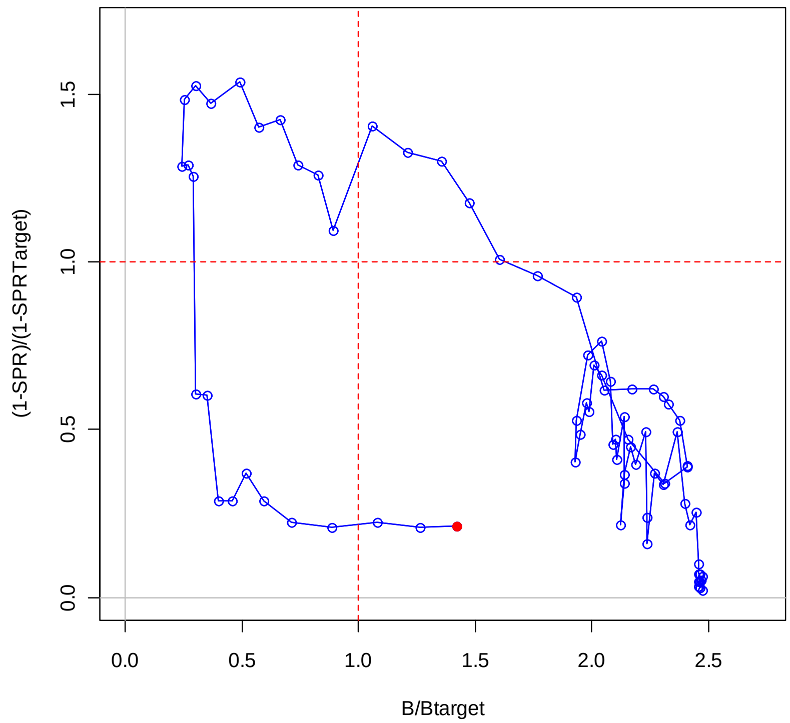
2008	0.23	0.16-0.30



South Model:

The base model indicates that the lingcod female spawning biomass off of California declined rapidly in the 1970s and early 1980's, reaching a low point of 2,320 mt in 1998, and has subsequently recovered to 13,466 mt, which is over 70% of the virgin level.

Year	Total biomass (million mt)	Age 2+ biomass (million mt)	Female spawning biomass (million mt)	~95% confidence interval	Estimated depletion	~95% confidence interval
1999	6,686	6,426	2,809	2,195-3,423	11.1%	9-14%
2000	8,130	7,043	3,157	2,428-3,886	12.5%	10-15%

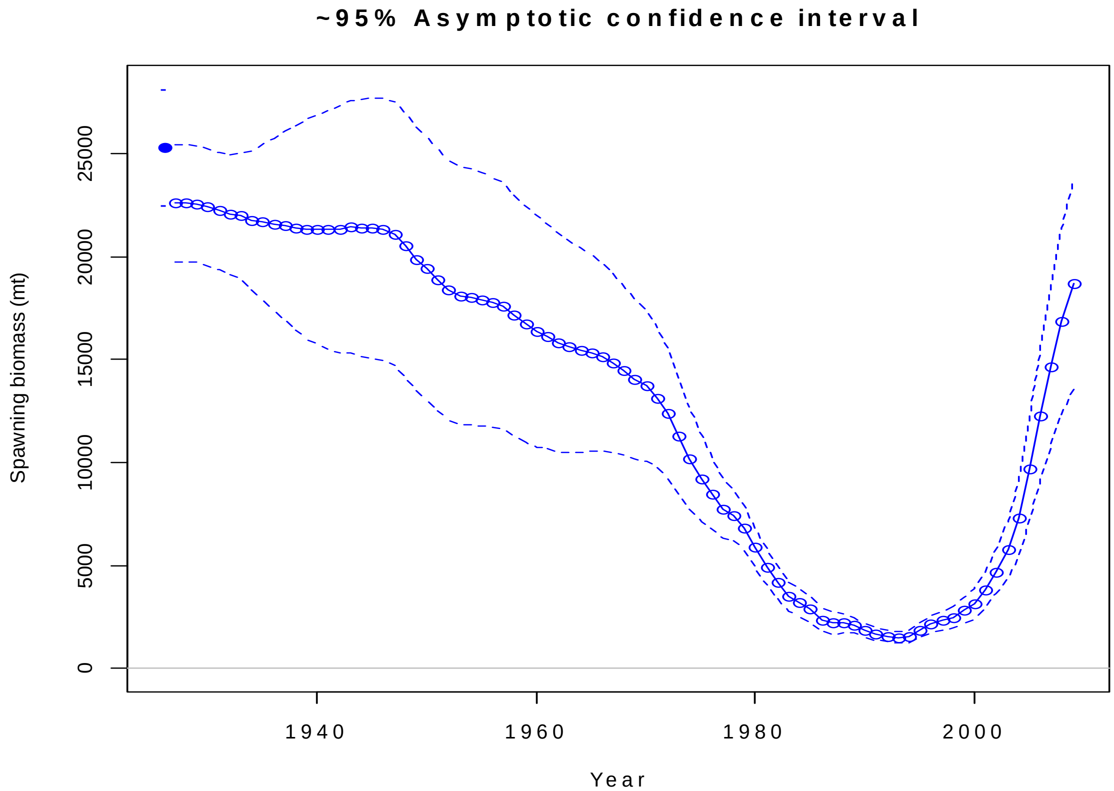
2007	26,488	26,240	14,652	10,757-18,546	57.9%	45-71%
2008	28,779	27,201	16,861	12,314-21,408	66.6%	51-82%
2009	31,266	30,875	18,656	13,581-23,731	73.7%	57-91%



Recruitment

Recruitments in the South were estimated from 1928-2007, with bias correction ramping in from 1960 to 1974 as data becomes informative. The base model indicates relatively strong recruitment events in 1976, 1983 and in 1999-2003, similar to the period of increased recruitment in the North, with a very high but uncertain recruitment in 2007. Recruitments subsequent to 2007 are drawn exclusively from the stock-recruit curve, with correspondingly high levels of uncertainty.

Recent estimated trend in Lingcod recruitment in the South.

Year	Estimated recruitment	~95% confidence interval
1999	9,703	6,387-13,108
2000	6,049	3,588-8,509
2001	7,217	4,209-10,225

Summary Tables for North and South

Catch in the following table reflect mortality associated with discard from the trawl fleet, where a 50% discard mortality rate is applied. Discard mortality in the recreational fleet, where only a 5% discard morality rate is applied, is minimal and is included in the landings estimates.

Coastwide recent trends (the coastwide SB_0 is estimated to be 58,386 mt)

Year	Landings	Catch	ABC	OY	SSB (mt)	Depletion	Recruitment

Unresolved Problems and Major Uncertainties

There are a number of issues that could be improved upon in future assessments. The proper break points for separate assessments have not been fully discerned. The break used here, between California and Oregon, is convenient in terms of data, although a break at Cape Mendocino would be likely more biologically accurate. The other artificial break, the U.S./Canada border, is also of concern, which could be alleviated with a bi-national assessment. Estimation of growth is a concern which we had hoped to address via the use of conditional age-at-length compositions. However it is not clear that this was achieved, and in fact we were forced to fix growth in the South due to much higher that expected length at age 20. This may be due to bias in ageing in any or all of the data sets or years, and should be more fully explored. The inability of either the North or South models to fit the NWFSC survey data is of concern, although it is not an ideal survey for lingcod. The overall scale of the assessment relative to the NWFSC indices appears plausible, in any case.

Decision Tables

For both the North and South models, the major axis of uncertainty used for the decision table was natural mortality (M). The base model use an M of 0.18 for females and 0.32 for males. The “Low M” alternatives use M = 0.16 and 0.285, and the “High M” alternatives use M = 0.20 and 0.355. Commercial catch projections include discard. The three levels of catch are from forecasts from the model runs with the three levels of M.

Research and Data needs

1) Validation of the ageing of lingcod to verify lack of bias or show bias in ageing.
2) Development of an expanded assessment for the North including British Columbia.
3) Investigate the effect of the year when recruitment is estimated on the estimates of B0 and of current status.
4) Investigation of the large survey estimate for lingcod in the 2003 NWFSC survey showed that catches from only three tows made up 63.5% of the total lingcod catch in the survey. The second and third large tows also had large catches of dogfish and the catches were subsampled for counts and detailed sampling. As a result only 2 lingcod were actually measured in the second largest tow (one male and one female) but these measurements were expanded to the whole catch. It is difficult and inappropriate to try to correct such estimates after the fact during the assessments. Instead onboard sampling procedures need to be developed to ensure that a proper and informative subsample of fish be measured during the survey.
5) The sensitivity run with no abundance indices produced a similar fit to the base case suggesting that there was little trend information in the abundance indices used in the base case. Can it be determined if the NWFSC survey is fishing in the right places for lingcod? Are there other survey techniques that can be used (e.g., longline, combined lingcod/sablefish pot survey, trap surveys)?
6) Investigate the suitability of using catches of lingcod in the IPHC survey as an alternate abundance index.
7) Re-examine the usefulness of the Washington tagging data for next assessment.
8) There was confusion over whether SS3 was using mid-year or beginning of year length at age resulting in larger than expected mean length at age for age 0 and 1. The method for setting the correct mean length at age for the younger ages needs to be clarified before the next assessment.
9) Further investigation of the age and length data needs to be done to understand if seasonal or area differences or some other causes are behind the outliers observed in the length-at-age data.
10) Look at environmental covariates for recruitment and time-varying growth and availability inshore.
11) The fact that lingcod males are nest-guarders was ignored when determining reproductive output. A cursory look at the proportion of sex ratio in the catch did not appear to indicate any serious changes for either species in recent years. However, we do not know what kind of change in sex ratio would indicate a serious change in reproductive success. The impact of nest-guarding on reproductive output should be investigated.
12) Many rockfish assessments use CPUE data from the CPFV fishery as an index of population abundance. The CPFV fishery is focused primarily on marketing a successful "fishing experience" that is related to the desirability of the species caught, quantity, body size, and fighting characteristics. The default assumption of proportionality between CPUE and abundance has not been evaluated for a fishery with these characteristics. Simulation modeling of fleet dynamics in a multi-species context is one possible way to address these issues.

Contents

1. Introduction

The assessment utilized data from the entire West Coast of the contiguous United States (waters off of Washington, Oregon and California). The lingcod (*Ophiodon elongatus*) population in these areas was modeled as two stocks in two separate assessment models. The two areas are (1) waters off of Oregon and Washington and (2) waters off of California. These areas were chosen due to a number of factors including: lack of demographic connectivity at moderate to large scales (~100-1000 km) along the coast despite general genetic similarities (Marko et al. 2007); data availability which restricts the number of areas it is possible to model, and which makes this split more feasible than others; evidence from comparison of length compositions and survey indices that the Eureka INPFC area is somewhat more like the areas to its north than those to its south, suggesting that the previously used division which grouped the Eureka area with the Southern area was less than optimal.

