## EXECUTIVE SUMMARY

## Stock

Spiny dogfish (Squalus suckleyi) in the Northeast Pacific Ocean occur from the Gulf of Alaska, with isolated individuals found in the Bering Sea, southward to San Martin Island, in southern Baja California. They are extremely abundant in waters off British Columbia and Washington, but decline in abundance southward along the Oregon and California coasts. This assessment focuses on a portion of a population that occurs in coastal waters of the western United States, off Washington, Oregon and California, the area bounded by the U.S.-Canada border on the north and U.S.-Mexico border on the south. The assessment area does not include Puget Sound or any other inland waters. The population within this area is treated as a single coast-wide stock, given the migratory nature of the species and the lack of data suggesting the presence of multiple stocks.

The spiny dogfish stock included in this assessment likely has interaction and overlap with dogfish observed off British Columbia. A spatial population dynamics model, which included data from several tagging studies in the Northeast Pacific Ocean, estimated movement rates of about $5 \%$ per year between the U.S. coastal sub-population of dogfish and that found along the west coast of Vancouver Island in Canada. Given this relatively low estimated rate of exchange, it was considered appropriate to proceed with the assessment for the limited area of species range, recognizing that the scope of this assessment does not capture all of the removals and dynamics which likely bear on the status and trends of the larger, transboundary population.

## Catches

In the coastal waters of the U.S. west coast, spiny dogfish has been utilized since early $20^{\text {th }}$ century. The history of dogfish utilization included a brief but intense fishery in the 1940s, which started soon after it was discovered that livers of spiny dogfish contain high level of vitamin A. During the vitamin A fishery, removals averaged around 6,821mt per year reaching their peak of $16,876 \mathrm{mt}$ in 1944. The fishery ended in 1950 with the advent of synthetic vitamins. In the mid1970s, a food fish market developed for dogfish when the species was harvested and exported to other counties, primarily Great Britain. This fishery existed until very recently and the landings averaged around 450 mt per year. For the last 10 years landings ranged between 164 and 876 mt .

Even though spiny dogfish was heavily harvested in the 1940s, in general this species is not highly prized and is mostly taken as bycatch in other commercially important fisheries. It is often discarded when bycaught. It has been taken by three major gear groups, including trawl, hook-and-line and a variety of nets. Since 2002, the discard rates in the trawl fishery were on average $85 \%$ of all encountered dogfish catch and in the hook-and-line fishery $52 \%$.The vast majority of commercial catch (more than $90 \%$ ) has been landed in Washington. A small portion of the catch is taken recreationally.

The landings of spiny dogfish were reconstructed back to 1916 from variety of published sources and databases. Gear-specific discards were also reconstructed outside the model and included as separate fleets. The fishery removals in the assessment were divided among eight fisheries bottom trawl, bottom trawl discard, midwater trawl, hook-and-line, hook-and line discard, other gears (primarily nets), recreational fishery and at-sea hake fishery bycatch.

Table ES-1. Recent removals (mt) of spiny dogfish by fleet (BT=bottom trawl, BTD=bottom trawl discard, MDT=midwater trawl, ASH=at-sea hake fishery bycatch, HKL=hook-and-line, HKLD=hook-and-line discard, OTH=others, REC=recreational).

## Data and Assessment

This is the first assessment for spiny dogfish off the continental U.S. Pacific Coast. In the assessment, the Stock Synthesis modeling platform (version 3.21f) was used to conduct the analysis and estimate management quantities. The modeling period begins in 1916, assuming an unfished equilibrium state of the stock in 1915. The assessment treats females and males separately due to differences in biology and life history parameters between genders.

The model includes eight fishing fleets (bottom trawl, bottom trawl discard, midwater trawl, hook-and-line, hook-and line discard, other gears, recreational fishery and at-sea hake fishery bycatch) that operate within the entire area of assessment. Fishery-dependent biological data are derived from both port and on-board observer sampling programs. Discard information is provided by the West Coast Groundfish Observer Program.

Fishery-independent data are derived from four NOAA Fisheries trawl surveys conducted by Northwest and Alaska Fisheries Science Centers on the continental shelf and slope of the Northeast Pacific Ocean, and one International Pacific Halibut Commission longline survey. Surveys data used in the assessment included abundance indices and fishery-independent biological samples that together provide information on relative trend and demographics of the spiny dogfish in the assessed area.

Figure ES-1. Reconstructed time series of spiny dogfish removals (mt) by fleet.

## Stock spawning output

The spiny dogfish spawning output in the assessment is reported in thousands of fish. The unexploited level of spawning stock output is estimated to be 70,724 thousands of fish (95\% confidence interval: $35,598-105,850$ ). At the beginning of 2011, the spawning stock output is estimated to be 44,660 thousands of fish ( $95 \%$ confidence interval: 8,937-80,383), which represents $63 \%$ of the unfished spawning output level.

Historically, the spawning output of spiny dogfish showed a relatively sharp decline in the 1940s, during the time of the intense dogfish fishery for vitamin A. During a 10-year period (between 1940 and 1950), the spawning output dropped from $99 \%$ to under $70 \%$ of its unfished level. Between 1950 and 1974 the catches of spiny dogfish were minimal, and the spawning
output started to increase (mostly as a result of maturation of younger dogfish that were not selected by the vitamin A fishery). For the last thirty five years, spawning output of spiny dogfish has been slowly but steadily declining due to fishery removals (an export food fish fishery developed in the mid-1970s) and low productivity of the stock.

Table ES-2. Recent trend in estimated spiny dogfish spawning output and depletion level.

| Year | Estimated spawning <br> stock output (1,000s) | $\mathbf{9 5 \%}$ confidence <br> interval | Estimated <br> depletion |
| :---: | :---: | :---: | :---: |
| 2002 | 46,450 | $10,760-82,140$ | $66 \%$ |
| 2003 | 46,042 | $10,352-81,730$ | $65 \%$ |
| 2004 | 45,849 | $10,155-81,542$ | $65 \%$ |
| 2005 | 45,527 | $9,837-81,215$ | $64 \%$ |
| 2006 | 45,168 | $9,484-80,850$ | $64 \%$ |
| 2007 | 45,022 | $9,333-80,711$ | $64 \%$ |
| 2008 | 44,939 | $9,240-80,636$ | $64 \%$ |
| 2009 | 44,638 | $8,943-80,331$ | $63 \%$ |
| 2010 | 44,641 | $8,932-80,349$ | $63 \%$ |
| 2011 | 44,660 | $8,937-80,383$ | $63 \%$ |

Figure ES-2. Time series of estimated spawning output of spiny dogfish (1,000s fish) with $95 \%$ confidence interval.

## Recruitment

The fecundity of dogfish in the Northeast Pacific Ocean has been well studied, with pregnant females having relatively few pups per litter ( 5 to 15), and with relatively little variability among individuals. Unlike fish producing millions of eggs, the low fecundity of dogfish suggests both low productivity in general and a more direct connection between spawning output and recruitment than for many species.

In the assessment, therefore, the spawner-recruit relationship was modeled using a functional form which allows a more explicit modeling of pre-recruit survival between the stage during which embryos can be counted in pregnant females to their recruitment as age 0 dogfish. The recruits were taken deterministically from the stock-recruit curve since the relatively large size of dogfish pups at birth $(20-30 \mathrm{~cm})$ suggest that variability in recruitment would be lower than for a species with a larval stage, which is subject to higher mortality rates.

Table ES-3. Recent trend in estimated recruitment for spiny dogfish.

| Year | Estimated <br> recruitment (1,000s) | 95\% confidence <br> interval |
| :---: | :---: | :---: |
| 2002 | 18,043 | $5,591-30,494$ |
| 2003 | 17,930 | $5,456-30,402$ |
| 2004 | 17,876 | $5,391-30,360$ |
| 2005 | 17,786 | $5,285-30,286$ |
| 2006 | 17,685 | $5,166-30,203$ |
| 2007 | 17,644 | $5,115-30,172$ |
| 2008 | 17,620 | $5,084-30,155$ |
| 2009 | 17,535 | $4,983-30,086$ |
| 2010 | 17,536 | $4,980-30,091$ |
| 2011 | 17,541 | $4,982-30,099$ |

Age-0 recruits (1,000s) with $\sim 95 \%$ asymptotic intervals

Figure ES-3. Time series of estimated recruitment (1,000s fish) with 95\% confidence interval.

## Reference Points

Unfished spawning stock output for spiny dogfish is estimated to be 70,724 thousands of fish ( $95 \%$ confidence interval: 35,598-105,850). The stock is declared overfished if the current spawning output is estimated to be below $25 \%$ of unfished level. The management target for spiny dogfish is defined as $40 \%$ of the unfished spawning output ( $\mathrm{SB}_{40 \%}$ ), which is estimated by the model to be 28,290 thousand of fish ( $95 \%$ confidence interval: 14,239-42,340), which corresponds to an exploitation rate of 0.006 . This harvest rate provides an equilibrium yield of 831 mt at $\mathrm{SB}_{40 \%}$ ( $95 \%$ confidence interval: 421-1241 mt). The model estimate of maximum sustainable yield (MSY) is 848 mt ( $95 \%$ confidence interval: 430-1267 mt). The estimated spawning stock output at MSY is 33,229 thousands of fish (95\% confidence interval: 16,72349,736 ). The exploitation rate corresponding to the estimated $\mathrm{SPR}_{\mathrm{MSY}}$ of $\mathrm{F} 79.26 \%$ is 0.0053 .

Because of the extremely low productivity and other reproductive characteristics of the stock, fishing at the target of SPR $45 \%$ is expected to severely reduce the spawning output of spiny dogfish over the long term. Conversely, fishing at a rate that would maintain spawning output near $40 \%$ of the unfished level would require a target SPR of about $77 \%$ as estimated by the assessment model. The Council's Scientific and Statistical Committee should consider the appropriateness of using the current proxy harvest rate for spiny dogfish.

## Spawning depletion with ~95\% asymptotic intervals

Figure ES-4.Time series of estimated spawning depletion of spiny dogfish with 95\% confidence interval

## Exploitation Status

The assessment shows that the stock of spiny dogfish off the continental U.S. Pacific Coast is currently at $63 \%$ of its unexploited level and, therefore, not overfished. Historically, the abundance of spiny dogfish has always been above the management target of $\mathrm{SB}_{40 \%}$. During the last 10 years, relative exploitation rates (catch/summary biomass) are estimated to have hovered around $1 \%$ and SPR is estimated to be well above current management target of SPR 45\%. The assessment identified a period, which is during the vitamin A fishery in the 1940s, when the exploitation rate exceeded the current $\mathrm{F}_{\text {MSY }}$ proxy harvest rate.

Table ES-4. Recent trends in estimated spawning potential ratio (SPR) and exploitation rate for spiny dogfish.

| Year | SPR (\%) | Exploitation rate |
| :---: | :---: | :---: |
| 2001 | $69.80 \%$ | 0.00842 |
| 2002 | $66.32 \%$ | 0.00971 |
| 2003 | $73.20 \%$ | 0.00720 |
| 2004 | $64.92 \%$ | 0.01014 |
| 2005 | $63.08 \%$ | 0.01092 |
| 2006 | $73.37 \%$ | 0.00719 |
| 2007 | $76.09 \%$ | 0.00628 |
| 2008 | $63.64 \%$ | 0.01061 |
| 2009 | $79.31 \%$ | 0.00532 |
| 2010 | $78.97 \%$ | 0.00540 |

Figure ES-5. Time series of estimated spawning potential ratio (SPR) of spiny dogfish with SPR target of 0.45 . Values below target reflect harvest that exceeded current overfishing proxy.

Figure ES-6. Estimated spawning potential ratio (SPR) of spiny dogfish relative to its target of 0.45 versus estimated spawning output relative to its target of $\mathrm{SB}_{40 \%}$. Red dot indicates the point that corresponds to 2011.

## Management

Spiny dogfish on the west coast of the United States has been managed under the Other Fish complex since implementation of the Groundfish Fishery Management Plan (FMP) by the Pacific Fishery Management Council.

In 2005, reduction in acceptable biological catch (ABC) was instituted due to removal of the California substock of cabezon from the Other Fish complex. The same year, a 50\% precautionary optimum yield (OY) reduction was implemented to accommodate uncertainty associated with managing unassessed stocks. In 2006, a trip limit for spiny dogfish was imposed for U.S. west coast waters which varied between 45 and 91 mt per two months for all gears. In 2009, another ABC reduction was implemented due to removal of longnose skate from the Other Fish complex, but the $50 \%$ OY reduction was maintained.

In 2011, reduction in overfishing limnit (OFL) was implemented due to removal of the Oregon substock of cabezon from the Other Fish complex. 50\% precautionary reduction to the annual catch limit (ACL) was maintained, however, a scientific uncertainty buffer was specified as an ABC of 7,742 mt under the Amendment 23 framework.

Table ES-5. Management guidelines, recent trends in landings and estimated total catch for spiny dogfish.

| Year | Harvest Specifications (mt) for the Other Fish Complex |  | $\underset{(m t)^{b}}{\text { Landings }}$ | $\begin{gathered} \text { Total catch } \\ (\mathrm{mt}) \\ \hline \hline \end{gathered}$ |
| :---: | :---: | :---: | :---: | :---: |
|  | ABC/OFL ${ }^{\text {a }}$ | OY/ACL ${ }^{\text {a }}$ |  |  |
| 2001 | 14,700 | 14,700 | 810 | 1,879 |
| 2002 | 14,700 | 14,700 | 1,190 | 2,159 |
| 2003 | 14,700 | 14,700 | 730 | 1,593 |
| 2004 | 14,700 | 14,700 | 1,023 | 2,238 |
| 2005 | 14,700 | 14,700 | 801 | 2,396 |
| 2006 | 14,600 | 7,300 | 483 | 1,567 |
| 2007 | 14,600 | 7,300 | 539 | 1,364 |
| 2008 | 14,600 | 7,300 | 1,172 | 2,300 |
| 2009 | 11,200 | 5,600 | 378 | 1,147 |
| 2010 | 11,200 | 5,600 | 444 | 1,163 |

${ }^{\text {a }}$ The acceptable biological catch (ABC) specification prior to 2011 represents the MSY harvest level and the optimum yield (OY) represents the annual total catch limit. Implementation of Amendment 23 in 2011 changed these definitions to the overfishing limnit (OFL) as the MSY harvest level and the annual catch limit (ACL) as the annual total catch limit. Additionally, the definition of ABC changed under Amendment 23 to a level of harvest less than or equal to the OFL to accommodate the scientific uncertainty associated with estimating the OFL.
${ }^{\mathrm{b}}$ Includes at-sea hake fishery bycatch and recreational catches.

## Uncertainty

Uncertainty in the model was explored though asymptotic variance and sensitivity analyses. Asymptotic confidence intervals were estimated within the model and reported throughout the assessment for key model parameters and management quantities. To explore uncertainty
associated with alternative model configurations and evaluate the responsiveness of model outputs to changes in key model assumptions, a variety of sensitivity runs were performed, including increase and decrease in fishery removals, runs with different assumptions regarding historical discard, discard mortality, shape of selectivity curves, stock-recruitment parameters, and many others. The uncertainty regarding natural mortality was also explored through likelihood profile analysis. Also, a retrospective analysis was conducted where the model was rerun after successively removing data from recent years.

## Decision table

Three states of nature were defined based on the alternative time series of removals and natural mortality values. The middle (base case) scenario has catch time series and natural mortality (0.064) as used in the base model. For the "low" and "high" states of nature, the base model was first modified by decreasing the entire time series of removals by $25 \%$ and increasing by $50 \%$ for low and high catch scenarios respectively. The low and high catch scenario models were further modified by subtracting one standard deviation from the 2011 spawning output value from the low catch model and adding one standard deviation to the 2011 spawning output value from the high catch model. The natural mortality for low state of nature ( 0.061 ) was selected to match one standard deviation below the 2011 spawning output for low catch scenario. The natural mortality for high state of nature (0.066) was selected to match one standard deviation above the 2011 spawning output estimate for high catch scenario. The fourth state of nature based on the retrospective analysis that excluded the last three years of the time series was added to allow for decision table to broaden the uncertainty in the assessment estimates. The net effect is to add more pessimistic state of nature, in which the spawning depletion falls below the management target of $\mathrm{SB}_{40 \%}$ in recent years.

Twelve-year forecasts for each state of nature were calculated based on removals at SPR 45\% for the base model. Twelve-year forecasts were also produced with future catch fixed at the 20112012 OFL-based value provided by the Groundfish Management Team (GMT) and calculated as 28.4\% of the total Other Fish ACL (the percentage is derived from the dogfish contribution to Other Fish OFL). Finally, twelve-year forecasts for each state of nature were calculated based on removals at SPR 77\% for the base model, the level identified by the model as associated with the $\mathrm{SB}_{40 \%}$ target biomass level. Under the low state of nature, the catch at SPR $45 \%$ is projected to reduce the spawning stock output to $34.81 \%$ of the unfished level within 12 years. In all other scenarios covered by the decision table, the spawning output remains above the $40 \%$ target level throughout the 12 -year projection period. The highest level predicted in the 12 year projections is $75.65 \%$, which occurs when the SPR $77 \%$ catch series is applied to the high state of nature. In general, there is little change in stock size over the 12 year projections for any of the combinations of state of nature and removals.

## Research and data needs

In this assessment, several critical assumptions were made based on limited supporting data and research. There are several research and data needs which, if satisfied, could improve the assessment. These research and data needs include:

1) The ageing method for dogfish requires further research. The efforts should be devoted to both improving current ageing techniques based on dogfish spines and developing new
methods using other age structures, such as vertebrae. Double reads of dogfish spines indicate that the method of counting annuli on the unworn portion of dogfish dorsal spines is reasonably precise and has been validated using both oxytetracycline marking and bomb radiocarbon. However, more research is needed on the topic of unreadable annuli that are missing due to wear on the spines of older dogfish. Improving estimates of the statistical uncertainty associated with the age extrapolation methods would also be valuable. Ideally, an alternative method of ageing dogfish that does not rely on the highly uncertainty estimation of ages missing from worn spines may be necessary before age information can be a reliable data source in dogfish stock assessments.
2) The move to full observer coverage in 2011 will improve estimates of dogfish discard for the west coast. However, there is a considerable uncertainty in the historic discard amounts, especially prior to the commencement of the West Coast Groundfish Observer Program. Even more important is the need to improve estimates of discard mortality. Studies of this topic on the east coast used shorter tow durations than those in common fishing operations in these waters, and thus are likely to produce understimates of discard mortality. Data on tow duration could also be incorporated into future models to better refine discard mortality estimates from the trawl fishery.
3) Ongoing research using acoustic tags on dogfish released in central Puget Sound in the summer show regular seasonal movements to coastal waters during the winter and returns to Puget Sound in the subsequent summers. This suggests that biomass sampled by summertime surveys (including those from AFSC, NWFSC, and IPHC used in this analysis) may not be representative of the population size and distribution available to the fishery in other seasons. If the movements are very regular, the surveys may still provide a reliable relative index of abundance, but any differences in movement patterns due to climate or prey availability could impact these indices. Further research into how to account for such movement patterns should be conducted to inform future dogfish stock assessments. Acoustic or satellite tagging of dogfish in coastal waters could provide valuable insight into movement patterns along the coast and benefit future assessments.
4) There are high densities of dogfish close to the U.S.-Canada border, at the mouth of the Strait of Juan de Fuca which connects the outside coastal waters with the inside waters of Puget Sound and the Strait of Georgia. This distribution, combined with potential seasonal or directed movement patterns for dogfish suggest that U.S. and Canada should explore the possibility of a joint stock assessment in future years.

Table ES-6. Decision table of 12-year projections for alternative states of nature defined based on the alternative time series of removals and natural mortality of spiny dogfish and the retrospective analysis.

| Forecast | Year | Totalremovals (mt) | Retrospective run (data from the last three years removed) |  | Low M, low removals |  | Base model |  | High M, high removals |  |

Figure ES-7. Equilibrium yield curve for spiny dogfish from the assessment model (based on Table ES-8).

## 1. Introduction

The spiny dogfish is one of the most widely distributed sharks that inhabit temperate waters in both the Pacific and the Atlantic Oceans. It is a small to medium-sized cartilaginous fish that is generally found inshore areas to offshore depths of at least 1200 m (Ebert 2003). Although frequently observed as solitary individuals, spiny dogfish also form large localized schools of hundreds if not thousands of organisms (Compagno et al. 2005, Ebert 2003, Shepherd et al. 2002).

Taxonomically, it has been problematic as to whether spiny dogfish are monospecific or contains more than one species (Ebert et al. 2010, Verissimo et al. 2010). The North Pacific spiny dogfish was originally described by George Suckley from specimens collected in Puget Sound, and designated as Squalus suckleyi in 1854 (Girard 1854). The original description of the species was brief and did not provide details separating it from the North Atlantic Squalus acanthias, and it was later designated as subspecies of the Squalus acanthias (Ebert et al. 2010, Verissimo et al. 2010).

Recent molecular studies, however, have consistently found strong evidence of genetic divergence between North Pacific (from the Koreas and Japan, northward to Russia, the Bering Sea and the Aleutian Islands, and eastwards in the Gulf of Alaska, British Columbia and Washington south to southern Baja California) and non-North Pacific spiny dogfish (Franks 2006, Ebert et al. 2010, Verissimo et al. 2010, Ward et al. 2007). Also, the most recent taxonomic re-evaluation of the status of the North Pacific Squalus suckleyi combining the use of meristic, morphological and molecular data confirmed this species to be clearly distinct from the widespread Squalus acanthias (Ebert et al. 2010). The genetic divergence between North Pacific and non-North Pacific groups is also consistent with distinct differences in life history characteristics; North Pacific fish mature at an older age, reach larger maximum sizes and live longer than fish occurring outside North Pacific waters.

### 1.1. Distribution, biology and life history

In the North America, spiny dogfish occur from the Gulf of Alaska, with isolated individuals found in the Bering Sea, southward to San Martin Island, in southern Baja California. They are extremely abundant in waters off British Columbia and Washington, but decline in abundance southward along the Oregon and California coasts (Ebert 2003, Ebert et al. 2010).

This assessment focuses on a portion of a population that occurs in coastal waters of the western United States, off Washington, Oregon and California, the area bounded by the U.S.-Canada border on the north and U.S.-Mexico border on the south. The population within this area is treated as a single coast-wide stock. A map depicting the spatial scope of the assessment is shown in Fig. 1.

Spiny dogfish stock included in this assessment likely has interaction and overlap with dogfish observed off British Columbia, and it must be acknowledged that the scope of this assessment
does not capture all of the dynamics which likely bear on the status and trends of the larger, transboundary population.

About 1300 dogfish were tagged along the coast of Washington from 1942-1946, during the period of the strong directed fishery for dogfish. Only 50 of these fish were recaptured and had tags returned (4\%), of which $54 \%$ were recaptured within U.S. coastal waters, while $32 \%$ were recaptured in coastal Canada and $12 \%$ in the inside waters of Puget Sound and the Strait of Georgia. One fish was recaptured in coastal Japanese waters ( 7 years after being tagged). Because many of the releases were close to the U.S.-Canada border, and the fractions do not take into account the relative fishing pressure within each area, this study is of limited use in providing reliable information about dogfish movement rates.

A spatial population dynamics model (Taylor 2008), which included these tagging data (along with much larger tagging experiments conducted in Canada and inside U.S. waters of Puget Sound) estimated movement rates of about 5\% per year between the U.S. coastal sub-population of dogfish and that found along the west coast of Vancouver Island in Canada. The model also estimated movement rates of less than $1 \%$ per year between dogfish the U.S. coastal subpopulation of dogfish and that in the Puget Sound.

These sharks appear to prefer areas in which the water temperature ranges from 5 to $15^{\circ} \mathrm{C}$, often making latitudinal and depth migrations to follow this optimal temperature gradient (Brodeur et al. 2009). There is also evidence of seasonal movement along the coast based on both tagging data and timing of historical fisheries (Ketchen 1986). One estimate of the seasonal movement along the Pacific coast is a North-South shift of about 600 km from winter to summer (Taylor et al. 2009). This seasonal pattern is not as extreme as that found among spiny dogfish in Atlantic waters of the U.S., which are likely due to larger fluctuations in temperature. Dogfish have also been captured in high-seas salmon gillnets across the North Pacific between about $40^{\circ}$ and $50^{\circ} \mathrm{N}$ latitude (Nakano and Nagasawa, 1996), but the extent of these wide-ranging pelagic movements is poorly understood.

The biology and life history of spiny dogfish are relatively well studied (Campana et al. 2009, Di Giacomo et al. 2009, Taylor 2008, Trubizio 2009, Tribuzio et al. 2009, Tribuzio et al. 2010, Vega et al. 2009). This species is an opportunistic feeder that consumes a wide range of prey (whatever is abundant). Schooling pelagic fish, such as herring, make up the majority of its diet. They also feed on invertebrates such as shrimp, crab and squid. In turn, dogfish are preyed upon by larger cod, hake and other spiny dogfish (Beamish et al. 1992, Brodeur et al. 2009, Tanasichuk et al. 1991). Larger species of sharks as well as seals and killer whales also feed on dogfish.

Spiny dogfish have internal fertilization and ovoviviparous development. The internal development takes place over 22-24 months, the longest gestation period known for sharks. The number of pups in each litter ranges between 5 and 15 individuals depending on the size of the female (larger females bearing more pups). The size at birth is generally between 20 and 30 cm for both genders. Male spiny dogfish are reported to grow faster than females, but females reach larger sizes. This species is the latest maturing (with 50\% female maturity reported at 35.5 years)
and longest lived of all elasmobranchs (Cortés 2002, Saunders and McFarlane 1993, Smith et al. 1998, Taylor 2008). Life history traits of spiny dogfish make the species highly susceptible to overfishing and slow to recover from stock depletion since its slow growth, late maturation and low fecundity are directly related to recruitment and spawning stock biomass (Holden 1974, King and McFarlane 2003).

### 1.2. Historical and current fishery

Spiny dogfish in the west coast of the United States have been utilized for almost a thousand years, with those in Puget Sound first used by Native Americans (Bargmann 2009). The exploitation of spiny dogfish in coastal waters, however, started in the $20^{\text {th }}$ century. Even though the history of spiny dogfish utilization on the U.S. west coast included a brief but intense commercial fishery in the 1940s, in general this species is not highly prized and is mostly taken as bycatch in other commercially important fisheries.

Prior to 1936, coastal catches of spiny dogfish were extremely minimal, but in 1936, shortly after it was discovered that livers of spiny dogfish have high level of vitamin A, the large scale fishery for dogfish developed in the Pacific Northwest. Before World War II, Northeast Pacific dogfish livers could not compete with the cheaper and more potent sources of vitamin A from Europe. But when World War II started and European supplies were cut, dogfish shark livers became the major source of vitamin A in the United States, and the spiny dogfish fishery grew rapidly along the Pacific coast. The processed liver oils were used in pharmaceuticals, food processing and animal feed (Bargmann 2009, Ketchen 1986).

During the liver fishery, dogfish were targeted by three major gear groups, including setlines (which are longlines with numerous attached baited hooks spread along the bottom), set nets (many of which were old salmon gill nets and were readily available for the newly developed dogfish fishery) and bottom trawls. The timing of the dogfish liver fishery coincided with the development of bottom trawling in the U.S. Northwest, and though at the onset of the fishery the catches by trawl were low, by the mid-1940s trawling was the dominant type of fishing for dogfish.

In 1945, a sharp decline in spiny dogfish catches began. This decline occurred despite continued strong demand for vitamin A and high prices for dogfish livers, but because of decreased availability of the species in the Northeast Pacific Ocean (Bargmann 2009, Ketchen 1986). In 1950, with the advent of synthetic vitamins, demand for spiny dogfish livers declined and catches in the Northeast Pacific Ocean virtually ended.

Between 1950 and 1974, the landings of spiny dogfish remained minimal. By the late 1950s it was reported that species availability had increased. Also, in the late 1950s-early 1960s, dogfish earned a bad reputation among fishermen. They were blamed for driving off commercially valuable species such as herring and mackerel, while consuming large numbers of them. Spiny dogfish have also been observed biting through nets to get to their fish prey, releasing many of them and damaging fishing gear in the process. They were also reported damaging gear when become entangled in commercial nets. As a result, fishermen were trying to avoid areas with
higher chances of dogfish catches (such as soft bottoms, for example) to prevent encountering dogfish and potentially damaging their gear.

A market opportunity for dogfish opened in mid-1970s. In Europe, spiny dogfish has long been used an inexpensive source of human food, for fish and chips in particular. A decline in European dogfish supply provided an opportunity for developing an export dogfish food fishery in the U.S. Pacific coast. Also, during the late 1970s, shark cartilage started to be used in cancer treatment, and a portion of spiny dogfish catches have since been sold for medical research and treatment (Gregory Lippert, WDFW, pers. com.). As before, three types of gear were involved in catching dogfish (bottom trawl, setlines, and sunken gill nets), but since the mid-1980s catches by gillnets have been minimal.