Range
Lingcod are found along the coast of the northeast Pacific Ocean from the Aleutian Islands to Baja California with the center of abundance off of British Columbia and Washington state (Hart 1973). They are most abundant in waters less than 100 fathoms (183 m) in depth, but are occasionally found at depths exceeding 200 fathoms (366 m) (Smith and Forrester 1973, Jagielo 1988). Lingcod are demersal on the continental shelf, display a patchy distribution and are most abundant in areas of hard bottom with rocky relief (Rickey 1991).

Life History
Lingcod are top order predators of the family Hexagrammidae. Among the Hexagrammidaes, the genus Ophiodon is ecologically intermediate between the more littoral genera Hexagrammos, Agrammus and Oxylebius and the more pelagic Pleurogrammus (Rutenberg 1962). Larval lingcod hatch in the late winter or early spring and become epipelagic. Analysis of genetic variation indicates that lingcod are genetically similar throughout their range

Movement
Lingcod are generally considered non-migratory, though some tagged individuals have moved exceptional distances, and indirect evidence suggests a seasonal onshore movement associated with spawning (Jagielo 1995). U.S. and Canadian tagging studies have demonstrated movement between coastal areas off Washington and southwest Vancouver Island. However, there is little interchange between these areas and the inland marine waters of Puget Sound and the Strait of Georgia (Cass et al. 1990, Jagielo 1990). Most fish recovered in tagging studies are found near the point of release, but some exceptional movements have been reported. Cass et al. (1990) found that 95% of fish recovered from a tagging study off the west coast of Vancouver Island were recaptured near the point of release. One fish tagged as a juvenile was recovered 510 km to the south in Oregon. At Cape Flattery, Washington, Jagielo (1990) reported that only 19% of recoveries were further than 10km from the release point. However, recaptures came from as far north as Queen Charlotte sound (195 km) and as far south as Cape Falcon (120 km).

Stock differentiation/Spatial structure
There are no clear stock delineations for lingcod in U.S. waters. No distinct breaks are seen in the fishery landings and catch distributions (Figure 1). Survey catches imply a continuous distribution over most of the range, with the largest catches occurring over a swath of latitude and depth. Genetic studies have found coastal lingcod populations to be genetically similar throughout their range (Jagielo et al. 1996). Recent analyses indicate some genetic changes in the stock along the coast, but no distinct stock breaks. Marko et al. (2007) found surprisingly little

connectivity between stocks at moderate (~10 km) to large (~1000 km) ranges, indicating the need for regional assessment and management.

Spawning and Nest Guarding

In the late fall, male lingcod aggregate and become territorial in areas suitable for spawning. The proportion of male lingcod sampled from offshore trawl landings declines in the late fall, suggesting a pre-spawning departure of males from the trawl grounds (Miller and Geibel 1973 (California), Cass et al. 1990 (British Columbia), Jagielo 1994 (Washington)). Males are in spawning condition earlier in the year than females, and it appears that larger and older females spawn first (Cass et al. 1990). Mature females are rarely seen at the spawning grounds and appear to move into spawning areas for only a brief period to deposit eggs (Giorgi 1981). The observed timing of peak spawning activity has ranged from January (Wilby 1937) to early March (La Riviere et al. 1981).

Nest deposition typically occurs in rock crevices, on rock ledges, or under boulders in areas of swift current flow. Ambient oxygen levels are critical to egg survival (Giorgi 1981). Salinity and temperature affect egg survival as well (Cook et al. 2005). Spawning behaviour has been reported from the intertidal zone to a depth of 126 m (Giorgi 1981, O'Connell 1993).

Males remain territorial throughout the period of egg incubation, and appear to be more effective at guarding the nest from predation by vertebrates than by invertebrates (La Riviere et al. 1981, Low and Beamish 1928). Fish predators include greenling, seaperch, sculpins, rockfish and cabezon; invertebrate predators include sea urchins, starfish, anemone, gastropods, starfish and crab (Cass et al. 1990). In experiments where males were removed from nests, new males sometimes assumed a guardian role, but in one removal experiment, 4 of 7 nests were lost to predators within 22 days (Low and Beamish, 1978).

Early life

Hatching occurs over 1 to 7 days and between January and June (Jewell 1968, Low and Beamish 1978). Larval lingcod hatch at a length of 6-12 mm, and become epipelagic (Phillips and Barraclough 1977, Cass et al. 1990). Larvae in the Strait of Georgia first appear in the plankton in late February. Numbers peak in late April. Larvae were concentrated in the upper 3 m of the water column by day and disperse or migrate to deeper depths at night. Larvae begin to disappear from the upper water column by late May to early June and become demersal at about 70-80 mm and at about 3 months of age. Epipelagic larvae feed on small copepods and copepod eggs, shifting to larger copepods and fish larvae as they grow (Phillips and Barraclough 1977).

When about 3 months old, juveniles settle on sandy bottom areas near eelgrass or kelp beds. By age 1 or 2, lingcod move into rocky habitats similar to those occupied as adults, but shallower. Fishery and survey data indicate that male lingcod tend to be more abundant than females in shallow waters, and the size of both sexes increase with depth (Jagielo 1994). Newly settled juveniles have been sampled nearshore in June on sandy bottom areas near eelgrass or kelp beds (Buckley et al. 1984), and have been found at depth ranging from 20m in Canada (Phillips and Barraclough1977) to 55 m in California (Miller and Geibel, 1973). In Washington, juveniles have been collected from the mouth of the Pysht River in the Strait of Juan de Fuca, from Grays Harbor and Willapa Bay, and from coastal waters nearshore to these embayments (Buckley et al. 1984, Jagielo 1994). Coley et al. (1986) found juvenile lingcod in Grays Harbor in October, over hard bottom shell-cobble habitat near rocks in 9-15 m of water.

Miller and Geibel (1973) reported that juvenile lingcod in California are about 35 cm in length (1 year old) when they first move into nearshore rocky areas typical of adult habitat. Surveys off the west coast of Vancouver Island suggest that juveniles move from inshore areas to a wider range of flat bottom areas by September (Cass et al. 1990), and begin to move into habitats of similar relief and substrate as adult lingcod by age 2, but remain at shallower depths. Juvenile lingcod feed on small fishes including herring (*Clupea pallasii*), Pacific sand lance (*Ammondytes hexapterus*), flatfish (*Pleuronectidae*), shiner perch (*Cymatogaster aggregate*), and walleye pollock (*Theragra chalcogramma*), and an assortment of invertebrates including shrimp (*Neomysis macrops*) and prawns (*Pandalus danae*) (Cass et al. 1990).

Growth
Lingcod display sexually dimorphic growth. Females grow faster than and reach larger sizes than males.

Phillips and Barraclough (1977) estimated that young-of-the-year (YOY) growth was approximately 1.3 mm/day. Buckley et al. (1984) reported YOY growth from Jun to September in the Strait of Juan de Fuca also averaged 1.3mm/day. Samples from the mouth of the Pysht River averaged 96 mm in June, 135 mm in July, 173 mm in August and 200 mm in September (Jagielo 1994).

Jagielo (1994) estimated growth using a fixed length at age 1 of 30 cm, and estimated L_∞ for males of 93.21 cm and females of 131.05 cm, and k of 0.1694 for males and 0.1137 for females. He also found that the average length for YOY lingcod was 11.99 cm and for age 2 (48.1 cm) for Washington samples, and that growth trajectories diverge considerably by sex after age 3, as female lingcod tend to grow faster and live longer than male lingcod, while male lingcod mature at that age.

Maturation
Richards et al. (1990) examined coastwide trends in lingcod maturity and observed that male lingcod mature at a smaller size and age than female lingcod. They also noted that size at maturity increases with latitude (distance from the equator). Size at 50% maturity was estimated to be 63.6 cm for females and 57.1 cm for males (ages 3.9 and 3.5) off of Vancouver Island, whereas Miller and Geibel (1973) found size at 50% maturity to be 58.8 cm and 39.8 cm (and ages 5 and 2) for females and males off of California. Jagielo (1994) found ages of 50% maturity of 3.4 years for males and 4.6 years for females off Washington.

Fecundity
Hart (1967) reported the relationship between length and weight as $W = 0.000282406 \cdot L^{3.011}$. The fecundity exponent is not significantly different than the length-weight exponent, and is therefore essentially equivalent of a constant relationship between weight and egg number.

Natural mortality
Jagielo 1994 estimated M for male and female lingcod using three empirical models based on life history parameters (Hoenig 1983, Alverson and Carney 1975, and Pauly 1980). Estimates of M for male lingcod ranged from 0.23 to 0.39, while estimates for female lingcod range from 0.16 to 0.19. The averages of the estimates were 0.18 for females and 0.32 for males.

Starr et al. 2005 estimated natural mortality rates from a short term tag-recapture study and came up with ranges of 0.24-0.34 for females and 0.13-0.23 for males. However, these estimates do not take into account variation in M across the year (or between years), especially for males during nest-guarding.

History of the fishery

The fishery for lingcod has a very long history. Lingcod was among the species found in remains from 51 archaeological sites representing the period between 6200 BC and 1830 AD on the central California coast from San Mateo to San Luis Obispo (Gobalet and Jones 1995). More recently, the commercial fishery off of California dates back more than a century, and the fishery off of Washington and Oregon dates back nearly as far.

Prior to 1977, Lingcod stocks in the northeast Pacific were managed by the Canadian Government within its waters, and by the individual states in waters (out to three miles) off of the United States. With implementation of the Magnuson Fishery Conservation and Management Act (MFCMA) in 1977, primary responsibility for management of the groundfish stocks off Washington, Oregon and California shifted from the states to the Pacific Fishery Management Council (PFMC). The ABC for lingcod off of these states was set at 7,000 mt, and catch was consistently below this level. In 1994, a harvest guideline (HG) of 4,000 mt was set. In 1995, both the ABC and HG were dropped to 2,400 mt. Trip limits on commercial Lingcod catch were first instituted in 1995, when a 20,000 lb/month limit was imposed, and a minimum size was imposed for recreational fisheries of 22 inches. In 1998 to present, individual year ABC and OY levels were set, commercial trip limits became much more restrictive (starting at 1,000 mt/2 months in 1998), and recreational bag limit were set at 2 (or 1) lingcod with minimum sizes ranging from 22 to 30 inches (Tables 1-4).

Surveys

Research surveys have been undertaken to provide fishery-independent information about the abundance, distribution, and biological characteristics of groundfish. A coast–wide Shelf Survey was conducted in 1977 (Gunderson and Sample 1980) and was repeated every three years (thus referred to as the “Triennial” survey) through 2004. A cooperative survey conducted using commercial fishing vessels was undertaken on the slope in 1998 and expanded to cover the shelf beginning in 2003.

2. Data

2.1. Removals and regulations

Lingcod landings were estimated for the fishery off the West Coast of the continental United States from 1928 through 2008 (Figure 2; Table 5), with low-level “equilibrium” removals estimated for the period prior to 1928.

New reconstructed estimates of California commercial landings from 1931-2008 were obtained from Don Pearson, and the values from 1931-1980 were used in the (Southern area) assessment. California commercial landings from 1916-1930 were obtained from the 2004 assessment and were used to estimate the “equilibrium” landings level and 1928-1930 landings. Washington historical catches were obtained from Washington State (Farron Wallace, Pers. Comm.) and used for the years 1929-1979, with 1928 assigned the average of the following 9 years. Oregon Commercial catches were taken from Cleaver (1951) for the years 1928-1949 and from Smith (1956) for the years 1950-1953. Commercial landings data were not available for the years 1954 and 1955, and, consequently, those years were assigned values reflecting the surrounding years (130 mt and 120 mt). For 1956-1968, Oregon commercial landings were taken from Lynde (1986), while for 1969-1979, landings were provided by Oregon (Troy Buell, Pers. comm.).

Commercial landings for 1980 for Washington/Oregon were taken from Lynde (1986). PacFIN estimates of commercial landings were used for 1981-2008 for both the Washington/Oregon and California areas.

California recreational landings were obtained from John Field for the years 1928-1980. Washington and Oregon recreational landings prior to 1980 were taken from the previous assessment, and were below 100 mt prior to 1980 and were 0 prior to 1957. RecFIN estimates were used for the years 1980-1989 and 1993-2007 for Washington/Oregon and 1981-1989 and 1993-2007 for California, with GMT scorecard values used for both areas for 2008. Recreational catch for 1990-1993 were taken from the previous assessment.

In California, a 5-fish bag limit was enacted in 1980 followed by a 22 inch size limit in 1981. These regulations remained in effect for 17 years. In March 1998, the bag limit was reduced from 5 to 3 fish and concurrently the size limit was increased to 24 inches. The bag limit was lowered again from 3 fish to 2 fish with in January 1999. In January 2000, the size limit increased from 24 to 26 in. and a seasonal closure (January through February) was implemented from the U.S.-Mexico border north to Lopez Point (36˚ N., Monterey County), and for March through April from Lopez Point north to Cape Mendocino (40˚10' N., Humboldt County) The bag limit remained at 2 fish. A gear restriction was also enacted at this time limiting the number of hooks to 3, although this was primarily directed toward rockfish effort.

Discards

Annual discard amount/rates for 2003 through 2007 were provided by the West Coast Groundfish Observer Program (Table 6 provides estimate of the percent of total lingcod mortalities in the commercial fishery due to discarding). Since these data are provided with a break point at 40° 10' N rather than the Oregon/California border (42° N), and the majority of the data is from the North, including the area between 40° 10' N and 42° N, and the values are similar for most years between the two areas, a single time series of discard proportion was used for both area assessments.

Fishery Length compositions

Commercial fishery landed length compositions (Tables 7-9; Figures 3-5 and 27-28) were estimated from PacFIN for the years 1965-2008 for the North and 1978-1990 and 1992-2008 for the South. These data were sex-specific for the years 1976-2008.

Commercial fishery length compositions were constructed using BDS data retrieved from PacFIN on 6/18/2009. Length, age and sex data were acquired at the trip level, and then aggregated. Since trip level landings were not available for 80% of the length data, each length was treated as an individual sample. The input N for each year and area was calculated via Stewart's Method (Ian Stewart, pers. Comm.), which for fisheries is:

$$N_{effective} = N_{trips} + 0.138 N_{fish} \quad \text{if } N_{fish}/N_{trips} < 44$$
$$N_{effective} = 7.06 N_{trips} \quad \text{if } N_{fish}/N_{trips} \geq 44$$

The length compositions of discards in more recent years (2003-2007) were calculated with observer data from boats using bottom trawl gear (Figures 6 and 29). Although there were discards observed from fixed gear as well, discard mortality from that fishery is minimal for lingcod, and therefore is not representative of the discard mortalities which are modeled here. Individual lengths were scaled up by a straight expansion factor to the total discard for each observed tow.

Input N values for commercial trawl discard length compositions were calculated via Stewart's Method, but capped at the greater of the number of tows or 200 (Table 9).

Recreational length-composition data were retrieved as individual lengths from Oregon and California from RecFIN for the years 1993-2008. Additional length data from central California were obtained from John Field from the central/northern California CPFV monitoring program from 1987-1998. Input n values were set at 1/10th the number of fish, and for those years where both sources were combined for California (1993-1998), the total sample size was reduced by an additional 25% (Table 8). The recreational length compositions are shown in Figures 11-13 and 32.

Fishery conditional age-at-length compositions

Conditional age-at-length compositions were constructed from age and length data available from PacFIN for the years 1980-2008 for the North and for 1993-1998 and 2001-2004 for the South. Since most data did not include total trip catch amounts, each age was considered an individual sample (Table 7, Figures 7-10 and 30-31).

For the recreational fishery, conditional age-at-length compositions were constructed from age and length data available from Oregon for the years 1999-2008 (Figures 14-15). Again each sample was considered an individual observation (Table 8).

These age data were not used in the final base or bracketing models, but were used in sensitivity analyses.

Fishery catch-per-unit-effort indices

Three fishery catch-per-unit-effort (CPUE) indices were used in this assessment. Commercial CPUE indices were developed by Jagielo et al. (2000, 2003). They were constructed from Washington, Oregon and California trawl fishery logbook and fish ticket data dating back to 1976 (Table 10, Figures 16 and 33). Skipper's tow-by-tow estimates of retained catch were reconciled with fish ticket data (landing receipts). The adjusted catch and the skipper's estimate of tow duration was used to compute lingcod CPUE (lbs/hour). Following data verification and screening, a total of 490,971 tows in the northern area and 474,946 tows in the southern area were used in the analysis (Jagielo and Wallace, 2005). Because of significant changes in management beginning in 1998 both the northern and southern time series were truncated after 1997. Furthermore, the 1976 and 1977 tow data from the southern area were deemed of insufficient sample size and were dropped from the time series used in the assessment model. Tow-by-tow catch rates (CPUE) were fitted in a two-stage model process using a delta-lognormal GLM procedure to predict abundance indices across the time series for each area. The model included a year, month, depth, and location (PFMC area) effect. A bootstrap procedure was previously used to estimate the standard errors of the year by year index values; however, the previous STAT Star Panel concluded that the bootstrap estimates of standard errors were unrealistically low and recommended using an assumed annual CV of 0.20 in both the southern and northern index in the 2003 assessment (Jagielo et al. 2003). The northern trawl logbook index trend shows a sharply declining stock since 1976, and the southern trawl logbook index indicates a declining stock since 1979.

The third CPUE index used in this assessment is a dockside recreational CPUE index (Table 10, Figure 34) for California developed by Tom Wadsworth (Appendix 1). As with the commercial

CPUE indices, data beyond 1997 was not used in the assessment due to changes in management regulations.

2.2. Surveys

NMFS Cruises

The results from two fishery-independent surveys are used in this assessment:

1. The NWFS Triennial Shelf Survey that was conducted every third year from 1980-2004
2. The NWFSC Survey for the years 2003-2008.

The 1977 Triennial Shelf Survey was not used due to concerns about the first year of the survey's implementation.

Indices

Indices of abundance were derived from each of the above surveys and years using a generalized linear mixed model (GLMM) for each survey (John Wallace, pers. comm.). The GLMM models occurrence of lingcod in a survey haul as a binomial process and the size of the non-zero catches with a gamma model. Coefficients of variation (CVs) about the indices were produced from the GLMM as well. The GLMMs utilized three latitudinal strata, Washington/Oregon, California north of around Point Conception (34.5 degrees north) and California south of 34.5. There were also two depth strata (55-183 m and 183-400m), covering the usual extent of observation of lingcod. These six strata represent the four areas of different sampling densities in the NWFSC survey (and the Triennial survey since it did not sample in the Southern California Bight), and they also include the division between the North and South assessment areas at 42˚N (Table 11, Figures 17, 22, 35 and 40).

Central California Indices

Thomas Wadsworth developed several indices of abundance for lingcod and other species from various surveys, observer programs, and other fishery monitoring programs for central California (between Point Conception and Point Mendocino). These included SCUBA surveys, spearfish tournaments, Commercial Party Fishing Vessel logbooks and observer programs, and recreational dockside monitoring. All indices were based on the number of fish (rather than biomass) caught, landed or observed. This data was received by the lead author of this assessment on June 26, 2009, and year-by-year length compositions were not available for any of the data sets. Therefore, only the dockside boat survey index was included in the South assessment, as only that index can be tied directly to the selectivity of a fishery: the California recreational fishery. A complete description of all the potential indices is included in Appendix 1.

Length compositions

Length compositions were derived for the Triennial survey for the years 1986-2004 in the North (Figures 18-19) and 1989-2004 in the South (Figures 36-37). Length compositions were derived for the NWFSC survey for 2003-2008 for both the North (Figures 23-24) and South (Figures 41-42).

Length, age, and sex data were acquired at the tow level for both surveys and then aggregated within the area and depth strata. For each tow, the length composition of the sampled individuals was scaled up to represent the length composition of the trip landings through use of an expansion factor. In this assessment, the expansion factor was calculated as:

$$\text{Expansion Factor} = (WT_{total}/WT_{sampled})$$

with total weight divided by sample weight being the equivalent of total estimated number over sampled number. No down-weighting exponent was used for the NWFSC survey, as the survey data are collected at the tow level rather than the trip level. However, since for nearly all of the Triennial tows, all lingcod were lengthed, a power of 0.8 was used to downweight the expansion factors for those few tows that were not fully sampled. The initial effective N (input N) was calculated via Stewart's Method (Ian Stewart, pers. Comm.), which for surveys is

$$N_{effective} = N_{trips}+0.0707N_{fish} \quad \text{if } N_{fish}/N_{trips} < 55$$
$$N_{effective} = 4.89N_{trips} \quad \text{if } N_{fish}/N_{trips} \geq 55$$

where N_{fish} is the total number of fish sampled across all trips (Table 12).

Conditional-age-at length compositions

Conditional age-at-length compositions were constructed from age and length data using the same methods as for survey length compositions in the case of the NWFSC survey, and via the same methods as for the commercial fishery for the Triennial survey. These compositions were constructed for the Triennial survey for 1992-2004 in the North (Figures 21-22), and 1996-2004 in the South (Figures 38-39); and for the NWFSC survey from 2003-2008 (Figures 25-26 and 43-44).

These age data were not used in the final base or bracketing models, but were used in sensitivity analyses. A summary of data sources and years is given in Table 13.

2.3. Biology and life history

Natural mortality

Jagielo 1994 estimated M for male and female lingcod using three empirical models based on life history parameters (Hoenig 1983, Alverson and Carney 1975, and Pauly 1980). Estimates of M for male lingcod ranged from 0.23 to 0.39, while estimates for female lingcod ranged from 0.16 to 0.19. The average of the estimates was 0.18 for females and 0.32 for males. Those estimates continue to be used in the current assessment.

Sex ratio, maturation and fecundity

In this assessment, the sex ratio at birth is assumed to be 1:1. Maturity-at-length for females was taken from the last assessment with 50% maturity occurring at 68 cm in the north and 60 cm in the south. (Figures 45 and 94).

Fecundity was assumed to be proportional to weight (figures 46 and 95). Hart (1967) found fecundity to be essentially proportional to length cubed.

Length-weight relationship

The length-weight relationship was estimated by Jagielo (1994) using available survey data. The equation was fit to mean weight at length measured in the West Coast survey.
For males the relationship is:

$$W = 0.000003953\ L^{3.2149}$$

For females, the relationship is:

$$W = 0.00000176\ L^{3.3978}$$

where W is weight (k) and L is fork length (cm).