Spiny dogfish is a common bycatch species, often caught in other fisheries and largely discarded. For instance, it has long been bycaught in the fishery for the coastal population of Pacific hake, which is almost exclusively conducted with mid-water trawls. Large-scale harvesting of Pacific hake in the United States began in 1966, when factory trawlers from the Soviet Union and other countries began targeting this stock. After the 200-mile U.S. Exclusive Economic Zone was declared in 1977, a Joint-Venture fishery was initiated between United States trawlers and Soviet factory trawlers acting as mother-ships (larger, slower ships for fish processing and storage while at sea). By 1989 the U.S. fleet capacity had grown to a level sufficient to harvest the entire quota, and no further foreign fishing was allowed. The Pacific hake fishery is currently $100 \%$ observed by the at-sea hake observer program (A-SHOP) and data on bycatch species, including spiny dogfish, is being routinely collected.

### 1.3. Fisheries off Canada and Alaska

Fisheries for dogfish off the West Coast of Canada have largely paralleled those on the West Coast of the U.S. (Ketchen 1986). They have been characterized by a large fishery targeting dogfish for livers in the 1940s, a lack of markets in the 1950s-1970s, and a smaller fishery in recent decades. Dogfish fisheries in British Columbia include both the inside waters of the Strait of Georgia and coastal waters from extending throughout the coast from the U.S.-Canada border through the Queen Charlotte Islands. In the 1940s, the largest fraction of landings occurred in Northern British Columbia, but in the past two decades, the West Coast of Vancouver Island has made up the largest component of the landings in British Columbia (Ketchen 1986, Taylor 2008). Like the fisheries in U.S. waters, fluctuations in landings in Canada have largely been driven by market forces rather than availability. Although dogfish occur throughout the Gulf of Alaska, there has never been a commercial fishery in Alaskan waters (Tribuzio 2010).

### 1.4. Management history and performance

This is the first time that spiny dogfish has been assessed for the west coast of the United States. This species has been managed under the Other Fish complex since implementation of the Groundfish Fishery Management Plan (FMP) by the Pacific Fishery Management Council. The summary of management history of spiny dogfish and harvest specifications for the Other Fish complex is presented in Table 1.

In 2005, reduction in acceptable biological catch (ABC) was instituted due to removal of the California substock of cabezon from the Other Fish complex. The same year, 50\% precautionary
optimum yield ( OY ) reduction was implemented to accommodate uncertainty associated with managing unassessed stocks. In 2006, trip limit for spiny dogfish was imposed for U.S. west coast waters which varied between 45 mt and 91 mt per two months for all gears. In 2009, another ABC reduction was implemented due to removal of longnose skate from the Other Fish complex, 50\% OY reduction was maintained.

In 2011, reduction in overfishing limnit (OFL) was implemented due to removal of the Oregon substock of cabezon from the Other Fish complex. 50\% precautionary reduction to the annual catch limit (ACL) was maintained, however, a scientific uncertainty buffer was specified as an ABC of 7,742 mt under the Amendment 23 framework.

## 2. Assessment data

The data used in the assessment are summarized in Figure 2. These data include both fisherydependent and fishery-independent sources.

### 2.1. Fishery-dependent data

The fishery removals were divided in the assessment among eight fleets. Six of them are catch fleets, including bottom trawl, midwater trawl, hook-and-line, other gears (primarily nets), at-sea hake fishery bycatch, and recreational fishery. Bottom and midwater trawls were treated separately to reflect differences in gear selectivity since length frequencies of catch landed by the midwater trawl were dominated by smaller size fish than those of bottom trawl.

Spiny dogfish are often discarded when caught. Two out of six catch fleets (bottom trawl and hook-and-line) represent landed catch only, and not the total removals. Two discard fleets, therefore, were created to represent discard in bottom trawl and hook-and-line fleets. The amounts of dogfish discarded were estimated externally to the model, and time series of dead discard (discard amount by year multiplied by discard mortality) were included in the model the same way as catch for other fleets.

Removals of spiny dogfish were reconstructed back to 1916, assuming a zero equilibrium catch in 1915. The reconstructed time series of spiny dogfish removals by fleet are presented in Fig. 3 and Table 2. Figure 4 shows the spatial distribution of spiny dogfish catch, as observed by the West Coast Groundfish Observer Program between 2002 and 2010.

### 2.1.1. Commercial landings

Estimates of recent commercial landings of spiny dogfish (between 1981 and 2010) were obtained from the Pacific Fisheries Information Network (PacFIN), a regional fisheries database that manages fishery-dependent information in cooperation with west coast state agencies and NOAA Fisheries (www.pacfin.com). PacFIN reports both targeted catch and retained bycatch. Catch data were extracted by gear type and then combined into the fishing fleets used in the assessment.

Time series of historical (pre-1981) landings by fleet were reconstructed for each state separately and then combined to produce annual coast-wide estimates. Commercial landings summarized by fleet are shown in Fig. 5. The methods used to reconstruct historical landings are described below.

### 2.1.1.1. Washington

The vast majority of spiny dogfish commercial landings were made in Washington (Fig. 6). The records of spiny dogfish landings from the coastal waters of Washington were available since 1939. Landings between 1939 and 1940 were estimated from the 1939 and 1941 issues of Bulletins of Washington Department of Fisheries (which reported the total Washington landings, Puget Sound and the coastal area together) along with early catch records from Puget Sound provided by WDFW (Gregory Lippert, WDFW, pers. com.). The differences between values from the two sources gave the 1939 and 1940 estimates for coastal landings.

Records of spiny dogfish landings from 1941 were recently compiled by Bargmann (2009) based on earlier publications by Alverson and Stansby (1963) and Ketchen (1986). Between 1941 and 1956, it was a common practice not to land dogfish in the round (with processors removing the livers in their plants), but to land only the dogfish livers and discard the carcasses at sea (Bergman, 2003). To convert the liver weight to round weight, a variety of expansion factors (ranging between 8.33 and 10) were developed for different areas and periods (Averson and Stanley 1963, Holland 1957, Ketchen 1986). Bargmann (2009) reports dogfish landings in round weight. In Bargmann (2009), however, landings are not attributed to specific gears. Therefore, we used the Fisheries Statistics of the United States (which reports dogfish landings by gear, but in liver weight) to calculate the proportions of different gear contribution and applied these proportions to the Bargmann (2009) time series. The Fisheries Statistics of United States were available only through 1977. For 1978-1980 (the last three years of the pre-PacFIN era), we used 1975-1980 average gear proportions reported in Bargmann (2009) to apportion Washington dogfish landings time series among gears.

### 2.1.1.2. Oregon

Oregon records of dogfish landings go back to 1940. Historically, spiny dogfish was reported in Oregon as both "Grayfish" and "Shark, Grayfish." Time series of Oregon historical landings of spiny dogfish were provided by the Oregon Department of Fish and Wildlife (ODFW), which in collaboration with Northwest Fisheries Science Center (NWFSC), conducted a reconstruction of historical groundfish landings in Oregon (Karnowski et al. 2011).

A variety of data sources were used to reconstruct historical landings of spiny dogfish, including Oregon Department of Fish and Wildlife's Pounds and Value reports derived from the Oregon fish ticket (landing receipt) line data (1969-1989), Fisheries Statistics of the United States (19271977), Fisheries statistics of Oregon (Cleaver 1951, Smith 1956), Reports of the Technical SubCommittee of the International Trawl Fishery Committee (now the Canada-U.S. Groundfish Committee) (1942-1975) and many others.

It appears that (unlike Washington) Oregon landings of spiny dogfish sharks in the Fisheries Statistics in the United States were reported as round weights. The footnotes in the Fisheries Statistics of the United States indicate that although most carcasses of spiny dogfish prior to 1956 were discarded at sea, the poundage reported includes the total volume of "grayfish" caught. The Oregon records of spiny dogfish landings in the Fisheries Statistics of the United States were consistent with Bargmann (2009), who provided the total landed catch of spiny dogfish in Oregon as well.

A small portion of spiny dogfish in Oregon was also landed within the Animal Food market category, a portion of various fish that went to feed mink for the fur trade. Prior to World War II, mink food mainly consisted of red meat, but when meat became increasingly difficult and expensive to obtain, Oregon mink ranchers started to use fish fillet carcasses as a protein source for mink (Niska 1969). When the demand for fish fillet carcasses exceeded the supply, whole fish were specifically targeted to supplement the carcasses (Niska 1969). Spiny dogfish landings within Animal Food market category were reconstructed by Karnowski et al. (2011) back to 1942 from Jones and Harry (1961), Niska (1969), reports of the Technical Sub-Committee of the International Trawl Fishery Committee, Fisheries Statistics of the United States and ODFW Pounds and Values reports. Spiny dogfish was reported in the Animal Food between 1942 and 1979, and we added the estimated values by year to bottom trawl landings since Animal Food was landed exclusively by bottom trawl.

### 2.1.1.3. California

Time series of California gear-specific landings of spiny dogfish during the most recent "historical" period (between 1969 and 1980) were available from the California Cooperative Groundfish Survey (CalCOM) database.

Earlier landing records (between 1931 and 1968) were recently reconstructed by the Southwest Fisheries Science Center (SWFSC) (Ralston et al. 2010), but as is the case with Washington, these landings were not appointed to specific gear. To apportion early historical landings among gears, we applied Oregon dogfish gear proportions by year between 1940 and 1968 to California dogfish landings. Between 1931 and 1939, we assumed the gear compositions to be an average of the earliest three years of Oregon gear compositions.

### 2.1.2. Recreational removals

Recreational catches contributed a relatively small amount to overall removals of spiny dogfish (Fig. 3). Unlike commercial catches, the vast majority of recreational removals occurred in California (Fig. 7). The data on recreational removals of spiny dogfish were obtained from RecFIN (www.recfin.com), a regional source of recreational data managed by the Pacific States Marine Fisheries Commission (PSMFC) and directly from state agencies. RecFIN reports catches by fishing mode, including shore modes (man-made, beach and bank) and boat modes (party and charter boats, private and rental boats). Essentially, all the spiny dogfish recreational catches came from the boat modes (Fig. 8), and, therefore, all recreational removals in the assessment were combined and reported as one fishery. Recreational catches were reconstructed by state, and the approaches used to derive recreational catches are described below.

### 2.1.2.1. Washington

The records of spiny dogfish recreational catches in the coastal waters of Washington go back to 1980. No mention of a coastal recreational harvest of dogfish was found prior to that. Dogfish are encountered sporadically in the ocean fisheries, and are almost always released ( $96 \%$ average release rate). The total estimated removals has been minimal (on average 0.4 mt per year since 1980). Information on recreational catches has been collected by both state (WDFW Ocean Sampling Program (OSP)) and federal (Marine Recreational Fisheries Statistic Survey (MRFSS)) programs. From 1980-2003 (excluding the years 1990-1992), the MRFSS program provided
effort information from a random-digit dialing protocol and catch/trip information from intercept interviews. OSP has estimated total ocean recreational catch and effort by boat type, port and catch area since the 1960s (with the spiny dogfish information available since 1990). Boat trip sampling is conducted randomly by OSP to generate catch estimates for most ocean-caught species, including sharks. The OSP reports removals of spiny dogfish within the "Shark/Skate" catch category, but anecdotal evidence suggests that the majority of this category is comprised of spiny dogfish (with a small number of blue and sixgill sharks and skates). Since 2002 release data on all marine fish by species have also been estimated within OSP from angler interviews.

MRFSS data were obtained via the RecFIN database and OSP data were received directly from WDFW (Wendy Beeghley, pers. com.). From 1995 to present, the RecFIN database contains catch estimates generated by the OSP while prior to 1995 it is mostly MRFSS-generated catch estimates. WDFW expressed several concerns with MRFSS dogfish data. Particularly, between 1980 and 1986 and in 1989, MRFSS focused on bottom fish effort alone (and not on salmon effort), and dogfish caught and released by salmon anglers were not included in the estimate of recreational removals. Between 1995 and 2003, even though all anglers were interviewed, there have been concerns with the allocation of sampling effort between the coast and the Puget Sound. Therefore, we used data collected by OSP where possible (1990-2010) and MRFSS data when OSP data were not available (1980-1989).

To estimate the proportion of spiny dogfish within the OSP "Shark/Skate" category, we compared MRFSS removals of spiny dogfish relative to removals of other sharks and skates. We found that no other sharks and skates were reported by MRFSS, and, therefore, assumed removals of OSP "Shark/Skate" to be representative of spiny dogfish removals.

To estimate the amount of released fish in OSP data for the 1990-2001 period (prior to when OSP started to sample released catch), we calculated an average release rate from OSP data for 2002-2010 period and applied this rate to the 1990-2001 retained catch data. Finally, to estimate the proportion of dead discard in OSP data on released catch (this type of information has never been collected by OSP), we applied the ratio of dead discard to total discard from MRFSS to the entire OSP data series (1990-2010).

### 2.1.2.2. Oregon

The records of Oregon recreational catch of spiny dogfish go back to 1979, and the amount of reported removals was minimal through the entire time series (with the average of 0.1 mt ). The information on Oregon recreational catches was collected by the Oregon Ocean Recreational Boat Survey (ORBS) (1979- present) and by the federal MRFSS program (between 1980 and 2003, excluding the years 1990-1992).

The MRFSS data and the most recent ORBS data (2004 forward) were obtained via the RecFIN database. The early ORBS data (1979-2000) were provided by ODFW (Mark Freeman, pers. com.), but these early data included only the number of fish landed, neither discard nor average fish weights were reported. RecFIN provides data on the total amount of fish landed (catch type A) as well as dead (catch type B1) and alive (catch type B2) discard. No dead discard was
reported for spiny dogfish (but there were records of alive discard); therefore Oregon recreation removals were equal to type A catch.

In the assessment, we used ORBS data (received from ODFW) for the period between 1979 and 2000 and the data from RecFIN for the period between 2001 and 2010. Since ORBS catch data reported the number of fish retained, we converted these numbers into weight using average fish weight from RecFIN to estimate the time series of Oregon removals in metric tons by year.

### 2.1.2.3. California

California catches comprised the largest portion of spiny dogfish recreation removal with an average of 18 mt by year since 1981. Information on recreational catches has been collected by both the California Recreational Fisheries Survey (CRFS) and federal MRFSS programs. MRFSS program ended in 2003. In 2004, the California Department of Fish and Game (CDFG), in cooperation with the Pacific States Marine Fisheries Commission (PSMFC), started the California Recreational Fisheries Survey (CRFS) program to replace the MRFSS sampling program in California. This program aims to increase sampling effort for better catch and effort estimation, to increase spatial resolution of catches, and to identify targeted species.

The data from both programs are available via the RecFIN database, and these data were used to reconstruct time series of California recreational dogfish removals (retained catch plus dead discard, A+B1). Removal in 1980 ( 93 mt ) was found to be much higher than catches in other years. The RecFIN removals for other species in the 1980 were also found to be higher than those in other years. Anecdotal evidence suggests that effort during 1980, the first year of the MRFSS program, was likely poorly estimated, and therefore, the 1980 data point was excluded from the California time series of recreation catches. The average value of 1989 and 1993 was used for 1990-1992, the years when MRFSS data were not available.