Ageing error

Aging error (Figure 47) was derived using the double reads done by Washington State using a program designed for that purpose (Punt et al. 2008). This, of course, only accounts for the precision of age reading, not accuracy. While McFarlane and King (2001) did validate that the observed annuli are generally annual marks, via a mark-recapture study which used oxytetracycline (OTC) injections to leave a distinct mark on the otoliths that could be observed upon recapture of the fish and extraction of the otoliths, their results did find some error in ageing (>5% mis-aged) even for a single year at large, and under research settings, which generally have higher precision than under production ageing conditions. More work needs to be done to identify potential biases in production ageing of lingcod. One of the sources of error in ageing lingcod is that the first and second annuli can be re-absorbed as the fish ages. Beamish and Chilton (1977) developed a method that used mean annual diameter measurement to locate the position of the first and second annuli and thus minimize, but not eliminate, error due to this re-absorption.

Age data were not used in the base or bracketing models, but this ageing error matrix was used for the sensitivity analyses which included age data.

2.4 Changes in data from the 2005 assessment

Changes in data for this assessment include a new point of geographic division of the assessments (the Oregon/California border), expansion of the time period of the assessment back to 1928 (from 1956), updated landings and length composition data across time periods, fisheries and surveys; use of conditional age at length data, inclusion of the NWFSC survey data and discard data from the West Coast Groundfish Observer Program, and addition of the California dockside recreational CPUE index.

3. Assessment model

3.1 History of Modeling approaches

There have been six assessments of lingcod since 1986 covering part or all of the West Coast of the United States.

Adams (1986) conducted a yield per recruit analysis. Jagielo (1994) conducted an age-structured assessment of the status of the lingcod stock between Cape Falcon in Northern Oregon to 49 ˚N (off of southwest Vancouver Island in British Columbia - PMFC areas 3A, 3B, and 3C, including

Canada), using the Stock Synthesis program (Methot, 1990). Data included trawl and recreational catch from 1979-1993 with equilibrium catch before then, triennial shelf survey and trawl cpue indices, and length and age composition data. The final spawning output levels were estimated to be about 20% of pristine levels, and catch level recommendations ranged between 2500 and 3000 mt based on F40% to F20%.

The 1997 assessment (Jagielo et al.1997) expanded the area south to Cape Blanco (42°50' N), and retained the northern boundary of 49°00'N and the use of the Stock Synthesis model. Depletion in spawning output in this model was below 10% for 1997.

Adams et al. (1999) conducted a length-based, age-structured population model implemented in AD Model Builder (ADMB, Fournier 1996) for the southern area which had not yet been assessed (Eureka, Monterey, and Conception INPFC areas).

Jagielo et al. (2000) conducted age structured models in ADMB for two areas of the US: US Vancouver-Columbia (no longer including Canadian waters) and Eureka, Monterey, Conception INPFC areas. Jagielo et al. (2003) conducted age structured assessments for the two areas using Coleraine. Finally, Jagielo et al. (2005) conducted age structured assessments for the two areas using Stock Synthesis 2 (SS2). They found that the northern stock had recovered substantially from a low point in the 1990s was at 87% depletion, while the southern area had not recovered as well as was at 24% depletion, with a 64% coastwide depletion.

3.2 Current Model

Model

This assessment uses SS version 3.03a. While there are still two separate assessments for the north and south areas, the two areas are now defined by state boundaries – the Northern area being Washington and Oregon, and the southern area being California. This choice was made due to data availability and evidence that the Eureka area is somewhat more connected to the areas to the north than to those to its south. In the current division, the Eureka area is split in half as well. The parameters for the base models, both those that were estimated and those that were fixed, are given in Tables 14 and 15.

Length and age bins

The same length frequency bins were used as in the 2005 assessment. The first bin contained all fish less than 28 cm, followed 2-cm length bins up to 108 cm, with a maximum bin of all fish ≥ 110 cm in length.

Age bins included single year bins from age 1 to 13 and a plus group at 14 years of age and older.

Ageing error

Aging error was derived using the double reads from Washington State using a program designed for that purpose (Punt et al. 2008). The results used are shown in Figure 47.

Growth

Many growth parameters were estimated within both models for both males and females, including the von Bertalanffy growth rate parameters (k) and the CVs of length at ages 1 and 20.

The size at age 20 is also estimated in the North model, with the size at age 1 fixed at 30 cm in both models and the size at age 20 fixed in the South model. The estimated growth trajectories are shown in Figures 48 and 96.

Recruitment, stock-recruitment steepness and natural mortality

R_0 is estimated in both models, along with recruitment deviations from 1928 through 2007, with bias correction ramping I 1from 1950 to 1964 (North) and 1960 to 1974 (South), with $\sigma_r = 0.5$. Natural mortality is set at 0.18 for females and 0.32 for males in both models, which are the values used in the 1994-2005 assessments and which balances the estimates from various meta-analyses. In the previous assessment, steepness was set in the final model at 0.9. In the current assessment h is set to be 0.8; this lower value is intended to reflect, to some extent, multiple minimally connected stocks, with different levels of depletion, within each assessment area.

Selectivity and Retention

In initial runs, all 6 parameters of the double normal selectivity function were estimated for the fishery and each survey, along with the inflection point and slope of the logistic retention function. Various blocking schemes on fishery selectivity were tested in an effort to account for changes in depth of fishing and codend mesh size. However, only two time blocks are used in the base models, reflecting the large-scale changes in regulations for both the commercial and recreational fisheries up and down the coast over the past decade or so. Changes in both commercial and recreational selectivities, and in commercial discard rates are allowed in 1998.

All selectivities were allowed to be, and were domed shaped, with the exception of the southern Commercial fishery which was essentially asymptotic when fit. The selectivity pattern for the Triennial survey in the South was ill-defined, and so it was forced to be the same as the base model triennial selectivity in the North. Selectivities and retention patterns are shown in Figures 49-57 and 97-103. Modeled and observed discards are shown in Figures 58-59 and 104-105.

Likelihood contributions

The objective function, which was minimized to obtain the point estimates of the model parameters, included contributions by the data (survey and fishery biomass indices, fishery and survey length and conditional age-at-length composition data) and well as priors (essentially non-informative).

4. Results

4.1. Reference model results

Figures 60-66 and 106-112 show the time trajectories of the estimates of summary biomass, fishery exploitation rate, recruitment, and depletion in spawning output (see Tables 16-17 as well). The fits to the stock-recruitment relationships (Figures 63 and 119) indicate a substantial amount of variability. Figures 67-91 and 113-132 show the fits to the indices and compositional data for the North and South models, respectively. In both the North and the South there appears to be a variability in either growth or ageing, and likely the latter, as the fit to the conditional age-at-length data varies over time and between data sources. Figures 92-93 and 133-134 show management quantities: equilibrium yield plots and time series of surplus production for the two areas.

For both the North and South base models, catchability (q) for the NWFSC survey is between 0.5 and 1.0 (for the most highly selected lengths), indicating a plausible estimate of recent biomass. Although the catchability values are plausible, the actual fits to the NWFSC survey data are rather poor, especially in the South where the last two points are down but the modeled biomass and expected survey index continue to trend up. In fact, as seen by the retrospective analyses (below, Figures 135-136), the NWFSC survey index has very little influence on the results. While the survey is not ideal for lingcod, which tend to be found in higher densities in rocky areas (Jagielo et al. 2003), one would not necessarily expect such a divergence of index and trend, although it is possible that availability changes substantially from year to year.

4.2. Retrospective analysis

Retrospective analyses were conducted as if the assessment were carried out in the years from 2008 down to 2004 (without the last 1-5 years of data). No consistent retrospective pattern was seen in either the North or the South (Figures 135-136). In fact, these are remarkably stable in both models.

4.3 Pre-STAR Sensitivity Analyses

A number of sensitivities were done for each of the two modeled areas prior to the STAR panel. In both pre-STAR base models, as is usually the case, a few selectivity parameters were fixed in order to avoid issues with bounds. The first comparison in each case, therefore, is to a model with those parameters estimated. The result is nearly the same as the base but with a few more estimated parameters. The rest of the models are direct comparisons to the freed up model in each case. There are two general types of sensitivities. The first involves the removal or down-weighting of data. For these, a direct comparison of likelihood is not possible, but differences in the results are noted. The second involves changing the value of fixed parameters, or changing what is estimated. In these cases, likelihood comparisons are easier.

For the North, the sensitivity runs are as follows:

1) Base model with selectivity parameters freed up ("likebase").
2) Model without CPUE index data ("noCPUE").
3) Model without Triennial survey (index, length and age) data ("noTri").
4) Model without NWFSC survey (index, length and age) data ("noNW").
5) Model with size at age 1 increased from 30 to 32 cm ("Lmin32").
6) Model without age data (size at age 20 fixed at base model estimates) ("noAge").
7) Model without age data (size at age 20 fixed below 2004 model estimates) ("noAgealt").
8) Model with female M fixed at 0.2 instead of 0.18 ("Mfem.2").
9) Model with female M fixed at 0.23 instead of 0.18 ("Mfem.23").
10) Model with steepness (h) = 0.75 instead of 0.8 ("h.75").
11) Model with steepness (h) =0.85 instead of 0.8 ("h.85").
12) Model with commercial selectivity forced asymptotic pre-1998 ("Asym").
13) Model with discard fraction data CV at 0.5 instead of 0.1 ("Disc.5").

For the South, the sensitivity runs are as follows:
1) Base model with selectivity parameters freed up ("likebase").
2) Model without (commercial or recreational) CPUE index data ("noCPUE").
3) Model without Triennial survey (index, length and age) data ("noTri").

4) Model without NWFSC survey (index, length and age) data ("noNW").
5) Model with size at age 1 increased from 30 to 35 cm ("Lmin35").
6) Model with size at age 20 estimated for both females and males ("estLmax").
7) Model without age data ("noAge").
8) Model with female M fixed at 0.2 instead of 0.18 ("Mfem.2").
9) Model with female M fixed at 0.23 instead of 0.18 ("Mfem.23").
10) Model with steepness (h) = 0.7 instead of 0.8 ("h.7").
11) Model with steepness (h) =0.9 instead of 0.8 ("h.9").
11) Model with commercial selectivity forced asymptotic pre-1998 ("Asym").
13) Model with discard fraction data CV at 0.5 instead of 0.1 ("Disc.5").

The results from all of the sensitivities are displayed in Tables 18 and 19. In general, the results from the North indicate a much more stable model than do the results form the South.

4.4 STAR modifications

The major change in data use following the STAR panel was the removal of the age data. Outliers and inconsistent ageing appeared to be causing the age data to be more confounding than informative, especially for this fast growing species for which individual year classes are fairly well defined from the length data alone. Another major change was estimating recruitment back to 1928 (with bias correction ramping in mid-century or later). This allows for better accounting of the uncertainty in Bzero, and in the case of the North model, included a large recruitment in 1964.

4.5 Post-STAR Sensitivity Analysis

Post-STAR sensitivities for both North and South (Table 20 and 21) included:

1) Natural mortality = 0.16 (females) and 0.285 (males)
2) Natural mortality = 0.20 (females) and 0.355 (males)
3) Natural mortality = 0.22 (females) and 0.39 (males)
4) Stock recruitment steepness = 0.7.
5) Stock recruitment steepness = 0.9.

5. Future research

1) Validation of the ageing of lingcod to verify lack of bias or show bias in ageing.
2) Development of an expanded assessment for the North including British Columbia.
3) Investigate the effect of the year when recruitment is estimated on the estimates of B0 and of current status.
4) Investigation of the large survey estimate for lingcod in the 2003 NWFSC survey showed that catches from only three tows made up 63.5% of the total lingcod catch in the survey. The second and third large tows also had large catches of dogfish and the catches were subsampled for counts and detailed sampling. As a result only 2 lingcod were actually measured in the second largest tow (one male and one female) but these measurements were expanded to the whole catch. It is difficult and inappropriate to try to correct such estimates after the fact during the assessments. Instead onboard sampling procedures need to be developed to ensure that a proper and informative subsample of fish be measured during the survey.

5) The sensitivity run with no abundance indices produced a similar fit to the base case suggesting that there was little trend information in the abundance indices used in the base case. Can it be determined if the NWFSC survey is fishing in the right places for lingcod? Are there other survey techniques that can be used (e.g., longline, combined lingcod/sablefish pot survey, trap surveys)?
6) Investigate the suitability of using catches of lingcod in the IPHC survey as an alternate abundance index.
7) Re-examine the usefulness of the Washington tagging data for next assessment.
8) There was confusion over whether SS3 was using mid-year or beginning of year length at age resulting in larger than expected mean length at age for age 0 and 1. The method for setting the correct mean length at age for the younger ages needs to be clarified before the next assessment.
9) Further investigation of the age and length data needs to be done to understand if seasonal or area differences or some other causes are behind the outliers observed in the length-at-age data.
10) Look at environmental covariates for recruitment and time-varying growth and availability inshore.
11) The fact that lingcod males are nest-guarders was ignored when determining reproductive output. A cursory look at the proportion of sex ratio in the catch did not appear to indicate any serious changes for either species in recent years. However, we do not know what kind of change in sex ratio would indicate a serious change in reproductive success. The impact of nest-guarding on reproductive output should be investigated.
12) Many rockfish assessments use CPUE data from the CPFV fishery as an index of population abundance. The CPFV fishery is focused primarily on marketing a successful "fishing experience" that is related to the desirability of the species caught, quantity, body size, and fighting characteristics. The default assumption of proportionality between CPUE and abundance has not been evaluated for a fishery with these characteristics. Simulation modeling of fleet dynamics in a multi-species context is one possible way to address these issues.

Acknowledgements

A number of people helped with this assessment; providing data, often with short notice; helping to solve modeling issues; and editing questionable text. Without their efforts, it would not have been possible. Among those to whom much thanks is due are Beth Horness, John Wallace, Eliza Heery, Jason Cope, Jim Hastie, John Field, Troy Buell, Farron Wallace, Joanna Grebel, Theresa Tsou, Don Pearson, Ian Taylor, Ian Stewart, Rick Methot, Melissa Haltuch, Allan Hicks, John DeVore and Shirley Lee.

Table 4. Summary of California Recreational Management Measures Affecting Lingcod
Created: June 22, 2009
(Note: italics indicate in season changes)

Year	Description	Effective Date
1996	Statewide recreational bag limit: 5 lingcod Min Size:22 inches	3/1/1996
1998	Statewide recreational bag limit: 3 lingcod Min Size:24 inches	3/1/1998
1999	Statewide recreational bag limit: 2 lingcod Min Size:24 inches	3/1/1999
2000	Bag and Size Limits: o Statewide recreational bag limit: 2 lingcod Min Size:26 inches Management Area Seasons: o Open to all anglers south of Lopez Point, Monterey County (36° 00') from March to December. o Open to all anglers north of Lopez Point, Monterey County (36° 00') to near Cape Mendocino(40° 10'), Humboldt County January to February & May to December Recreational gear restriction: o No more than 3 hooks per line *Inseason closure for boat based anglers fishing for lingcod Statewide – closed November and December.*	3/1/2000 *11/1/2000*
2001	Management Area Seasons: o Recreational Management Areas created with seasonal closures: Northern Management Area (Near Cape Mendocino(40° 10') to Point Conception (34° 27')) Open to all anglers January to February & July to December. o Southern Management Area (Point Conception (34° 27') to U.S./Mexico border) Open to all anglers March to December. Recreational gear restriction: o No more than 2 hooks per line *Inseason closure for lingcod for all waters south of Cape Mendocino November to December*	3/1/2001 *11/1/2001*
2002	Bag and Size Limits: o Statewide recreational bag limit: 2 lingcod Min Size:24 inches Management Area Seasons: Recreational Management Areas redefined with seasonal closures o Northern Management Area (Oregon/California border to Near Cape Mendocino(40° 10')) no season closure. o Central Management Area (Near Cape Mendocino(40° 10') to Point Conception (34° 27')) Open to all anglers January to February & July to August. o Southern Management Area (Point Conception (34° 27') to U.S./Mexico border) Open to all anglers from March to October. Note: During rockfish/lingcod season closures no lingcod may be taken or possessed in waters deeper than 20 fathoms. *Inseason closure for lingcod for the waters deeper than 20 fathoms for all boat based anglers south of near Cape Mendocino (40° 10') July to December*	3/1/2002 *7/1/2002*
2003	Management Area Seasons and depth restrictions: o Northern Management Area: Lingcod may not be taken or possessed in waters greater than 27 fathoms.	3/1/2003

	- Central and Southern Management Areas: Open to all anglers from February to November. Note: During closure periods, lingcod may not be taken or possessed in waters greater than 20 fathoms. *Inseason closure for lingcod statewide for all boat-based anglers*	*12/8/2003*
2004	Management Area Seasons and depth restrictions: - Central Management Area: January and February open only in waters less than 30 fathoms, May to August open in waters less than 20 fathoms, waters of the Cordell Bank (Marin County) closed to fishing - Southern Rockfish Management Area: March to December open in waters less than 60 fathoms *Bag and Size Limits:* *Statewide recreational bag limit: 1 lingcod Min Size:30 inches* *Management Area Seasons:* *Recreational Management Areas redefined with seasonal closures* - *Northern Management Area (Oregon/California border to Near Cape Mendocino(40° 10')) Open to all anglers January to October. Lingcod may not be retained in waters greater that 30 fathoms.* - *North-Central Management Area (Near Cape Mendocino(40° 10') to Point Lopez (36° 00')) Open for boat based anglers from January to February & August to October in waters less that 20 fathoms. Shore based anglers and divers open from June to October.* - *South Central Management Area (Point Lopez (36° 00') to Point Conception (34° 27')) Open for boat based anglers June & August to October. Shore based anglers and divers open from June to October. In June and August boat based anglers and divers may only take lingcod in waters less that 30 fathoms. From September to October boat based anglers and divers may only take lingcod in waters less that 20 fathoms.* - *Southern Management Area (Point Conception (34° 27') to U.S./Mexico border) Open to all anglers from June to October. June to August lingcod may only be taken in water less than 60 fathoms. September to October lingcod may only be taken in water less than 30 fathoms.*	1/1/2004 *5/1/2004*
2005	Bag and Size Limits: - Statewide recreational bag limit: 2 lingcod Min Size:24 inches. Management Area Seasons and depth restrictions: - Northern Management Area: Boat based anglers open July to October in water less that 40 fathoms. Shore based anglers and divers open April to November. - North-Central Management Area **redefined** (Near Cape Mendocino(40° 10') to Pigeon Point (37° 11)) Boat based anglers and divers open July to November in water less that 20 fathoms. Shore based anglers open April to November. - Monterey South Central Management Area (Pigeon Point (37° 11) to Lopez Point (36° 00')) Open for boat based anglers July to November in waters less than 20 fathoms. Shore based anglers and divers open from April to November. - Morro Bay South Central Management Area (Lopez Point (36° 00') to Point conception (34° 27')) Open for boat based anglers May to September in waters less than 20 fathoms. Shore based anglers and divers open from April to November. - South Central Management Area (Point Conception (34° 27') to U.S./Mexico border) Open for boat based anglers April to September in waters between 30 and 60 fathoms from April to June then from July to September waters less than 40 fathoms. Shore based anglers and divers open from April to November. *Management Area Seasons:*	3/1/2005

	o *Northern Management Area: Boat based anglers open May to November in water less that 30 fathoms.* o *Morro Bay South Central Management open for boat based anglers May to September in waters less than 40 fathoms.* o *South Central Management Area open for boat based anglers April to November in waters less than 60 fathoms from April to August & November then from September to October waters less than 30 fathoms.*	*6/1/2005*
2006	<u>Management Area Seasons and depth restrictions:</u> o South Central Management Area (Point Conception (34° 27') to U.S./Mexico border) Boat based anglers open April to September. Lingcod may only be taken or possessed in waters between 40 and 60 fathoms from April to June. Lingcod may only be taken or possessed in waters less than 40 fathoms from July to September.	3/1/2006
2007	<u>Management Area Seasons and depth restrictions:</u> o Northern Management Area: Boat based anglers open May to November in water less that 30 fathoms. o North-Central Management Area boat based anglers open June to November in waters less that 30 fathoms. o Monterey South Central Management Area open for boat based anglers May to November in waters less than 40 fathoms. o Morro Bay South Central Management Area open for boat based anglers May to November in waters less than 40 fathoms. o South Central Lingcod Management Area open for all anglers April to November in waters less that 60 fathoms. *Inseason Changes: The Northern and North Central Management Areas Closed in October for all anglers*	3/1/2007 *10/1/2007*
2008	<u>Management Area Seasons and depth restrictions:</u> o Northern Management Area: Boat based anglers open May to November in water less that 20 fathoms. *Inseason Changes:* o *North Central Management Area split into two Management Areas.* o *North Central North of Point Arena Management Area (Near Cape Mendocino(40° 10') to Point Arena (38° 57.5')) and North Central South of Point Arena Management Area (Point Arena (38° 57.5') to Pigeon Point (37° 11)).* o *The Northern and North Central North of Point Arena Management Areas Closed in September for all groundfish anglers.*	1/8/2002 *9/2/2008*
2009	<u>Management Area Seasons and depth restrictions:</u> o North Central North of Point Arena Management Area open for boat based anglers May 15 to September 15 in waters less than 20 fathoms. o North Central North of Point Arena Management Area open for boat based anglers May 15 to August 15 in waters less than 20 fathoms. o North Central South of Point Arena Management Area open for boat based anglers June 13 to October 30 in waters less than 30 fathoms. o Monterey South Central Lingcod Management Area open for boat based anglers May to November 15 in waters less than 40 fathoms. o Morro Bay South Central Lingcod Management Area open for boat based anglers May to November 15 in waters less than 40 fathoms.	3/1/2009

Appendix 1. Indices of Abundance for Central California.