Limited information on historical (prior to 1980) recreation catches in California is available from annual reports from the Commercial Passenger Fishing Vessel (CPFV) sampling program, but none of those contained records of spiny dogfish catches.

### 2.1.3. Bycatch in Pacific hake fishery

The annual amounts of spiny dogfish bycatch in the Pacific hake fishery are available from the North Pacific Database Program (NORPAC). That time series cover the period between 1977 and 2010 and include catches removed by foreign and domestic fisheries as well as those obtained during the time of Joint Ventures (JV).

In recent years (1991-2010) virtually 100\% of hauls in the hake fishery are sampled for catch and species composition by the at-sea hake observer program (A-SHOP), and the total catch (retained and discarded) are estimated for both targeted and bycatch species for each haul. To derive the total amount of spiny dogfish bycatch by year, we simply summed the estimated catch in every haul within a year.

Prior to 1991, not every haul was sampled. For these years, NORPAC provided an expansion factor (one for each year), which is a ratio of total hauls to sampled hauls. We used these yearspecific expansion factors to estimate the total amount of spiny dogfish caught by multiplying
the amount of total catch in sampled hauls by the expansion factor. There were some records of dogfish data for years 1975-1976, but data in both years appear to be incomplete (in 1975, for example, there are only 5 records on spiny dogfish).

### 2.1.4. Discard

When not targeted, spiny dogfish is still common bycatch in fisheries for other commercially valuable species and is often discarded. A lack of market was identified as the main reason for discarding dogfish (Rogers and Pikitch 1992). Since 2002, the West Coast Groundfish Observer Program (WCGOP) has collected bycatch and discard information on board fishing vessels in the trawl and fixed gear fleets, along the entire coast and produced total fishing mortality estimates for all species observed. Prior to 2002, there were two studies of bycatch and discard in the trawl fishery, including the Enhanced Data Collection Project (EDCP) and the Pikitch study (Pikitch 1987, Pikitch et al. 1988).

The EDCP (administered by the ODFW) collected data on bycatch and discard of groundfish species off the Oregon coast from late 1995 to early 1999 (Sampson, pers.com.). The project had limited spatial coverage (Oregon waters only) and spiny dogfish was reported within the "Shark" category (no species composition samples were collected). Also, the EDCP primarily focused on the deepwater complex, or "DTS" (Dover sole, thornyheads and sablefish), and since spiny dogfish is a mostly shelf species, the project estimates of "Shark" discard rates might be not representative of the overall trawl fleet discard. For these reasons, the EDCP data were not included in the assessment.

The Pikitch study (Pikitch 1987, Pikitch et al. 1988) was conducted between 1985 and 1987, primarily within the Columbia INPFC area (Rogers and Pikitch 1992). Participation in the study was voluntary and included vessels using bottom, midwater and shrimp trawl gears. Discard rates were estimated using observations of retained and discarded catch of spiny dogfish. Because of the limited spatial coverage, the estimated discard rates from the Pikitch study were used as points for comparison with discard fleet time series, estimated from WCGOP data. The WCGOP provided the time series of total mortality estimates in trawl and hook-and-line fleets between 2002 and 2009. The data included landings and discards of spiny dogfish (summed to total mortality, and aggregated by year and fleet). We calculated discard ratios of spiny dogfish relative to spiny dogfish encountered catch. We then explored a number of variables (and their combinations) as possible predictors of spiny dogfish discard, using linear regression analysis.

Coast-wide landings of spiny dogfish were found to be the most significant predictor of dogfish discard rates ( $\mathrm{R}^{2}=0.92, p<0.0001$ ), with higher discard associated with smaller landings (Fig. 9). A similar linear relationship was found for hook-and-line gear, where spiny dogfish landed catch was the best examined predictor of discard ratios $\left(\mathrm{R}^{2}=0.65, p=0.0002\right.$, Fig. 10). No other relationship examined was statistically significant ( $p>0.05$ ). Specifically, the following predictors of spiny dogfish discard rates were explored, but rejected for both trawl and fixed gear ( $\mathrm{R}^{2}$ associated with regression for each predictor is also provided):

- Landings of all groundfish species. A regression resulted in $\mathrm{R}^{2}$ of 0.05 when landings of groundfish species included those of Pacific hake, and in $\mathrm{R}^{2}$ of 0.07 when hake landings were excluded.
- Landings of subsets of species that co-occur with spiny dogfish. There have been two studies which examined assemblages of groundfish species caught together in the groundfish trawl fishery on the U.S. West Coast. Rogers and Pikitch (1992) employed several clustering techniques to analyze data from the Pikitch study and define consistent assemblages of species. Heery and Cope (pers.com.) did the same, but using 2002-2008 WCGOP data. Both studies yielded similar results of no consistent or strong associations between spiny dogfish and other species, even though dogfish was a part (but in small amounts) of each of the identified assemblages. One of the clustering methods used by Rogers and Pikitch (1992) identified a dogfish assemblage (in which most of the catch was spiny dogfish), but these results were not consistent with other clustering techniques used. Cope and Haltuch (pers.com.) used two clustering methods to identify groundfish assemblages from fishery-independent data collected by the AFSC triennial and NWFSC shelf-slope surveys (both of these surveys were used in this assessment, Section 2.2). Spiny dogfish was found to be a part of two assemblages: (A) the "dover-hake-rexslender sole" complex, and (B) the "English-sanddab-petrale" complex, even though it was not among "core" assemblage species consistently caught together. We used all the species from (A) and (B) assemblages identified by Cope and Haltuch and their combinations to explore possible relationships between the landings of these subsets of species and spiny dogfish discard. Those regressions did not yield $\mathrm{R}^{2}$ values larger than 0.2 .
- Price per pound of spiny dogfish. The regression resulted in an $R^{2}$ of 0.03 , and $R^{2}$ value did not change when simple average or catch-weighted price per pound was used.

In addition, we explored patterns of dogfish discard by state and season, but no specific patterns were evident, other than the ones described above.

We used the relationships between spiny dogfish landings and discard ratios derived from the WCGOP data to reconstruct discard amounts in bottom trawl and hook-and-line fleets back to 1950, when the vitamin A fishery ended. Prior to 1950, it was assumed that all fish were retained. We compared our estimated trawl discard ratios for 1986 and 1987 with those calculated from the Pikitch study. Both estimates were very close, with the discard rate just above $90 \%$ (calculated as a ratio of dogfish discarded catch to total encountered catch of dogfish).

Given the lack of historical discard data and uncertainty in discard estimates, we conducted a number of sensitivity analyses with alternative assumptions regarding discard of spiny dogfish, including one with a minimum threshold applied for historical discard (i.e. discard was not allowed to drop below a specified amount). The uncertainty in discard was also explored when the entire time series of removals (landings and discard) were either increased or decreased (the details are provided in Section 7.1).

For at-sea hake fishery, we had data on the total removals of spiny dogfish (retained and discarded catch together), and therefore, there was no need to estimate time series of discard separately. Also, the discard mortality in at-sea hake bycatch fleet was assumed to be $100 \%$, mostly due to long duration of hauls and large amount of fish brought on board. Figure 11 shows a snapshot of spiny dogfish bycatch within the at-sea hake fishery to support the assumption of $100 \%$ discard morality for this fleet.

There have been no studies performed on discard mortality of spiny dogfish in the Northeast Pacific Ocean for neither bottom trawl nor hook-and line fleet. In spiny dogfish assessments conducted elsewhere, different values of discard mortality were assumed, from $5 \%$ to $50 \%$ for bottom trawl and from 6\% to 75\% for hook-and-line gears, but all sources noted considerable uncertainty in these estimates. We assumed trawl discard mortality to be 100\% (analogous to midwater trawl targeting Pacific hake), and hook-and-line discard mortality to be $50 \%$. Given the uncertainty in assumed values, alternative assumptions regarding discard mortality in both fleets were explored via sensitivity analyses (see Section 7.1.3).

For the midwater and other gear fleets, no discard information was ever collected. The landings in both fleets were minimal, except for the period of the vitamin A fishery and in the beginning of food fish fishery in the 1970s when other gear catches increased. We assumed discard for these two fleets to be zero, recognizing that this might be an underestimation; the uncertainty in commercial removals were explored through the sensitivity analyses (see Section 7.1.1).

### 2.1.5. Fishery biological data

Biological information for commercial landings was obtained from PacFIN. Washington data was also received directly from WDFW (Theresa Tsou, pers. com.). Most of the biological samples of landings were collected by port samplers at the dock. A portion of biological samples (on discarded dogfish) were collected by observers at sea during the period of an Exempted Fishing Permit (EFP) fishery in 2003 and 2004, issued by the NMFS to the WDFW to measure the bycatch rates of canary rockfish and yelloweye rockfish in the dogfish fishery.

The biological data from the Pacific hake fishery collected by the A-SHOP were available through NORPAC. Recreational fishery data were obtained via the RecFIN database. Finally, biological information for trawl and hook-and-line discard was provided by WCGOP.

The biological data included sex, length and age data on individual organisms (amount varied by data source, Fig. 2). When lengths were measured as fork lengths (the case of commercial landings and A-SHOP data), measurements were converted to total "natural" (measured without extending the tail) lengths using the relationships estimated by Cheng (WDFW, pers. com.).

### 2.1.5.1. Length composition data

The summary of sampling efforts by fleet, state and year which were used to generate length frequency distributions are shown in Table 3. We used only randomly collected samples. Most of the length data were reported for females and males separately, except for recreational and hook-and-line discard data collected by EFP observers that was reported for both genders combined.

Majority of the length samples from landed catch were collected in Washington, but since the vast majority of spiny dogfish landings were made in Washington (Fig. 6), it was considered appropriate to use mostly Washington data to represent coast-wide fleets.

The initial input sample sizes ( $N_{\text {input }}$ ) for length frequency distributions by year were calculated as a function of the number of trips and number of fish sampled using the method developed by Stewart and Miller (NWFSC):

$$
\begin{array}{ll}
N_{\text {input }}=N_{\text {trips }}+0.138 N_{\text {fish }} & \text { when } \frac{N_{\text {fish }}}{N_{\text {trips }}}<44 \\
N_{\text {input }}=7.06 N_{\text {trips }} & \text { when } \frac{N_{\text {fish }}}{N_{\text {trips }}} \geq 44
\end{array}
$$

The method is based on analysis of the input and model derived effective sample sizes from west coast groundfish stock assessments. A piece-wise linear regression was used to estimate the increase in effective sample size per sample based on fish-per-sample and the maximum effective sample size for large numbers of individual fish (Stewart and Miller, pers.com.).

### 2.1.5.2. Age data

Unlike teleost fish, dogfish lacks hard structures commonly used for age determination (Ketchen 1975, Gallagher and Nolan 1999), and the traditional method of estimating the age of dogfish has been to count the growth bands visible on the surface of their second dorsal fin spine (Ketchen 1975, Beamish and McFarlane 1987). These bands are deposited annually, as validated using recaptures of tagged dogfish injected with oxytetracycline (McFarlane and Beamish 1987), and bomb radiocarbon studies (Campana et al. 2006).

The dorsal spines are, however, subject to wear, and the majority of spines are believed to have included some annuli that can no longer be counted. A method of accounting for these missing ages was proposed by Ketchen (1975). The relationship between spine diameter at the least readable point and the number of missing ages could be approximated by the relationship between the base diameter and number of ages counted on the spines of younger dogfish that were determined to be unworn. Ketchen (1975) modeled this relationship using the equation:

$$
Y=\alpha X^{\beta}
$$

where $X$ is the spine base diameter in millimeters, $Y$ is the estimated age in years from conception, and $\alpha$ and $\beta$ are constant coefficients.

Another method of extrapolating the number of missing ages on worn spines has recently been proposed (Cheng 2011). This new approach assumes that the spine diameter grows according to a von Bertalanffy growth curve and estimates the number of missing ages as a random effect in a nonlinear mixed effects model fit to 3 diameter measurements along the unworn part of the dorsal spine. The assumption of growth according to the von Bertalanffy function is reasonable given a strong correlation ( $\rho=0.95$ ) between spine base diameter and fish total length.
Furthermore, the use of multiple measurements along the spine and accounting for individual
variability in spine growth are valuable additions to account for in calculating the number of missing ages.

For this assessment, age estimates for both the older Ketchen (1975) method (hereafter described as "Age Method 1") and the newer Cheng (2011) method (hereafter described as "Age Method 2") were considered. The age data were provided by WDFW for 4843 fish sampled including 4252 samples from commercial fisheries starting in 2003 and 591 from the 2010 NWFSC shelfslope survey. Ages estimated using the newer, Age Method 2, were provided by WDFW, along with measurements of spine diameter and annuli counts, which were then used to apply Age Method 1 for comparison.

The calculation of parameters for Age Method 1 was based on 513 unworn spines. This included 260 samples from commercial fisheries and 253 from the 2010 NWFSC shelf-slope survey. Only the first readings were used (no double reads). The resulting parameters estimates were $\alpha=$ 2.1636, $\beta=1.4564$ for females, and $\alpha=2.1353, \beta=1.4264$ for males. Fits of the estimated relationship to the measurements of unworn spines are shown in Fig. 12.

The two ageing methods produced very different age estimates for the largest fish when missing ages were extrapolated. For the 1043 fish with length greater than 80 cm , the mean difference between ages from Age Method 1 and Age Method 2 was 12.4 years.

The patterns of length at age also show strong differences between ageing methods. The pattern of male length at age for ages calculated using Age Method 1 is more consistent between worn and unworn spines than Method 2 (Figs. 13-15). For example, of the 205 age samples from male dogfish with length between 45 and 50 cm , the mean age of the 70 fish with unworn spines was 9.3 years, whereas the mean estimated age associated with the 135 worn spines was 11.3 years when estimated by Age Method 1 and 17.2 years when extrapolated by Age Method 2.

It is expected that there be a correlation between age and degree of wear, so the older fish at a given size would be expected to have more worn spines. However, a contributing factor to the large difference in ages between two methods is the pattern that the number of missing ages calculated using Age Method 2 is at minimum 3 years (which produces a 3-year gap in estimated ages at the outset between those determined from the unworn spines and those with extrapolated annuli, Fig. 13), as opposed to Method 1, where the spine diameter at the last readable point in some cases estimated to be narrower than the diameter at birth and thus no annuli are estimated as missing (Fig. 12).

The pattern of female length at age does not appear to follow von Bertalanffy function well for either age method (Fig. 14), with the distribution of age and length for the largest fish less consistent with that of younger fish when Age Method 1 is applied.

Although in the assessment, we explored a variety of ways to utilize age data (including, downweighting age data to 0.1 in the likelihood compared to values of 1.0 for the other data source), the base model does not include age data, since some aspects of both methods raised questions about the ageing process, and further research into these methods would be valuable.