Thomas Wadsworth

1.1. Study area

The study area extended from Cape Mendocino (40°38 N, 124°35' W) southward to Point Conception (34°27' N, 120°28' W) (Fig. 1). This area, often designated as 'central California', is used commonly for management by the Pacific Fishery Management Council. The nearshore marine environment has been defined by the CDFG California Nearshore Fishery Management Plan (2002) as beginning at the high-tide line and extending to 120 feet (~37 m). However, my study area begins at the low tide line, therefore only including the subtidal nearshore areas. The study area was further defined as including all rocky reef habitats in the nearshore environment and some deeper reefs where some surveys collect data on nearshore rocky reef fishes. This habitat is defined as areas of consolidated hard rock covering the seafloor as opposed to sand or mud substrate (Allen 2006).

1.3. Abundance surveys

1.3.1. Survey selection

Determining which current or historic surveys to include in this study required employing several criteria. Survey datasets had to: 1) include abundance measurements in the form of count and effort for at least one of the study species; 2) collect at least two samples each year within the boundaries of central California; 3) conduct at least some sampling in nearshore rocky reef habitats; and 4) contain at least four years of data using the same methodology. Abundance data spanning less than a few years does not provide enough information to satisfactorily depict a population trend for species living multiple years (Edward Dick, National Marine Fisheries Service, pers. comm.). Most nearshore rocky reef species require at least a few years to recruit to the fishery (Allen 2006). Therefore, a minimum criterion of at least four years of data was set for an abundance survey to be analyzed in this study, enough time to assess the impact of a few years of recruitment pulses on the stock.

I initially identified 35 surveys of abundance that collected data on nearshore rocky reef species in central California (Appendix 1). Many of these surveys consolidated their datasets into centralized databases, the California Commercial Port Sampling Program (CALCOM) and Recreational Fisheries Information Network (RecFIN). Several surveys were not included in this study because: 1) data were not yet digitized; 2) permission for use could not be obtained; 3) effort data were not consistently collected; or 4) they did not sample study species within the study area. Of the 35 surveys I reviewed, nine fit the necessary criteria to be analyzed in this study (Table 2).

1.3.2. Survey Data Organization

For each survey used in analyses, data were organized by excluding all species, samples and explanatory variables that did not fit the criteria for my study. Stephens and MacCall (2004) refer to this process as 'subsetting' the data, or determining what information is useful for the project. Some records or entire survey years within the dataset were removed prior to analysis because a record: 1) did not have sufficient effort data; 2) was collected outside the spatial boundaries of the study; 3) did not have data on one or more of the explanatory variables chosen to include in models; 4) was collected in a variable level with little or no intra-annual replication (e.g. all winter records were removed if only a few samples were collected across the entire survey time-series); or 5) was the only sample for that respective year (only years with more than one sample were used to allow for precision analysis).

Catch and effort data were sorted separately from one another. For fishing surveys, every distinct site recorded was considered a sample. Some surveys recorded catch at several sites fished by a given boat in one day, in others only the port location was recorded and a single trip was a sample. Each transect was considered a sample for SCUBA surveys. For each sample, a positive or zero count (catch or observation) was included for a given species. Effort data often had to be re-formatted before analysis could proceed. All fishing time that was recorded in boat hours at a given site was converted to decimal hours and multiplied by the number of anglers actively fishing to calculate fish catch-per-angler-hour. An assumption of the model was that the amount of sampling effort alone did not change the probability of counting a fish species. In surveys where researchers did not record the number of anglers fishing at each site, it was assumed that all anglers fished the entire trip. The volume of water surveyed in each SCUBA transect was determined in order to calculate fish count density. Once the final set of samples was identified for each dataset, I calculated the proportion of total samples where each study species was counted at least once.

I also selected categorical explanatory variables to include in analysis, based on information contained in each survey database. Only those variables that I deemed likely to influence the abundance count of a given survey were considered. I created categories for 'year' and 'season' based on sampling dates in all cases. Season was based on calendar dates: winter (December 22nd – March 20th), spring (March 21st – June 21st), summer (June 22nd – September 21st) or fall (September 22nd – December 21st). I grouped survey sampling locations into 'subregions' in most cases, due to the lack of appropriate replication at the more specific sampling sites recorded by the survey. Each additional variable (if applicable) was divided into 2-4 categories, defined with regard to the distribution of samples among levels. In some cases, categories were already chosen by samplers, and these were preserved. In all cases, variables (aside from year, season and location) were only considered for inclusion in models if they were regularly recorded by a given survey. In some cases where a small percentage of samples did not have information on a given explanatory variable, those samples were removed from analysis so that each sample had information on all categories.

Orthogonality in sampling was assessed for each survey dataset by creating tables of sample distributions across explanatory variable levels. I considered sampling to be orthogonal if all data cells for explanatory variable level combinations had at least five samples (e.g. every location in every year must have at least five samples in all seasons sampled). Samples from variable levels were not removed unless the number of samples was extremely small (< 10 samples) across all years. If sampling was non-orthogonal for an explanatory variable in a given year, all data for that year was removed only if sampling was very unbalanced (i.e. many samples in one level, few or none in other levels) *and* the time-series was not broken (e.g. it was the first year of a time-series). It was assumed that if sampling was non-orthogonal for a given explanatory variable, any results indicating differences in densities among levels could be incorrect due to missing information. In some cases, sampling was orthogonal for some or all variable pairs (e.g. all locations sampled in all years) but not for multiple variable combinations.

The sections below describe the nine surveys analyzed in this survey (and the one dataset I created by combining two surveys). Each section summarizes information on: the groups responsible for collecting data, survey methodologies, survey timespan and how I organized data for each to be analyzed.

1.4.3. CDFG Marine Reserve Fish Density and Habitat Associations (CDFG SCUBA)

The CDFG SCUBA survey was a fishery-independent study by CDFG personnel during 7 years from 1992 to 98. However, only the years 1995-98 (4 years total) were used for my analyses because variable methodologies were used in early years. Samples were collected using different types of SCUBA transects from Monterey to Lopez Pt. (Big Sur). Only samples collected using the 30 m transect method were used for analysis. The 30 m transects were not conducted in the years 1992-94, so those years were removed from analysis. In 30 m transects, dive buddy pairs swam the length of a benthic transect (near the bottom) and counts for each species were *combined* for the two divers (for detailed methods, see VenTresca et al. 2001). The measure of effort for this survey was the 360 m^3 volume surveyed.

Explanatory variables included in models of species for the CDFG SCUBA survey (if significant) were: ‘Year’, ‘Season’, ‘Subregion’, ‘Depth Zone’ and ‘Visibility.’ Sampling season were assigned in models as: summer or fall. Study sites were all rocky reef habitats (as defined by side-scan sonar) and transects were located at random within these areas. Sampling sites were grouped into subregions, assigned in the models as:

Monterey Peninsula, Pt. Lobos Ecological Reserve (PLER), Pt. Sur-North BCER border, BCER, or South BCER Border-Lopez Point. Depth zones were: deep (15.0-23.0 m), medium (12.0-14.99 m), or shallow (4.0-11.99 m). Visibility was: good (6.6-12.2 m), low (0.9-3.99 m), or moderate (4.0-6.5 m). Sampling was non-orthogonal across all levels for variable pairs, so interactions were not tested.

1.4.4. PISCO Collaborative Central Coast Abundance Surveys (PISCO SCUBA)

The PISCO SCUBA survey is an ongoing fishery-independent study by University of California personnel. Data for 1999-2007 were used in my study (9 years total) from Santa Cruz County to Pt. Conception. The Partnership for Interdisciplinary Studies of Coastal Oceans (PISCO) utilizes SCUBA surveys to collect data on nearshore fishes following their protocols (http://www.piscoweb.org/). Individual divers swam transects 30 m long by 2 m wide by 2 m high and counted all fish (including juveniles), but only fish above 15 cm were included in this study. The measure of effort for this survey was the 120 m^3 volume surveyed.

Explanatory variables included in the models of species for the PISCO SCUBA survey (if significant) were: ‘Year’, ‘Season’, ‘Subregion’, ‘Level/Depth Zone’, ‘Visibility’ and ‘Transect Replicate.’ Sampling season was assigned in modelS as: summer and fall. Study sites were all rocky reef habitats and transects were located at random within these areas. Sampling sites were grouped into subregions, assigned in the models as: Santa Cruz County, Monterey Peninsula, South PLER Border-North BCER border, BCER, or Pt. Buchon-Pt. Conception. Depth was recorded for each benthic or midwater transect, I split these into the transect level (benthic or midwater) and the depth zones within which the measurements fell. Level/depth zones were assigned as: Bottom (2.0-10.99 m), Bottom (11-25 m), Midwater (1.0-7.99 m), or Midwater (8.0-19 m). Visibility was recorded in meters for each transect, I categorized measurements as: poor (0-2.99 m), medium (3.0-5.99 m), or good (6.0-26 m). 'Transect Replicate' was a category to indicate whether a given SCUBA transect sample was conducted first or subsequently (i.e. second or higher) for a given date, site and level/depth zone. Transect replicates were included as: 1st transect or repeat transect. Sampling was orthogonal only for the variable pair 'Year' and 'Season', therefore this was the only interaction tested.

1.4.5. TENERA Inc. Diablo Canyon Nearshore Reef SCUBA Survey (TENERA SCUBA)

This ongoing fishery-independent survey, was designed and carried out by Tenera Environmental, Inc. The survey utilized SCUBA survey methods (CRANE 2004), and was limited to a small cove near Diablo Canyon, California. Data from 1976-2007 were included in my study (32 years total). Survey methodology consisted of two divers surveying a single 50 m x 2 m x 2 m (200 m^3) transect at the same time but starting at opposite ends. A sample consisted of the total fish count for both divers on each transect.

Explanatory variables included in models of species for the TENERA SCUBA survey (if significant) were: 'Year', 'Season', and 'Transect Replicate'. Sampling 'Season' was assigned in models as: winter, spring, summer and fall. 'Transect Replicate' was: 1st Transect or Repeat Transect. Depth ranges of transects were recorded but not included in models for this survey because ranges overlapped and differed very little. A location variable was not included in the model for this survey, since transects were all within the same small cove. Sampling was non-orthogonal across all levels for all variable pairs, so interactions were not tested.

1.4.6. CDFG Central California Marine Sportfish Hook-and-Line Survey (CDFG H&L)

This fishery-independent survey chartered fishing vessels to take scientists to fishing locations as directed from Monterey to Pt. Estero (north of Morro Bay). All fish were identified, measured and counted by scientists aboard fishing vessels. Effort was recorded by CDFG personnel as the number of minutes and anglers fishing at a given site during a trip. The survey was conducted during 17 years: 1978-82, 1985, 1987-89, 1991-94 and 1995-98. Only samples from 1978-82 and 1995-98 were included in my analyses, because other years did not include effort data. All samples without effort were removed from the dataset, including every sample from 1985-94 and some samples for 1995-98. This survey was split into two different datasets for analysis: 1978-82 (5 years) and 1979-82; 1995-98 (8 years). During 1978-82 samples were taken in all seasons from Monterey to Pt. Estero (Big Sur), while during 1995-98 sampling was only during fall months in Big Creek Ecological Reserve (BCER). Therefore, the time-series 1979-98 represents trends only within BCER (1978 was not included because only one sample was taken in BCER).

Explanatory variables included in models of species for the CDFG H&L 1978-82 time-series (if significant) were: ‘Year’, ‘Season’ and ‘Subregion.’ Season of sampling was assigned in models as: winter, spring, summer, or fall. Sampling sites recorded by the survey were grouped into subregions, included in models as: Monterey, Pt. Pinos-Carmel, Pt. Lobos-Soberanes, BCER, Lopez, Pt. Sur-Partington Pt., Jade Cove-Ragged

Point or Pt. Sierra Nevada-Pt. Estero. Sampling was non-orthogonal across all levels for variable combinations, meaning interactions between variables were not assessed. The model for the 1979-98 time-series did not include 'Subregion' or 'Season' as variables.

1.4.7. CDFG Creel Survey of CENCAL Spearfish Tournaments (CDFG CENCAL)

The Central California Council of Diving Clubs (known as CENCAL) organized several annual recreational spearfishing tournaments for decades from Cape Mendocino to Pismo Beach. California Department of Fish and Game (CDFG) personnel identified, counted and measured all fishes caught at CENCAL tournaments since 1958, and the survey was ongoing as of 2007. However, several years were not included in my analysis because one or zero samples were taken. A few other years could not be used because the survey did not record all variables included in the final model for this survey. In summary, years included in analyses were 1959-68, 1973, 1975-77, 1980-96, 1998-2006 (40 years total).   Individual spearfisher effort expended was the number of hours divers spent searching for and spearing fish. All individual effort times was summed to find the total effort for the meet. A sample for this survey was defined as a single tournament. All of these tournaments required that divers capture fish using the free diving method. Most divers employ kayaks (or other human-powered boats) to aid in searching for fish during the tournament time limit. Prizes are awarded to divers with the largest, most numerous and most diverse fish catches.

Explanatory variables included in models of species in the CDFG CENCAL survey (if significant) were: 'Year', 'Season', 'Subregion' and 'Water Conditions.' Sampling season was assigned in models as: spring, summer or fall. Only 2 samples were collected from winter months and these were removed because any assumptions made on so few samples for this season across 40 years would be statistically unsupportable. The tournament locations were grouped into subregions to increase the very low replication rate, and were included in models as: north (Fort Bragg-San Francisco Bay), central (San Francisco-Carmel), or south (Pt. Lobos-Pismo Beach). 'Water Conditions' was a qualitative rating combining visibility and surge, defined by divers as: poor (low visibility, high surge), fair (moderate visibility and surge), or good (high visibility, low surge). Sampling was non-orthogonal across all levels for variable combinations, meaning interactions between variables were not assessed.

1.4.8. CDFG Commercial Party Fishing Vessel Logbooks (CPFV Logbooks)

The commercial party fishing vessel (CPFV) fishery includes not only the nearshore, but also deeper waters within a few hours boat ride from California harbors. Fish were identified and recorded in logbooks by CPFV crew. The total of kept and released fish was used as a measure of catch by species for analysis. Effort was recorded by CPFV crew as the total number of minutes spent fishing for an entire trip and total number of anglers onboard.

Logbooks were compiled and digitized by CDFG personnel for 1980-2007 (28 years). However, only two nearshore rocky reef species (*O. elongatus* and *S. marmoratus)* were recorded to the species-level before 2001. Therefore, only data for 2001-07 were used for analysis (7 years total). Data for unused years (1980-2001) were grouped under the category 'rockfish' for rockfish species, whereas all sea perches were recorded as 'surfperch. ' In 2001, three species of nearshore rockfish (*S. mystinus*, *S.*

carnatus and *S. pinniger*) as well as *H. decagrammus*, were added as categories on the logbook forms. In 2005, *S. melanops* was added as a category, however, three years of data collection (2005-07) was not enough to include this species in my analysis. Although the category 'rockfish' still remained in logbooks, the assumption was that CPFV crew recorded fish to the species-level where these categories existed.

Explanatory variables included in models for the CPFV Logbooks survey (if significant) were: 'Year', 'Season' and 'Subregion.' The season of the sample was assigned in models as: winter, spring, summer, or fall. Subregions were constructed using block numbers recorded by CPFV crew indicating where the majority of fishing occurred. Subregions used for this survey were: Cape Mendocino-Pt. Reyes, Pt. Reyes-Pillar Pt., Pillar Pt.-Santa Cruz Lighthouse, Santa Cruz Lighthouse-Pt. Sur, Pt. Sur-Pt. Buchon, or Pt. Buchon-Pt. Conception. Sampling was orthogonal across all levels for variable pairs, but not for 'Year', 'Season' and 'Subregion' together. Interactions between the 'Year' and 'Season', 'Year' and 'Subregion', and 'Season' and 'Subregion' were tested.

1.4.9. PSMFC MRFS / CRFS Dockside Boat Survey (PSMFC Dockside)

In this survey, the Pacific States Marine Fisheries Commission (PSMFC) interviewed recreational anglers at harbors throughout the study area for 1980-2007 (25 years total). Each interview of a Commercial Party Fishing Vessel (CPFV) or private fishing boat was considered a sample for my analyses. Shore based fishing data was collected by this survey, but not included in my analyses due to the low likelihood of catching study species from shore. The recreational boat fishery covers nearshore waters, but also deeper areas within a few hours boat ride from California harbors. When fishing for rocky reef species, both private and CPFV anglers primarily used similar methods of anchoring or drifting (not trolling) and jigging baits or lures. CPFV trips typically have 20-80 passengers, whereas passenger vessels have 2-5 anglers, both vessel types may fish for up to 8 hours in a day. Effort was recorded by CDFG personnel as the number of minutes and anglers fishing for an entire trip (as reported by interviewees). Only fish kept by anglers and identified by PSMFC interviewers were used to calculate catch per hour for a sample. Released fish were not included in catch totals because this information was reliant on angler identifications. Samples were included in analyses if the primary or secondary target species or group (i.e. rockfish) reported to interviewers was any study species or 'group.' A small percentage of anglers told interviewers they were fishing for anything they could catch, often recorded by PSFMC as 'unidentified.' These trips were included for analysis, although anglers could have been fishing in locations unlikely to contain nearshore rocky reef species.

The Marine Recreational Fisheries Statistical Survey (MRFSS) covered the years 1980-89 and 1993-2003, whereas the California Recreational Fisheries Survey (CRFS) extended from 2004-2007. Both monitored the same fishery, but the CRFS program sampled more sites, more regularly. Whereas the MRFSS survey recorded the effort of anglers in hours, the CRFS survey used anglers per trip as a measure of effort at high traffic sites and angler hours at less popular sites. To combine these two programs into one survey, I used all sites surveyed by the MRFSS program and only the lower traffic sites (that recorded angler hours) from the CRFS program.

Explanatory variables included in models of species for the PSMFC Dockside survey (if significant) were: 'Year', 'Season', 'Subregion', 'Distance From Shore' and 'Boat Type.' Sampling season was assigned in models as: winter, spring, summer and fall. The location of each dockside sample was recorded by this survey, but not the location of fishing. Samples were split into several subregions based on the dockside interview location, included in models as: Cape Mendocino-Pt. Reyes, Pt. Reyes-South San Francisco, Pacifica-Capitola, Moss Landing-Ragged Pt., or Pt. Piedras Blancas-Pt. Conception. The distance from shore fished during the majority of a boat trip was included in models as: less than three miles or more than three miles. The type of fishing boat was: private or charter (CPFV). Sampling for the PSMFC Dockside survey was orthogonal for year and all variable levels, but not for multiple variable combinations (e.g. all subregions and seasons were sampled in 1989, but not all seasons were sampled in the subregion Moss Landing-Ragged Pt.). Therefore, I tested for interactions between 'Year' and 'Season', 'Year' and 'Subregion', and 'Season' and 'Subregion'.

1.4.10. CDFG CPFV On-Board Sampling Program (CDFG Observers)

The CDFG Observers survey was based on the observations of CDFG personnel while onboard CPFVs from 1987-1998. Data for 1987 were not included in my analyses due to non-orthogonality in sampling, leaving a time-series of 11 years. Trips were chosen to carry observers at random for each of the major ports in the state. CPFV trips included nearshore waters, but also deeper areas within a few hours' boat ride from California harbors. Although CPFV trips targeted many different species, the CDFG Observers survey only monitored trips targeting rocky reef species. Therefore, all samples inside the latitudinal range of central California were included in analysis. General fishing methods mirrored those defined for CPFV vessels in the PSFMC Dockside survey. However, effort was recorded by observers, as the number of minutes and anglers fishing at a given site during a trip. In addition, observers recorded, identified and counted any fish caught and returned to the ocean, as well as those kept by anglers. In many cases, only a portion of the anglers were observed on each trip. The sum of released and kept fish for observed anglers was used to determine the catch rate of each sample.

Explanatory variables included in models of species for the CDFG Observers survey (if significant) were: 'Year', 'Season', 'Subregion' and 'Depth Zone.' Sampling season was assigned in models as: winter, spring, summer, or fall. Locations were recorded by the PSFMC Observers survey as sites with coordinates. I grouped these locations into the same subregions as the CPFV Logbooks survey. The depth range fished was recorded by observers as a maximum and minimum depth for each site, but this could not be included in models because the time fished at each depth was not recorded. However, observers also recorded whether most fishing occurred deeper or shallower than 40 fathoms (~73 meters) for each sample. This 'Depth Zone' category was included as: less than 73 meters or more than 73 meters. The depth range of samples used for this survey was 3-275 meters, however only 3% were over 150 meters. Sampling was non-orthogonal across all levels for variable combinations except for 'Year' and 'Subregion', therefore only these interactions were tested.

1.4.11. PSMFC MRFSS/CRFS CPFV Observers Survey (PSMFC Observers)

The PSMFC Observers survey was based on the observations of PSMFC personnel onboard CPFVs across California. The Marine Recreational Fisheries Statistical Survey (MRFSS) covered the years 1999-2003, while the California Recreational Fisheries Survey (CRFS) extended from 2004-present. Together, the MRFS and CRFS observer surveys spanned a total of 9 years. Both monitored the same fishery, but the CRFS program sampled more CPFV trips in a given year. The survey was basically an extension of the CDFG Observers survey, using similar methods except in choosing samples to include. Unlike the CDFG Observers survey, all types of CPFV trips were observed by PSMFC. These included trips targeting salmon (*Oncorhynchus* spp.), tuna (family Scombridae), flatfish (order Pleuronectiformes) as well as nearshore and shelf rocky reef species. Because observers did not record the target group for the trips, it was difficult to sort out the trips focusing on the rocky reef assemblage. All trolling trips were removed, which accounted for most the salmon and tuna trips. Any trip that did not catch at least one species of nearshore rocky reef species was eliminated.

Explanatory variables included in the models for this survey (if significant) were: ‘Year’, ‘Season’ and ‘Subregion’. Variables were collected and categories defined using the same methods as for the CDFG CPFV Observers survey. The depth range of samples used for this survey was 5-340 meters, however only ~0.4% of samples were at depths over 150 meters. Sampling was non-orthogonal across all levels for variable combinations except for ‘Year and ‘Season’, therefore only interactions between those variables were tested.