Furthermore, both methods depend on measurements of spine diameter, which are highly correlated with total length of fish, and therefore, any estimated ages, which include an extrapolation for missing ages, are not independent from the length measurements.

### 2.2. Fishery-independent data

The assessment utilizes fishery-independent data from four bottom trawl surveys conducted on the continental shelf and slope of the Northeast Pacific Ocean by NOAA Fisheries' Northwest (NWFSC) and Alaska Fisheries Science Centers (AFSC), including: 1) AFSC triennial shelf survey, 2) AFSC slope survey, 3) NWFSC shelf-slope survey, and 4) NWFSC slope survey, as well as one hook-and-line survey conducted by the International Pacific Halibut Commission (IPHC). Details on latitudinal and depth coverage of trawl surveys by year are presented in Table 4.

The AFSC triennial survey was conducted every third year between 1977 and 2004 (in 2004 this survey was conducted by the NWFSC using the same protocols). Survey methods are most recently described in Weinberg et al. (2002). The basic design was a series of equally spaced transects from which searches for tows in a specific depth range were initiated. Over the years, survey area varied in depth and latitudinal range (Table 4). Prior to 1995, the depth range was limited to $366 \mathrm{~m}(200 \mathrm{fm}$ ) and the surveyed area included four INPFC areas (Monterey, Eureka, Columbia and U.S. Vancouver). After 1995, the depth coverage was expanded to 500 m (275 fm ) and the latitudinal range included not only four INPFC areas covered by the earlier years, but also part of the Conception area with a southern border of $34^{\circ} 50^{\prime} \mathrm{N}$. For all years, except 1977, the shallower surveyed depth was $55 \mathrm{~m}(30 \mathrm{fm})$; in 1977 no tows were conducted shallower than $91 \mathrm{~m}(50 \mathrm{fm})$. Because of the differences in depth surveyed in 1977 and the large number of "water hauls", when the trawl footrope failed to maintain contact with the bottom (Zimmermann et al. 2001) the data from the 1977 survey were not used in the assessment. The tows conducted in Canadian and Mexican waters were also excluded.

In the assessment, the triennial survey was divided into two periods - between 1980 and 1992, and between 1995 and 2004; separate catchability coefficients $(Q)$ were estimated for each time period. This was done to account for differences in spatial coverage before and after 1995 (Table 4) and to reflect a change in the timing of the survey. In its early years, the survey was conducted from mid-summer to early fall, but from 1995 on, the survey began at least a full month earlier (Fig. 16).

The AFSC slope survey was initiated in 1984. The survey methods are described in Lauth (2000). Prior to 1997, the survey was conducted in different latitudinal ranges each year (Table 4). In this assessment, only data from 1997, 1999, 2000 and 2001 were used - these years were consistent in latitudinal range (from $34^{\circ} 30^{\prime} \mathrm{N}$. latitude to the U.S.-Canada border) and depth coverage (183-1280 m; 100-700 fm).

The NWFSC shelf-slope survey has been conducted annually since 2003, and the data between 2003 and 2010 were used in the assessment. The survey consistently covered depths between 55 and $1280 \mathrm{~m}(30$ and 700 fm$)$ and the latitudinal range between $32^{\circ} 34^{\prime}$ and $48^{\circ} 22^{\prime} \mathrm{N}$. latitude, the extent of all five INPFC areas on the U.S. west coast (Table 4). The survey is based on a
random-grid design, and four industry chartered vessels per year are assigned an approximately equal number of randomly selected grid cells. The survey is conducted from late May to early October, and is divided into two passes, with two vessels operating during each pass. The survey methods are described in detail in Keller et al. (2007).

The NWFSC slope survey was conducted annually from 1999 to 2002 (Keller et al. 2007). The surveyed area ranged between $34^{\circ} 50^{\prime}$ and $48^{\circ} 07^{\prime} \mathrm{N}$. latitude, encompassing the U.S. Vancouver, Columbia, Eureka, Monterey INPFC areas, and a portion of the Conception, and consistently covered depths from 100 to 700 fm (183-1280 m) (Table 4).

The IPHC has conducted an annual longline survey for Pacific halibut off the coast of Oregon and Washington since 1997 (no surveys were performed in 1998 or 2000). Beginning in 1999, this has been a fixed station design, with roughly 1,800 hooks deployed at 84 locations each year (station locations differed in 1997, and are therefore not comparable with subsequent surveys). Dogfish catch has historically occurred at many of the 84 stations in the design (Fig. 17). Dogfish bycatch has been recorded during this survey on the first 20 hooks of each 100-hook skate (one skate is the basic unit of longline survey gear). The gear used to conduct the survey, while designed to efficiently sample Pacific halibut, is similar to longline gear that has been used in some targeted dogfish fisheries. Some variability in exact sampling location is practically unavoidable, and leeway is given in the IPHC methods to center the set on the target coordinates while allowing wind and currents to dictate the actual direction in which the gear is deployed. This can result in different habitats being accessed at each fixed deployment location across years.

### 2.2.1. Survey indices

Indices of abundance for each of the four bottom trawl surveys were derived using a generalized linear mixed model (GLMM), including vessel-specific differences in catchability (via inclusion of random effects), for each survey time series following the methods of Helser et al. (2004). This assessment's GLMM indices were generated using the same basic method, but reprogrammed by John Wallace (NWFSC, pers. com.) utilizing a package which uses OpenBUGS (http://www.openbugs.info) (an offshoot of WinBUGS) running under the statistical programming language R. The Delta-GLMM approach explicitly models both the zero and nonzero catches and allows for skewness in the distribution of catch rates through the use of a gamma or lognormal error structure. Index uncertainty is estimated using a Markov Chain Monte Carlo (MCMC) approach as described in Helser et al. (2007). The survey indices and standard error of the natural log of biomass estimated in this assessment are shown in Table 5.

The bottom trawl survey indices (Table 5) show significant changes in abundance throughout the survey time series, which are not consistent with what is known about the dynamics of $K$ strategy organisms, such as spiny dogfish. Such fish exhibit slow growth, late maturation, a long gestation period and low fecundity. A pattern of high variability in abundance from year to year was especially pronounced for the NWFSC shelf-slope survey (Table 5), for which abundance of spiny dogfish was shown to decrease more than in half in 2004 and then again in 2005. The most probable explanation for high variability in index estimate by year is that it reflects patchiness in the spatial distribution of spiny dogfish, when survey can encounter either a large school, only
diffusely scattered individuals, or none at all ("zero tows"). The spiny dogfish often forms large schools, which supports the hypothesis of patchy distribution, and extreme variation in density of fish (among hauls) encountered by a survey.

In the NWFSC shelf-slope survey, most of the positive dogfish hauls occurred shallower than $183 \mathrm{~m}(100 \mathrm{fm})$ as shown in Fig. 18. The average amount of spiny dogfish in a positive haul was 45 kg , and $95 \%$ of positive hauls were less than 85 kg . However, a few hauls had between 4,000 and $16,585 \mathrm{~kg}$ of dogfish (Fig. 19), and the estimates for survey index in years with those large hauls are the highest (Fig. 19, Table 5). This indicates that the gamma distribution used within the GLMM to estimate survey indices cannot adequately describe abundance of schooling fish such as spiny dogfish. Currently, a research is under way to develop alternative error distributions for GLMM approach, for example applying mixture distribution methods (Thorson et al., 2011) to account for schooling and solitary individuals. However, since these techniques are not currently available, additional variance was estimated for all trawl surveys used in the model to account for patchiness in spiny dogfish distribution and highly variable catches.

The IPHC longline survey catch data were standardized using a Generalized Linear Model (GLM) with binomial error structure. Catch-per-hook was modeled, rather than catch per station due to the variability in the number of hooks deployed and observed each year. The binomial error structure was considered logical, given the binary nature of capturing (or not) a dogfish on each longline hook. The modeling approach is identical to that used in recent yelloweye rockfish assessments (Stewart et al. 2009), which includes a more detailed description of survey design and methods.

The IPHC index trends are fairly stable over the full time series (1999 through 2010). This index is both the longest time series available for dogfish, and is also less subject to the influence of a few large tows that appear to drive some of the variability in the trawl surveys described above. Additional variance was added to IPHC survey as well, but it was fixed at a relatively low level of 0.1 , and the alternative assumptions regarding the value of additional variance added to this survey was explored via sensitivity analysis (see Section 7.1.5).

### 2.2.2. Survey biological data

Biological data were collected within three trawl surveys, including AFSC triennial and slope surveys and NWFCS shelf-slope survey. No biological samples were available for the NWFSC slope and IPHC surveys. The available biological data included sex, length, age and weight of individual fish (amount varied by survey, Fig. 2). The length data were used to develop length frequency distributions and weights, sampled within NWFSC shelf-slope survey, were used to estimate Weight-Length relationship by gender (Section 2.3.4). No ages were explicitly used in the model (see Section 2.1.5.2 for details).

### 2.2.2.1. Length composition data

Length frequency distributions were derived by year for three out of five surveys (for which data were available). A summary of sampling efforts by survey and year which were used to generate length frequency distributions are shown in Table 6. When a large proportion of the length data were recorded as unidentified sex, the sexes were combined (as in the case of the 1998 AFSC triennial survey and 1998 AFSC slope survey). The 1986 and 1993 length data from AFSC
triennial survey were not used in the assessment, since very few fish were samples (for each survey) and all of them were collected in a single haul.

The initial input sample sizes for the survey length frequency distribution data were calculated as a function of both the number of fish and number of tows sampled using the method developed by Stewart and Miller (NWFSC, pers.com.):

$$
\begin{array}{ll}
N_{\text {input }}=N_{\text {tows }}+0.0707 N_{\text {fish }} & \text { when } \frac{N_{\text {fish }}}{N_{\text {trips }}}<55 \\
N_{\text {input }}=4.89 N_{\text {tows }} & \text { when } \frac{N_{\text {fish }}}{N_{\text {tows }}} \geq 55
\end{array}
$$

### 2.3. Biological parameters

Several biological parameters used in the assessment were fixed at the externally estimated values, which were either derived from the available data or obtained from published sources. The data and approaches used to estimate biological parameters (fixed in the model) are described below.

### 2.3.1. Natural mortality

To estimate natural mortality $M$, we explored several methods that relate $M$ with different life history parameters, including longevity, growth rate and age-at-maturity (Charnov 1993, Hoenig 1983, Jensen 1996, Rikhter and Efanov 1976, Roff 1986). Hoenig (1983) developed a model that related total mortality to the maximum age of fish. Since Hoenig's analysis was based largely on unexploited fish stocks, total mortality in his model is often assumed to be natural mortality. Based on the Hoenig's method the natural mortality of spiny dogfish was estimated at $0.064 \mathrm{yr}^{-1}$. This estimated value is within a range of those estimated for spiny dogfish by other studies. It is also consistent with natural mortality for dogfish shark in the Northeast Pacific Ocean (0.065) estimated by Smith et al. (1998). The value $0.064 \mathrm{yr}^{-1}$ was used in the base model, and a likelihood profile analysis was performed to explore how informative the data in model are regarding the value of $M$.

### 2.3.2. Growth

The von Bertalanffy growth function (von Bertalanffy 1938) was used to model the relationship between length and age in spiny dogfish. This is the most widely applied somatic growth model in fisheries (Haddon 2001), and has been commonly used to model growth in spiny dogfish. Also, the most recent evaluation of the growth models for spiny dogfish in the Gulf of Alaska (Tribuzio et al. 2010) reported the von Bertalanffy function to be the most reasonable for both females and males.

Male spiny dogfish were reported to grow slightly faster than females, but females reach larger sizes, therefore, time-invariant growth was modeled for each gender separately. Stock Synthesis modeling framework uses the following version of the von Bertalanffy function:

$$
L_{A}=L_{\infty}+\left(L_{1}-L_{\infty}\right) e^{-k\left(A-A_{1}\right)}
$$

Where $L_{A}$ is length (cm) at age $A, k$ is the growth coefficient, $L_{\infty}$ is asymptotic length, and $L_{1}$ is the size associated with a minimal reference age.

Given that age data were not used in the assessment (due to concern with extrapolating unreadable annuli along the worn part of the spine, Section 2.1.5.2), the growth parameters in the base model were fixed. All growth parameters (except female $L_{\infty}$ ) were fixed at the estimated values from ages generated by Age Method 1, which (unlike those generated by Age Method 2) exhibits consistent pattern between ages estimated from unworn and ages with statistical extrapolation applied. The female $L_{\infty}$ was treated differently than other parameters because the uncertainty in age data associated with extrapolation was particularly high for females, which is evident from the length at age pattern generated by both ageing methods considered in this assessment (Figs. 13-15). For females, $L_{\infty}$ was fixed at the value of 109 cm estimated by Taylor and Gallucci (2009). The female $L_{\infty}$ of 109 cm from Taylor and Gallucci (2009) is consistent with the average size of the 100 largest females in our dataset. All of the parameters used in the assessment are consistent with other growth studies conducted on spiny dogfish in the Northeast Pacific Ocean.

### 2.3.3. Maturity and fecundity

The relationship between female size and maturity was taken from recently published work (Taylor and Gallucci 2009), based on 499 fish collected in Puget Sound in the 2000s (Fig. 20). The logistic function used was:

$$
M \%=\frac{1}{1+e^{\beta(L-L 50 \%)}}
$$

Where $M \%$ is the proportion of mature females in the stock, $\beta=-0.27$ is a parameter controlling the rate of increase in maturity and and $L 50 \%=88.2 \mathrm{~cm}$ is the length at $50 \%$ maturity.

The fecundity of mature fish was also set equal to values from Taylor and Gallucci (2009), which were calculated from 106 pregnant fish from the maturity study for which counts of embryos were available (Fig. 20). A linear relationship between female length ( $L$ ) and fecundity (expressed in number of pups) was assumed:

$$
\text { Pups }=\alpha+\beta L
$$

with estimated parameters $\alpha=-14.7$ and $\beta=0.214$. This relationship results in an increase from 0 pups at the size of 66 cm (when maturity is less than $0.3 \%$ ) to about 7 pups per litter at 100 cm (when maturity is $97 \%$ ) and about 15 pups per litter at the largest size of 136 cm .

### 2.3.4. Weight-length relationship

To establish the relationship between weight and length, the following equation was used:

$$
W=\alpha(L)^{\beta}
$$

Where $W$ is individual weight (kg), $L$ is total natural length (cm) and $\alpha$ and $\beta$ are coefficients used as constants. Data from NWSFC shelf-slope survey collected in the years 2007-2010 were
used to estimate weight-length parameters by sex. Based on the length and weight observations from 1579 females and 1720 males, the parameters $\beta$ were estimated as $\alpha=2.3065 \cdot 10^{-6}$ for females and $3.4911 \cdot 10^{-6}$ and for males, and $\beta=3.1526$ for females and 3.0349 for males (Fig. 21).

## 3. Model description

This report describes the latest version of the assessment model that includes changes made during the STAR Panel (these changes are listed in Section 5).

### 3.1. Assessment program

This assessment model was developed using the Stock Synthesis (SS) modeling program developed by Dr. Richard Methot at the NWFSC (Methot 2005, 2011). The most recent version (v3.21f) distributed on June 16, 2011 was used. This version includes modifications made to specifically accommodate the biology and life history of spiny dogfish. Particularly, it provides a new stock-recruitment option to express the relationship in terms of offspring survival rather than recruitment (Section 3.4.2), which is more reasonable for such low fecund species as spiny dogfish. This SS version also incorporates a new fecundity option when the female fecundity is expressed as a function of length so that the model can easily incorporate the results of the spiny dogfish fecundity study conducted in the 2000s (Taylor and Gallucci 2009).

### 3.2. General model specifications

This assessment area is limited to coastal waters of the Unites States west coast, off Washington, Oregon and California, bounded by the U.S.-Canadian border on the north and U.S.-Mexican border on the south. The assessment area does not include Puget Sound or any other inland waters. The spiny dogfish population within the assessment area is treated as a single coast-wide U.S. stock, given the migratory nature of the species and the lack of data suggesting the presence of multiple stocks.

As mentioned in the Introduction, the stock included in this assessment very likely has interaction and overlap with dogfish observed off British Columbia. A spatial population dynamics model (Taylor 2008), which included data from a tagging study in the 1940s and from much larger tagging experiments conducted in Canada and inside U.S. waters of Puget Sound, estimated movement rates of about 5\% per year between the U.S. coastal sub-population of dogfish and that found along the west coast of Vancouver Island in Canada. Given this relatively low estimated rate of exchange, it was considered appropriate to proceed with the assessment for the limited area of species range, recognizing that the scope of this assessment does not capture all of the removals and dynamics which very likely bear on the status and trends of the larger, transboundary population.

The modeling period begins in 1916, assuming that in 1915 the stock was in an unfished equilibrium condition. Fishery removals are divided among 8 fleets (6 catch and 2 discard fleets). These fleets are: 1) Bottom trawl, 2) Bottom trawl discard, 2) Midwater trawl, 4) Bycatch in atsea Pacific hake fishery, 5) Hook-and-line, 6) Hook-and-line discard, 7) Other gears, and 8) Recreational. The time series of removals for each fleet were reconstructed outside the model and entered in the SS data file. Historical catches were reconstructed by state, and then combined into coast-wide fleets, defined based on gear groups. Since discarded catch was included in the
model as catch time series, no retention curves were specified in addition to fleet selectivities. Removals associated with research surveys are also treated as fleets. The data for each fleet used in the assessment are summarized in Fig. 2.

This is a sex-specific assessment model. The sex-ratio at birth is assumed to be 1:1. Females and males have separate growth curves and sex-specific weight-at-length parameters. The model assumes a constant natural mortality of $0.064 \mathrm{yr}^{-1}$ for both genders. The length frequency distributions are represented as thirty one $4-\mathrm{cm}$ bins ranging between 12 and 132 cm . Length is expressed as total natural length measured without extending the fish tail. Population length bins are defined at a finer 2 - cm scale, ranging between 10 and 136 cm .

### 3.3. Likelihood components

In the model, likelihood estimates for the various data components were obtained by comparing expected values from the model with the actual observations from sample data based on "goodness of fit" procedures for log likelihood. The likelihood components of the model include: 1) survey abundance indices, 2) mean size of fish in the discard fleets, and 3) fishery and survey length frequency distributions.

### 3.4. Model parameters

In the assessment, there are parameters of three types, including life history parameters, stockrecruitment parameters and selectivity parameters. These parameters were either fixed or estimated within the model. Reasonable bounds were specified for all parameters. Survey catchability was estimated for each index of abundance; no prior assumptions were made regarding catchability.

### 3.4.1. Life history parameters

Life history parameters that were fixed in the model included natural mortality and growth for both genders, weight-at-length for males and females, maturity-at-length and fecundity-at-length. The estimates for these fixed parameters were either derived from data available or obtained from the literature, as described in Section 2.3.

### 3.4.2. Stock-recruitment parameters

The fecundity of dogfish in the Northeast Pacific Ocean has been well studied (Ketchen 1972, Tribuzio 2004, Taylor and Gallucci 2009), with pregnant females having relatively few pups per litter, and with relatively little variability between individuals. Unlike fish producing millions of eggs, the low fecundity of dogfish suggests both low productivity in general and a more direct connection between spawning output and recruitment than for many species.

The spawner-recruit relationship was modeled using a new functional form that was recently added to SS, which allowed a more explicit modeling of pre-recruit survival between the stage during which embryos can be counted in pregnant females to their recruitment as age 0 dogfish (Richard Methot and Mark Maunder, pers.com.). This new method may be useful for a variety of low fecund species, as well as providing additional flexibility in the spawner-recruit relationship that may be explored for any stock. The method is an expansion and improvement on similar approaches previously applied to dogfish (Wood et al. 1979, Taylor 2008), which assumed a linear decline in age 0 survival as a function of population density.

The survival of pre-recruit dogfish at equilibrium is calculated as:

$$
S_{0}=\frac{R_{0}}{B_{0}}
$$

Where $R_{0}$ is the recruitment at equilibrium, resulting from the exponential of the estimated $\log \left(R_{0}\right)$ parameter, and $B_{0}$ is the equilibrium spawning output (in units of number of embryos), calculated by projecting the numbers at age forward under natural mortality, starting with $R_{0}$ at age 0 , then converting to numbers at length for the estimated growth parameters and variability in length at age, and finally applying the maturity and fecundity relationships to get total spawning output.

Recruitment for each year in the time series is then calculated as:

$$
R_{y}=S_{y} B_{y}
$$

Where $B_{y}$ is the spawning output in year $y$, and $S_{y}$ is the pre-recruit survival given by the equation:

$$
S_{y}=\exp \left(-z_{0}+\left(z_{0}-z_{\min }\right)\left(1-\left(\frac{B_{y}}{B_{0}}\right)^{\beta}\right)\right)
$$

Where

$$
\begin{aligned}
& z_{0}=-\log \left(S_{0}\right) \\
& \quad \text { is the pre-recruit mortality rate at equilibrium, } \\
& z_{\min }=z_{0}\left(1-z_{\text {frac }}\right)
\end{aligned}
$$

is the limit of the pre-recruit mortality as depletion approaches 0 , parameterized as a function of $z_{\text {frac }}$ (which represents the reduction in mortality as a fraction of $z_{0}$ ) so the expression is well defined over a parameter range $0<z_{f r a c}<1$, and,
$\beta \quad$ is a parameter controlling the shape of density-dependent relationship between spawning depletion and pre-recruit survival.

The steepness ( $h$ ) of the spawner-recruit curve (defined as recruitment relative to $R_{0}$ at a spawning depletion level of 0.2 ) can be derived from the parameters above according to the relationship

$$
h=0.2 \exp \left(z_{0} z_{f r a c}\left(1-0.2^{\beta}\right)\right)
$$

By modeling the relationship in terms of mortality instead of survival (as in Taylor 2008), annual deviations in recruitment can be modeled (implemented in SS by replacing $B_{y}$ in the equation above with $B_{y} e^{r_{y}}$ where $r_{y}$ is the deviation in recruitment in year $y$ ). Attempts to model recruitment deviations in this assessment indicated that the data did not provide adequate detail to get reasonable estimates. Furthermore, the relatively large size of dogfish pups at birth (20-

30 cm , Tribuzio 2004) would suggest that variability in recruitment would be lower than for a species with a larval stage, which is subject to higher mortality rates.

### 3.4.3. Selectivity parameters

Gear selectivity parameters used in this assessment were specified as a function of size. Agebased selectivity was set to 1.0 for all ages beginning at age 0 . Separate size-based selectivity curves were fit to each fishery fleet and survey, for which length composition data were available. Selectivity curves for those fleets that lack length data were "mirrored" to fleets with length data.

A double-normal selectivity curve was used for all fleets. This curve has six parameters, including: 1) peak, which is the length at which selectivity is fully selected, 2) width of plateau on the top, 3) width of the ascending part of the curve, 4) width of the descending part of the curve, 5) selectivity at first size bin, and 6) selectivity at last size bin.

Peaks (parameter 1) and widths of the ascending part of the curves (parameter 3) were estimated by the model for all fleets. The initial selectivity parameters (parameter 5) were fixed so that the smallest bin had a selectivity of 0 for most fleets, except for midwater trawl, at-sea hake bycatch and discard fleets, since those fleets were found to encounter organisms from the smallest data bin (12-15 cm).

Selectivity curves of bottom trawl and hook-and-line fleets were assumed to be asymptotic because examination of length composition data revealed that these fleets are catching the largest fish observed. The selectivities of discard fleets and the recreational were allowed to be domeshaped, but in initial runs, the estimates were essentially asymptotic, and therefore, these selectivities were made asymptotic by fixing the selectivity at the last size bin (parameter 6) at a large value. We also fixed the width of plateau on the top (parameter 2 ) and the width of the descending part of the curve (parameter 4) at intermediate values since these parameters are redundant when selectivity is fixed as asymptotic. Selectivity of bottom trawl and hook-and-line fleets during the time of vitamin A fishery (prior to 1950) were assumed to be the same as corresponding discard fleets, since fish of all sizes were retained at the time of that fishery.

Midwater and at-sea hake bycatch fleets were allowed to be dome-shaped. Their selectivity curves were identical due to almost identical length frequency distributions of catch for these fleet (at-sea hake fishery is conducted by midwater trawl as well). It was, therefore, considered appropriate to assume the same selectivities for midwater and at-sea hake fleets and they were set to mirror each other.

The NWFSC shelf-slope survey selectivity curve was also assumed to be asymptotic because this survey covered the entire latitudinal range of the assessment and went deep enough to include the entire depth range of the species. Selectivity curves of AFSC triennial and AFSC slope surveys were estimated to be dome-shaped since they covered only a portion of the latitudinal extent of the assessment and the depth range of the species. Allowing slope surveys to be domeshaped is further justified biologically by the fact that spiny dogfish does not exhibit ontogenetic shift when older larger individuals are moving to deeper water (as observed in a number of
groundfish in the Northeast Pacific Ocean), larger individuals occur in both shelf and slope areas (Fig. 22). Therefore, lack of survey spatial coverage in either shelf or slope areas could potentially lead to not selecting larger organisms in the population.

No length composition data were available for the "Other gear" fleet, NWFSC slope survey and IPHC survey. The Other gear fleet was assumed to have the same selectivity the Hook-and-line discard fleet, since historical records suggest that the set nets (a major component of the Others) were selecting the same-sized fish as hook-and-line gear. This fleet was set to mirror hook-andline discard rather that hook-and-line fleet because the other gear fleet was primarily in operation at the time of vitamin A fishery and organisms of all sizes were retained. The selectivity for NWFSC slope survey was set to mirror the AFSC slope survey since both surveys used the same type of gear, and had the same depth coverage. Finally, IPHC hook-and-line survey selectivity was also set to mirror that of the Hook-and-line discard fleet since the gear used to conduct the survey is similar to longline gear that is used in some commercial longline fisheries from which the length samples of discarded dogfish are collected.

Different assumptions regarding shape of selectivity curves were explored via sensitivity analysis before and during STAR Panel review (Section 7.1.4).

## 4. Model selection and evaluation

### 4.1. Alternate model configurations

A large number of alternative model configurations of different levels of complexity were explored in order to formulate a base model that would realistically describe the population dynamics of this stock and would balance realism and parsimony. A selected number of the most relevant alternate model configurations that were considered but rejected are described in the sensitivity analyses section (Section 7.1). These configurations include alternative assumptions regarding commercial removals, historical discard and discard mortality of spiny dogfish, different assumptions regarding shape of selectivity curves, alternate values for natural mortality $(M)$, variation in extend of extra variance added to IPHC survey, and different assumed stockrecruitment relationship (Beverton-Holt model).

We evaluated the alternative models based on overall model fit and convergence criteria. Key assumptions and structural choices were made based on whether the model estimated parameters and outputs make sense and are consistent with information available for the species. The base model reflects the best aspects from these exploratory analyses. It appears to be parameterized sufficiently to fit the observed data, while maintaining reasonable parameter values and parsimonious explanations for the underlying model processes.

### 4.2. Convergence status

A number of tests were done to verify model convergence. The Hessian matrix for the base model was positive definite. The maximum gradient component for the base model was 0.000028 . We also assessed the model's ability to recover similar likelihood estimates when initialized from dispersed starting points (jitter option in SS). Out of the 25 tests, 16 produced the same result as the base model and the rest produced different results, but with lower likelihood
(higher negative log-likelihood). Taken together, this evidence provides every indication that the base model is truly the set of parameter estimates producing the best fit the data.

## 5. Response to the STAR Panel recommendations

During the STAR Panel review, analysis and evaluation of the base model were performed to explore data sources and better understand model performance. The STAR Panel provided useful recommendations that were incorporated into the base model. Specific changes made to the preSTAR model during the STAR Panel review included:

1) Not to use age data. In the pre-STAR model, age data were downweighted to 0.1 in the likelihood (compared to values of 1.0 for the other data source) because both ageing methods explored within the assessment raised concerns regarding statistical extrapolation of the unreadable annuli on the worn part of the spines (see Section 2.1.5.2).
2) Keep female $L_{\infty}$ fixed at the value of 109 cm as estimated by Taylor and Gallucci (2009), and fix the other growth parameters at the values estimated from ages generated by Age Method 1 (instead of estimating those parameters within the model).
3) Use selectivity curves of bottom trawl discard and hook-and-line discard fleets to describe selectivity of bottom trawl and hook-and line fleets respectively during the time of vitamin A fishery (when all sizes of fish were retained).
4) Mirror selectivity of the Other gear fleet to the selectivity hook-and-line discard (instead of hook-and-line) since the other gear fleet contribution was the most during the vitamin A fishery when fish of all sizes were retained.
5) Mirror selectivity of IPHC longline survey to that of hook-and-line discard fleet (instead of hook-and-line fleet).
Comparison of likelihood components, selected parameters and reference points between base and pre-STAR model are provided in Table 7. The comparison of outputs between base and preSTAR models as well with subsets of changes made during the STAR Panel (changes 1 and 2 in the list above) are provided in Figs. 23-24.

## 6. Base model results

The list of the explicit parameters used in the base model and their values (either fixed or estimated) is provided in Table 8. The life history parameters estimated within the model are reasonable and consistent with what we know about the species. Both sexes follow the same trajectory in their growth. Males grow slightly faster than females, but with females reaching larger sizes (Fig. 25). Figures 26-29 show weight-at-length relationships by sex, female maturity-at-length, fecundity-at-weight and spawning output-at-length generated based on fixed parameters that were derived from data outside the model. Female fecundity and spawning output are expressed in number of pups (Section 3.4.2).