1.4.12. CDFG/PSFMC CPFV Observers dataset (All Observers)

I created the All Observers survey by combined data from the CDFG and PSMFC CPFV surveys into a single dataset (1988-2007). The close similarities in all aspects of methods for the two surveys make it reasonable to analyze all 20 years of data together. Results did not replace either original (separated) Observers survey, instead results were compared with original surveys and other surveys that sampled the same time-span. The explanatory variables used for this GLM (if significant) were: 'Year', 'Season' and 'Subregion' (defined in CDFG Observers description). This time-series was non-orthogonal for all variable pairs.

1.5. Analysis

The error distribution used in GLMs can be continuous (e.g. normal or Gaussian, log-normal, gamma) or discrete (e.g. Poisson, binomial or negative binomial) (Dick 2004). I chose a discrete distribution, the negative binomial (NB), for all GLMs. A primary reason for choosing the NB distribution is its usefulness for datasets containing few or many zero counts to be analyzed (Maunder and Punt 2004). Zero fish counts were present or common for all of the abundance surveys used in this project (often 40% or more). If not included in the model, zero records may invalidate assumptions of the analysis as well as creating difficulties in computations (Lambert 1992, Maunder and Punt 2004). Using the normal or most other distributions requires ignoring zero records when analyzing abundance survey data may, which can bias the resulting index in a positive direction (Maunder and Punt 2004). Therefore, zero records were included in calculating an index value for each year of the time series. However, some distributions that allow for zeros, do not function correctly if the number of zeros is very low (e.g.

binomial) (Edward Dick pers. comm.). The NB distribution is not negatively affected by data with few zeros.

Discrete distributions such as the NB and the Poisson are useful if the dependent variable is a count of fish caught or observed as opposed to a continuous measurement (e.g. fish weight) (Maunder and Punt 2004). The NB and Poisson distributions are useful for modeling count data of relatively rare phenomena. Data overdispersion may occur if intra-annual sample variance is greater than the mean. This was another key reason for using the negative binomial distribution, because this distribution reflects the overdispersion not captured by the Poisson (which assumes variance equals the mean) (Seavy et al. 2005). It is also useful to employ the Akaike's information criterion (AIC) or other model selection criteria to compare the fit of models with different distributions to the same data. The AIC was used to compare models of the same data using the negative binomial and Poisson distributions, and the NB distribution proved to have the lower AIC values. The NB distribution, for the purposes of this analysis, can be viewed as a Poisson distribution with a mean that follows the gamma distribution (Hilborn and Mangel 1997).

A link function can be used to relate the linear sum of explanatory variable effects (i.e. the linear predictor term) to the mean value of the response variable (Crawley 1993). The log link, commonly accepted for use with the NB distribution (McCullagh and Nelder 1989), was used in all GLMs. This link function restricts GLM index values to positive numbers, applicable for working with abundance survey data (Agresti 2002).

An abundance survey sample (*i*) can be modeled by a GLM with negative binomial distribution and log link as:

$$\log(\mu) = x_i\beta$$

Where x = design matrix composed of all observations and explanatory variables, β = all coefficients - or levels - for each variable (e.g. spring, summer, fall for the season variable) and μ = the true mean response (Dick 2004). Fitted model values are found by: $\mu_i = \mu D_i$, where D is an error term drawn at random from the NB distribution (Dick 2004). To extract the 'year effect' from this model, the index of abundance for each year of a given study (μ_y) was calculated by the equation:

$$\mu_y = \exp(\alpha + \beta_y)$$

where α is the model intercept and β_y is the regression coefficient for the 'year' variable both back-transformed to display original data scale measurements (Ralston and Dick 2003).

To design a GLM model that best fits a given abundance survey dataset, variable selection analysis was completed for each species. This process compared models of the same dataset using different combinations of explanatory variables (e.g. years, season, location, etc.). Including factors with large fish count variation among levels in a GLM will reduce model variance, evidenced by lower AIC scores. However, when non-significant explanatory variables are incorporated in the model, variance may increase due to unnecessary complexity, creating a less precise index (Maunder and Punt 2004). Analysis of Variance (ANOVA), Akaike Information Criteria (AIC) and Bayesian Information Criteria (BIC) can all be used to evaluate these competing models. The AIC is useful for variable selection in datasets with at least 40 data points (Burnham and Anderson 2002). The BIC may provide results with less bias for large sample sizes (n >

1000) (Burnham and Anderson 2002). To create a model with only those variables that explain a significant amount of fluctuation in data, a 'penalty' term is employed for both AIC and BIC (Hilborn and Mangel 1997). The BIC is calculated similarly to the AIC, but includes a penalty term that increases with sample size, while the penalty term for AIC remains constant. Use of the BIC can reduce the chance of selecting unneeded explanatory variables for GLMs in surveys with large sample sizes.

The GLMs used in my analysis tested 'main effects' only. Interaction terms were not used in GLMs in my study, but they were tested where appropriate (i.e. when sampling was orthogonal across factor levels). ANOVAs were used to test the significance of explanatory variables in GLMs with an F-test ($\alpha < 0.05$). Every significant variable was included in the final GLM for each species in a given survey (non-significant factors were not included). The only exception is that I included the variable 'Year' in all GLMs. This is because the purpose of using GLMs in my study was to detect a trend in abundance data over a time-series. Interaction models were also tested using ANOVAs, indicating whether interaction terms were significant. BIC was employed in addition to ANOVAs for testing interactions when sample sizes were greater than 1000 to compare results.

The intra-annual precision of fish count and effort samples was characterized in this study for each species in each survey using a coefficient of variation (CV). If a given year had less than two associated survey samples it was not included in analysis, because with no annual variability a CV could not be calculated (Dick 2004). The log-transformed yearly index values resulting from each negative binomial GLM were back-transformed to the original data format to compute the yearly CV. This step exponentiates the GLM values, allowing the variability of the original data to be analyzed (Edward Dick pers. comm.). In order to calculate the CV for each year of a given dataset, I used a jackknife procedure, which has been used in existing stock assessments (e.g. Ralston and Dick 2003). CVs were calculated for each year using standard errors derived from a jackknife process. The jackknife (Tukey 1958) is a specialized form of the bootstrap technique, which estimates standard errors for the GLM index values using the same number of iterations as data points (Efron and Tibshirani 1993).

The downloadable statistical program, R (http://www.r-project.org/), was used for selecting data distributions and explanatory variables and computing GLMs. I created a generic R-script that was tailored to suit each survey's dependent and explanatory variables in calculating the yearly index values and CVs based on original survey data for each species. ANOVAs (as well as AIC and BIC) were computed in R to evaluate the significance of explanatory variables and interaction terms. Each GLM was run in R and output was organized into yearly abundance index and CV values.

Table A1.1. The nine historical and ongoing abundance surveys of nearshore rocky reef fishes within central California used in my study. Survey time-span indicates the range of years for data included in my analysis. The first 4 surveys listed were fishery-independent, the final 5 surveys were fishery-dependent.

GIS map by Lee Murai.

Figure A1.1. The project study area, central California nearshore (3-40 meters), is highlighted in red. The rocky reef habitats comprise a portion of these depths. Deeper areas are included in some of the surveys analyzed here if they sample the correct species assemblage. The region extends from Cape Mendocino (N40°38 W124°35') at the north end to Point Conception (N34°26' W120°35') at the south end. Important landmarks in the region and 20-meter ocean bathymetry lines are included.

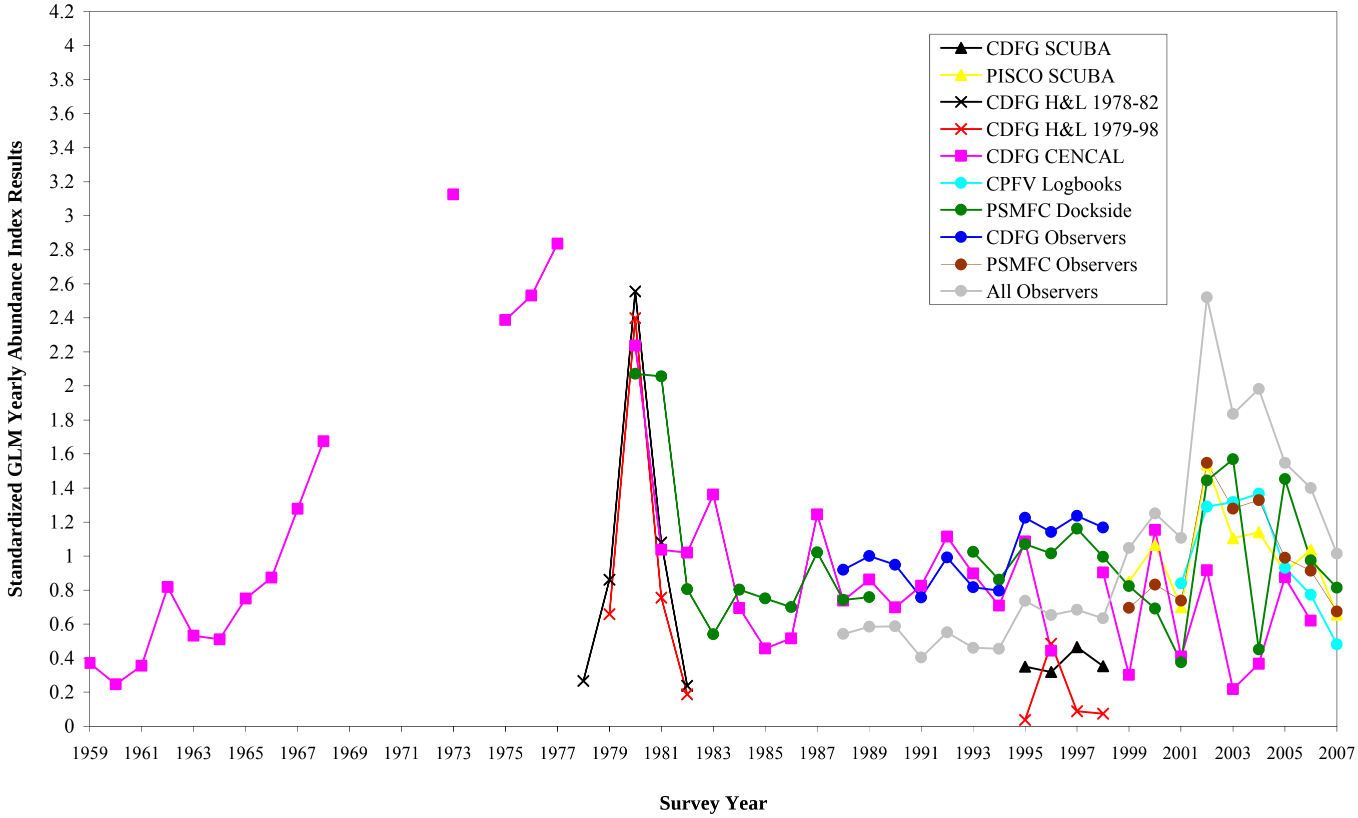

Figure A1.2 Standardized yearly index GLM model results for Ophiodon elongatus, as sampled by all surveys in the study except the TENERA SCUBA survey. Each set of yearly index values were standardized by dividing each value by the average of all values for a given survey resulting in a distribution with mean of 1, enabling comparisons among surveys with different index value magnitudes, but still displaying yearly variability.