The base model was able to capture general trends for indices in all surveys, which were either stable or decreasing (Figs. 30-34). The estimated biomass in the 2003 and 2004 NWFSC shelfslope survey exhibits a significant decline, which is not consistent with the dynamics of K strategy organisms, such as spiny dogfish, with slow growth, late maturation and low fecundity. The most probable explanation for such a decline is that it reflects patchiness in the spatial distribution of spiny dogfish, when survey can encounter either a large school or only diffusely
scattered individuals. The NWFSC shelf-slope survey encountered one extremely large haul of spiny dogfish in 2003 and several larger than average hauls in 2004 (Fig. 19), which supports the hypothesis of patchy distribution and extreme variability in survey catches. The model also estimates large variance around those estimates.

The base model fits the length frequency distributions well. The quality of fit varies among years and fleets, which reflects the differences in quantity and quality of data. The Pearson residuals, which reflect the noise in the data both within and among years, did not exhibit any strong trends. In the assessment iterative re-weighting was used to achieve consistency between the input sample sizes and the effective sample sizes for length and age composition samples based on model fit. This reduces the potential for particular data sources to have a disproportionate effect on total model fit. Observed and effective sample sizes for length frequency observations, the model fit to length frequency distributions and Pearson residuals by fleet and gender are shown in Figs. 35-91.

The size selectivity curves from the base model are shown in Figs. 92-104. For the bottom trawl discard and hook-and-line discard fleets, the model estimated higher selectivity for smaller fish than those of corresponding catch fleets (bottom trawl and hook-and-line), which is consistent with the fact that smaller fish are more frequently discarded. The AFSC triennial, AFSC slope and NWFSC slope survey selectivity curves were estimated as dome-shaped, which is consistent with the fact that those survey had only a limited spatial coverage of the assessment area and species range within the assessment area (Table 4).

The time series of total and summary biomass, spawning output, depletion relative to $B_{0}$, recruitment, and fishing mortality are presented in Figs. 105-109 and Table 9. The spawning output showed a relatively sharp decline in the 1940s, during the time of the intense dogfish fishery for vitamin A. During a 10-year period (between 1940 and 1950), the spawning output dropped from 99\% to under 70\% of its unfished level. Between 1950 and 1974 the catches of spiny dogfish were minimal, and the spawning output started to increase (mostly as a result of maturation of younger dogfish that were not selected by the vitamin A fishery). For the last thirty-five years, spawning output of spiny dogfish has been slowly but steadily declining due to fishery removals (an export food fish fishery developed in the mid-1970s) and low productivity of the stock. Currently, the spawning output is estimated to be at the level of $63 \%$ of its unfished level (Fig. 110). Predicted numbers at age from the base case for females and males are provided in Appendix A.

## 7. Model uncertainty

Parameter uncertainty in the assessment is explicitly captured in the asymptotic confidence intervals estimated within the model and reported throughout this assessment for key parameters and management quantities (Figs. 107, 108, 110). These intervals reflect the uncertainty in the model fits to the data sources in the assessment, but do not include the uncertainty associated with alternative model configurations and fixed parameters. To explore uncertainty associated with alternative model configurations and evaluate the responsiveness of model outputs to changes in model assumptions, a variety of sensitivity runs were performed.

### 7.1. Sensitivity analyses

A large number of configurations of the base model addressing alternative assumptions regarding key model parameters and structural choices were explored via the sensitivity analysis. Only the most relevant ones are reported here. Results of these selected sensitivity runs are summarized in Tables 10-12 and Figs. 111-112, 114-118.

### 7.1.1. Alternative assumptions about fishery removals

Commercial landings of spiny dogfish are relatively well documented because of dogfish utilization history on the U.S. west coast and unique appearance of this species. However, there is an uncertainty associated with discard estimates used in the model as well as discard mortality rates applied (landings and discard (with associated discard mortality) together comprise the total fishery removals). To explore the model sensitivity to uncertainty in spiny dogfish removals (that include both landings and discard), we ran the model assuming: 1) $50 \%$ increase in removals, and 2) $25 \%$ decrease in removals, in all the fleets, except for at-sea hake bycatch since it is $100 \%$ observed by A-SHOP. Although these runs differed in the absolute estimate of $B_{0}$ and current biomass (Fig. 111), the trends in spawning depletion as well as estimated depletion levels varied only slightly (Fig. 112, Table 10).

### 7.1.2. Alternative assumptions about historical discard

No information is currently available about the historical discard during the period between 1950 (when vitamin A fishery ended) and 1975 (when the export fish food fishery began). We could locate only one document on coastal historical dogfish discard, which is a one-trawler, one-trip snapshot. This document confirms that discard did take place, but it does not provide enough information to estimate the magnitude of discard for the entire fleet. Given the limitations of the historical discard data, in the base model, the relationship for predicting the discard derived from WCGOP data was assumed for the entire period after the vitamin A fishery. An alternative assumption about historical discard was explored when a minimum threshold applied to historical discard (i.e. discard was not allowed to drop below a specified amount); this minimum threshold was calculated as an average of the 1950-1974 discard (Fig. 113). The results show that the model is only slightly sensitive to this assumption, and neither spawning output nor spawning depletion noticeably changed when alternative historical discard time series was assumed (Figs. 114-115, Table 10).

### 7.1.3. Alternative assumptions about discard mortality

We also explored the model sensitivity to the alternative assumptions regarding dogfish discard mortality. In the base model, $100 \%$ discard mortality was assumed for trawl discard fleet and $50 \%$ for hook-and-line discard. In the alternative runs, we assumed both discard fleets to have: 1 ) $100 \%$ discard mortality, and 2) $50 \%$ discard mortality. We also ran the model assuming $6 \%$ mortality for hook-and-line discard fleet and 5\% for bottom trawl discard fleet. Those values are used by the Integrated Fisheries Management Plan (IFMP) for Pacific Canadian groundfish fisheries, except for the fact that IFMP uses 5\% discard mortality for the first two hours of a trawl fishing event with $5 \%$ for each additional hour (no historical data on tow length were available for this assessment). The runs with both fleets having $100 \%$ and $50 \%$ did not produce large differences in comparison with the base model in the sense of depletion level, but the run with the lowest discard mortality rates produced more depleted stock that estimated by the base
model. In general, most of the model results in this sensitivity and others show a slight declining trend in the most recent years. The model with the lowest discard mortality has the lowest total mortality in the past 30 years compared to the peak in the 1940s. Therefore, for this model to produce a slight decline in recent years, the status of the stock in the 1970s, when the recent fishery restarted, has to be lower so that a smaller increase in total mortality (with little additional mortality from discard) can be enough to cause the stock to stop rebuilding.

### 7.1.4. Alternative assumptions about gear selectivity

In the base model, a few selectivity curves were fixed to be asymptotic (see Section 3.4.3). Prior to the STAR Panel, we conducted a number of runs to explore model sensitivity to assumptions regarding shape of fleets' selectivity curves. Those runs resulted in a range of outputs, but the one with no selectivity curves fixed as asymptotic produced the most extreme result when the depletion level was estimated to be at $100 \%$. Given the low productivity of the stock and the intense period of fishing in the 1940s, this result seems implausible.

### 7.1.5. Alternative assumptions about extra variance for the IPHC survey

Prior to STAR Panel, a sensitivity analysis was also conducted on the base-case addition of 0.1 to the standard deviation, in log space, for the IPHC survey biomass estimate. In one alternative, no extra variance was added and in the other, the model was allowed to freely estimate it. Model results were not sensitive to either alternative formulation. The estimated parameter value was 0.204 , compared to 0.1 in the base case. Estimates of $B_{0}$ and depletion level from the models with the low and high estimates of the parameter bracketed the base model estimates of $B_{0}$ and depletion.

### 7.1.6. Alternative assumptions of spawner-recruit relationship

Sensitivities were conducted to explore alternative assumptions about the spawner-recruit relationships. The relationship used in this model is parameterized in terms pre-recruit survival (Section 3.4.2). The parameters controlling the relationship, which may be estimated or fixed, are equilibrium recruitment ( $R_{0}$ ), a parameter controlling the potential decrease in pre-recruit mortality as spawning output is reduced ( $\mathrm{z}_{\text {frac }}$ ), and a parameter controlling the shape of the mortality-depletion relationship ( $\beta$ ). This is unlike the Beverton-Holt spawner-recruit relationship, which is parameterized in terms of $R_{0}$ and steepeness ( $h$ ), representing the recruitment at a spawning depletion of 0.2 , as a fraction of $R_{0}$.

The base model uses the survival-based relationship with $z_{\text {frac }}=0.4$ and $\beta=1.0$. Five sensitivities were conducted for the survival-based relationships, exploring alternative values of $z_{\text {frac }}$ fixed at 0.2 and 0.6 , as well as estimated, and alternative values of $\beta=0.5$ or 2.0 . Four sensitivities were conducted using a Beverton-Holt spawner-recruit relationship instead of the survival-based relationship. These had $h$ fixed at $0.284,0.3$, and 0.4 , as well as estimated. The value of $h=$ 0.284 was chosen to match the steepness of the base model, calculated as a derived quantity rather than a parameter input. In all models, the $R_{0}$ parameter was estimated.

Comparisons of model output are shown in Figs. 116-118 and Tables 11-12. All models showed a similar pattern in depletion, but the extent of decline in the 1940s and the scale of the trajectory since then vary among cases. In the cases where the $z_{\text {frac }}$ parameter in the survival-based spawner-recruitment relationship and $h$ in the Beverton-Holt relationship estimated, they both hit
the lower boundary: $z_{\text {frac }}=0$ and $h=0$. These values are associated with a biologically unrealistic stock with no surplus-production and the increases in spawning output from the 1950s through 1970s in these cases are entirely the result of maturation of younger dogfish that were not selected by the 1940s target fishery, as opposed to density-dependent increases in recruitment. The model with Beverton-Holt spawner-recruit relationship with $h=0.284$ set to match the result of the base model produced very similar results to those from base model, both in terms of population trajectories and yield. Sensitivities with parameters associated with higher productivity than the base model ( $z_{\text {frac }}=0.6, \beta=2.0$, and a Beverton-Holt relationship with with $h=0.3$ or 0.4 ) had higher equilibrium biomass estimates, and thus were less depleted and had higher current status. Those sensitivities with parameters associated with less productive stocks ( $z_{\text {frac }}=0$ or $0.2, \beta=0.5$, and a Beverton-Holt relationship with with $h=0.2$ ) showed greater depletion and lower equilibrium yield.

Over the range of depletion values estimated in these sensitivities, none of the values for prerecruit survival (Fig. 118, bottom row) were above 1.0. However, one advantage of the new survival-based spawner-recruit curve is that it allows these values to be contained within a biologically reasonable range. Projections with Beverton-Holt relationships indicate that prerecruit survival increases to about 0.9 for $h=0.4$ as spawning depletion approaches 0 . With $h=0.6$, the limit of pre-recruit survival is about 2.0 , a value associated with recruitment of 2 age 0 recruits for every estimated embryo in the spawning output. Such patterns could only occur if either fecundity was very strongly density dependent or a large fraction of recruitments came from areas outside the area modeled in this study.

### 7.2. Retrospective analyses

A retrospective analysis was conducted where we re-ran the model sequentially removing data from the last 3 years. A 3-year retrospective analysis was conducted by running the model using data only through 2007 ("Retrospective in 2008"), a 2-year retrospective analysis was conducted by running the model using data only through 2008 ("Retrospective in 2009") and a 1-year retrospective analysis was conducted by running the model using data only through 2009 ("Retrospective in 2010") (Figs. 119-120). Much of the data in this assessment is from recent years, so a large change in result would be expected for this retrospective analysis. For example, slight changes in selectivities were observed for selected fleets in some of the retrospective runs; these changes, when put together, could be translated into changes in overall dynamics and model output. Also, the index form the IPHC longline survey showed a general decline over the years 1999-2006 which has not continued in subsequent years. Likewise, the first two years of the NWFSC shelf-slope survey showed the highest abundance. All these factors contribute to the retrospectives with the most data removed producing estimates of a more depleted stock with greater recent declines in abundance.

### 7.3. Likelihood profile analyses

A likelihood profile was conducted over a range of values of natural mortality between $M=$ 0.050 and $M=0.075$ (Figs. 121-122). The profile showed that the length composition data had the greatest change in likelihood over this range of $M$ values with the best fit to the length data occurring at $M=0.054$. The indices of abundance fit best at higher $M$ values with equally good fit for $M \geq 0.064$. The likelihood contribution from mean body weight showed little change over the profiled values of $M$. The estimates of $B_{0}$ and depletion were very sensitivity to the choice of
$M$, with lower mortality values leading to lower estimates of equilibrium spawning output and lower status in 2011. As $M$ is increased above 0.065 , the $B_{0}$ estimates increase quickly and with $M>0.070$ the 2011 status is estimated to be at $100 \%$ of $B_{0}$. Although the profile is illustrative of the influence of natural mortality on estimates of population scale and stock status, none of the data sources in the model are assumed to provide information sufficient to estimate $M$.

## 8. Reference points

Unfished spawning stock output for spiny dogfish is estimated to be 70,724 thousands of fish ( $95 \%$ confidence interval: $35,598-105,850$ ). The stock is declared overfished if the current spawning output is estimated to be below $25 \%$ of unfished level. The management target for spiny dogfish is defined as $40 \%$ of the unfished spawning output ( $\mathrm{SB}_{40 \%}$ ), which is estimated by the model to be 28,290 thousand of fish ( $95 \%$ confidence interval: 14,239-42,340), which corresponds to an exploitation rate of 0.006 . This harvest rate provides an equilibrium yield of 831 mt at $\mathrm{SB}_{40 \%}$ ( $95 \%$ confidence interval: 421-1241 mt). The model estimate of maximum sustainable yield (MSY) is 848 mt ( $95 \%$ confidence interval: 430-1267 mt). The estimated spawning stock output at MSY is 33,229 thousands of fish ( $95 \%$ confidence interval: 16,72349,736 ). The exploitation rate corresponding to the estimated $\mathrm{SPR}_{\mathrm{MSY}}$ of $\mathrm{F} 79.26 \%$ is 0.0053 .

Because of this extremely low productivity and other reproductive characteristics of the stock, fishing at the target SPR of $45 \%$ is expected to severely reduce the spawning output over the long term. Conversely, fishing at a rate that would maintain spawning output near $40 \%$ of the unfished level would require a target SPR of about 77\%. The Council's Scientific and Statistical Committee should consider the appropriateness of using the current proxy harvest rate for spiny dogfish.

The summary of spiny dogfish reference points from the base model is shown in Table 13. The equilibrium yield curve developed based on reference point values is shown in Fig. 134.

## 9. Status of the stock

The assessment shows that the stock of spiny dogfish off the continental U.S. Pacific Coast is currently at $63 \%$ of its unexploited level and, therefore, not overfished (Fig. 110). Historically, the abundance of spiny dogfish has always been above the management target of $\mathrm{SB}_{40 \%}$. Time series of estimated spawning potential ratio (SPR) with current SPR target of 0.45 (Fig. 124) demonstrate that currently harvest does not exceed current overfishing proxy. The assessment identified a period, which is during the vitamin A fishery in the 1940s, when the exploitation rate exceeded the current FMSY proxy harvest rate (Fig. 124). Time series of estimated spawning potential ratio (SPR) relative to its target of 0.45 versus estimated spawning output relative to its target of $\mathrm{SB}_{40 \%}$ also demonstrate that currently stock is not overfished and overfishing is not occurring (Fig. 125).

Time series of total and summary biomass as well as spawning output, recruitment and fishing mortality are shown in Figs. 105-109. Recent trends in estimated spiny dogfish exploitation and stock level from the assessment model are presented in Table 14.

Historically, the spawning output of spiny dogfish showed a relatively sharp decline in the 1940s, during the time of the intense dogfish fishery for vitamin A. During a 10-year period
(between 1940 and 1950), the spawning output dropped from $99 \%$ to under $70 \%$ of its unfished level. Between 1950 and 1974 the catches of spiny dogfish were minimal, and the spawning output started to increase (mostly as a result of maturation of younger dogfish that were not selected by the vitamin A fishery). For the last thirty five years, spawning output of spiny dogfish has been slowly but steadily declining due to fishery removals (an export food fish fishery developed in the mid-1970s) and low productivity of the stock.

## 10. Decision table

Three states of nature were defined based on the alternative time series of removals and natural mortality values. The middle (base case) scenario has catch time series and natural mortality (0.064) as used in the base model. For the "low" and "high" states of nature, the base model was first modified by decreasing the entire time series of removals by $25 \%$ and increasing by $50 \%$ for low and high catch scenarios respectively. The low and high catch scenario models were further modified by subtracting one standard deviation from the 2011 spawning output value from the low catch model and adding one standard deviation to the 2011 spawning output value from the high catch model. The natural mortality for low state of nature ( 0.061 ) was selected to match one standard deviation below the 2011 spawning output for low catch scenario. The natural mortality for high state of nature (0.066) was selected to match one standard deviation above the 2011 spawning output estimate for high catch scenario. The fourth state of nature based on the retrospective analysis that excluded the last three years of the time series was added to allow for decision table to broaden the uncertainty in the assessment estimates. The net effect is to add more pessimistic state of nature, in which the spawning depletion falls below the management target of $\mathrm{SB}_{40 \%}$ in recent years. Comparison of spawning output and spawning depletion of four states of nature is provided in Figs. 126-127. The comparison of likelihood component values, selected parameters and reference points of three states of nature defined based on time series of removals and natural mortality is also given in Table 15.

Twelve-year forecasts for each state of nature were calculated based on removals at SPR 45\% for the base model. Twelve-year forecasts were also produced with future catch fixed at the 20112012 OFL-based value provided by the Groundfish Management Team (GMT) and calculated as 28.4\% of the total Other Fish ACL (the percentage is derived from the dogfish contribution to Other Fish OFL). Finally, twelve-year forecasts for each state of nature were calculated based on removals at SPR 77\% for the base model, the level identified by the model as associated with the $\mathrm{SB}_{40 \%}$ target biomass level. Under the low state of nature, the catch at SPR $45 \%$ is projected to reduce the spawning stock output to 34.81 \% of the unfished level within 12 years. In all other scenarios covered by the decision table, the spawning output remains above the $40 \%$ target level throughout the 12-year projection period. The highest level predicted in the 12 year projections is $75.65 \%$, which occurs when the SPR $77 \%$ catch series is applied to the high state of nature. In general, there is little change in stock size over the 12 year projections for any of the combinations of state of nature and removals. Decision table with difference forecast options described above for four states of nature is provided in Table 16.

## 11. Regional management consideration

Spiny dogfish is a migratory species found in the U.S. west coast from Alaska to Southern California. They are extremely abundant in waters off British Columbia and Washington, but decline in abundance southward along the Oregon and California coasts.

The stock included in this assessment (from the U.S.-Canada border on the north to U.S.-Mexico border on the south) very likely has substantial interaction and overlap with dogfish observed off British Columbia. From a seasonal perspective, this is particularly important, because spring aggregations of dogfish that have been targeted off Washington may well have migrated to areas north of the border by the time that trawl surveys have commenced off the US coast. In a population sense, it must be acknowledged that the scope of this assessment does not capture all of the removals and dynamics which very likely bear on the status and trends of the larger, transboundary population.

It was considered appropriate to proceed with the assessment for the limited area of U.S. west coast based on the recent estimated annual directed (not seasonal) movement rates of about 5\% per year between the U.S. coastal sub-population of dogfish and that found along the west coast of Vancouver Island in Canada (Taylor 2008). Nevertheless, it is extremely important to pursue collaborative efforts between U.S. and Canada to more accurately describe the dynamics and access the status of stock, especially given the vulnerability of the stock, which exhibits slow growth, the longest gestation period known for sharks and is the latest maturing of all elasmobranchs.

## 12. Research and data needs

In this assessment, several critical assumptions were made based on limited supporting data and research. There are several research and data needs which, if satisfied could improve the assessment. These research and data needs include:

1) The ageing method for dogfish requires further research. Double reads indicate that the method of counting annuli on the unworn portion of dogfish dorsal spines is reasonably precise and has been validated using both oxytetracycline marking and bomb radiocarbon. However, more research is needed on the topic of unreadable annuli that are missing due to wear on the spines of older dogfish. Cheng (2011) has proposed important improvements to the statistical methods applied to these calculations, but the differences in patterns of age at length between worn and unworn spines resulting from those calculations suggests that addition research is needed. Improving estimates of the statistical uncertainty associated with the age extrapolation methods, including that proposed in Cheng (2011) would also be valuable. Tribuzio et al. (2010) explored a variety of refinements to the age estimation and growth for dogfish in Alaska that could be applied for west coast dogfish. Ideally, an alternative method of ageing dogfish that does not rely on the highly uncertainty estimation of ages missing from worn spines may be necessary before age information can be a reliable data source in dogfish stock assessments. Future assessment could also benefit from additional age readings of dogfish spines that have not yet been examined, including thousands of samples collected in the NWFSC shelf-slope survey from 2004-2009.
2) The move to full observer coverage in 2011 will improve estimate of dogfish discards for the west coast. However, there is considerable uncertainty in both the historic discard amounts, especially prior to the commencement of the West Coast Groundfish Observer

Program. Even more important is the need to improve estimates of discard mortality. Studies of this topic on the east coast used shorter tow durations than those in common fishing operations in these waters, and thus are likely to produce understimates of discard mortality (NEFSC, 2006). Data on tow duration could also be incorporated into future models to better refine discard mortality estimates from the trawl fishery.
3) Ongoing research using acoustic tags on dogfish released in central Puget Sound in the summer show regular seasonal movements to coastal waters during the winter and returns to Puget Sound in the subsequent summers (Andrews, pers.com.). This suggests that biomass sampled by summertime surveys (including all those from AFSC, NWFSC, and IPHC used in this analysis) may not be representative of the population size and distribution available to the fishery in other seasons. If the movements are very regular, the surveys may still provide a reliable relative index of abundance, but any differences in movement patterns due to climate or prey availability could impact these indices. Further research into how to account for such movement patterns should be conducted to inform future dogfish stock assessments. Acoustic or satellite tagging of dogfish in coastal waters could provide valuable insight into movement patterns along the coast and benefit future assessments.
4) There are high densities of dogfish close to the U.S./Canada border, at the mouth of the Strait of Juan de Fuca which connects the outside coastal waters with the inside waters of Puget Sound and the Strait of Georgia. This distribution, combined with potential seasonal or directed movement patterns for dogfish suggest that U.S. and Canada should explore the possibility of a joint stock assessment in future years. The data used in these assessment are far more comprehensive than that used by Taylor (2008), but the spatial modeling approach used in that analysis might be considered as a starting point for spatial considerations in a future international assessment.

## Acknowledgements

The authors thank everyone who contributed to the development of this assessment and provided the data - Rick Methot, Jim Hastie and FRAM assessment team (Jason Cope, Melissa Haltuch, Owen Hamel, Allan Hicks, Stacey Miller, Andi Stephens, Ian Stewart, John Wallace, Chantel Wetzel) for fruitful discussion of this assessment as well as assessment related topics, Beth Horness (NWFSC) and Claude Dykstra (IPHC) for providing survey data and promptly responding to data requests, Brad Stenberg (PacFIN), Theresa Tsou, Greg Lippert, Greg Bargmann, Wendy Beeghley, Wayne Palsson and Henry Cheng (WDFW), Mark Karnowski and Mark Freeman (ODFW), Don Pearson (SWFSC), Joann Eres and Jana Robertson (CDFG) for providing commercial and recreational fishery data, Jason Jannot and Marlene Bellman (WCGOP) for discard and total mortality data as well as insight into observer program data collection and processing, John DeVore (PFMC) for spiny dogfish management related information, Sean Matson (NWR) for editorial suggestions and overall advice, and Calin Taylor for editing the assessment report. The authors also thank the STAR Panel members (Theresa Tsou, Kevin Stokes, Matthew Cieri and Paul Spencer) for their thorough review of the assessment.

TABLES

Table 1. Chronology of the regulatory history of spiny dogfish by the Pacific Fishery Management Council.

a/ The acceptable biological catch (ABC) specification prior to 2011 represents the MSY harvest level and the optimum yield (OY) represents the annual total catch limit. Implementation of Amendment 23 in 2011 changed these definitions to the overfishing limit (OFL) as the MSY harvest level and the annual catch limit (ACL) as the annual total catch limit. Additionally, the definition of ABC changed under Amendment 23 to a level of harvest less than or equal to the OFL to accommodate the scientific uncertainty associated with estimating the OFL.

Table 2. Time series of reconstructed spiny dogfish removals (in metric tons) by fleet (BT=bottom trawl, BTD=bottom trawl discard, MDT=midwater trawl, ASH=at-sea hake fishery bycatch, HKL=hook-and-line, HKLD=hook-and-line discard, OTH=others, REC=recreational).

## APPENDIX B: Spiny dogfish assessment model files

## B-1: Stock Synthesis starter file

```
#V3.21f
# Starter File for Spiny Dogfish Assessment 2011
Spiny_Dogfish.DAT
Spiny_Dogfish.CTL
0 # 0=use init values in control file; 1=use ss3.par
1 # run display detail (0,1,2)
1 # detailed age-structured reports in REPORT.SSO (0,1)
0 # write detailed checkup.sso file (0,1)
0 # write parm values to ParmTrace.sso
# report level in CUMREPORT.SSO (0,1,2)
1 # Include prior_like for non-estimated parameters (0,1)
1 # Use Soft Boundaries to aid convergence
3 # Number of bootstrap datafiles to produce
10 # Turn off estimation for parameters entering after this phase
10 # MCMC burn interval
2 # MCMC thin interval
0 # jitter initial parm value by this fraction
-1 # min yr for sdreport outputs (-1 for styr)
-2 # max yr for sdreport outputs (-1 for endyr; -2 for endyr+Nforecastyrs
0 # N individual STD years
0.0001 # final convergence criteria
0 # retrospective year relative to end year
1 # min age for calc of summary biomass
1 # Depletion basis: denom is: 0=skip; 1=rel X*B0; 2=rel X*Bmsy; 3=rel X*B_styr
1.0 # Fraction (X) for Depletion denominator
4 # (1-SPR)_reporting: 0=skip; 1=rel(1-SPR); 2=rel(1-SPR_MSY); 3=rel(1-SPR_Btarget);
4=notrel
1 # F_std reporting: 0=skip; 1=exploit(Bio); 2=exploit(Num); 3=sum(frates)
0 # F_report_basis: 0=raw; 1=rel Fspr; 2=rel Fmsy ; 3=rel Fbtgt
999
```

## B-2: Stock Synthesis forecast file

```
#V3.21f
# Forecast File for Spiny Dogfish Assessment 2011
# for all year entries except rebuilder; enter either: actual year, -999 for styr, 0
for endyr, neg number for rel. endyr
1 # Benchmarks: 0=skip; 1=calc F_spr,F_btgt,F_msy
1 # MSY: 1= set to F(SPR); 2=calc F(MSY); 3=set to F(Btgt); 4=set to F(endyr)
0.45 # SPR target (e.g. 0.40)
0.4 # Biomass target (e.g. 0.40)
#_Bmark_years: beg_bio, end_bio, beg_selex, end_selex, beg_relF, end_relF (enter
actual year, or values of 0 or -integer to be rel. endyr)
0 0 0 0 0 0
1 #Bmark_relF_Basis: 1 = use year range; 2 = set relF same as forecast below
2 # Forecast: 0=none; 1=F(SPR); 2=F(MSY) 3=F(Btgt); 4=Ave F; 5=input annual F
12 # N forecast years
0.2 # F scalar (only used for Do_Forecast==5)
#_Fcast_years: beg_selex, end_selex, beg_relF, end_relF (enter actual year, or
values of 0 or -integer to be rel. endyr)
0 0 -10 0
1 # Control rule method (1=catch=f(SSB) west coast; 2=F=f(SSB) )
0.4 # Control rule Biomass level for constant F (as frac of Bzero, e.g. 0.40)
0.1 # Control rule Biomass level for no F (as frac of Bzero, e.g. 0.10)
1 # Control rule target as fraction of Flimit (e.g. 0.75)
3 #_N forecast loops (1-3) (fixed at 3 for now)
3 #_First forecast loop with stochastic recruitment
0 #_Forecast loop control #3 (reserved for future bells&whistles)
0 #_Forecast loop control #4 (reserved for future bells&whistles)
0 #_Forecast loop control #5 (reserved for future bells&whistles)
2011 #FirstYear for caps and allocations (should be after years with fixed inputs)
0 # stddev of log(realized catch/target catch) in forecast (set value>0.0 to cause
active impl_error)
0 # Do West Coast gfish rebuilder output (0/1)
1999 # Rebuilder: first year catch could have been set to zero (Ydecl)(-1 to set to
1999)
2002 # Rebuilder: year for current age structure (Yinit) (-1 to set to endyear+1)
1 # fleet relative F: 1=use first-last alloc year; 2=read seas(row) x fleet(col)
below
# Note that fleet allocation is used directly as average F if Do_Forecast=4
2 # basis for fcast catch tuning and for fcast catch caps and allocation (2=deadbio;
3=retainbio; 5=deadnum; 6=retainnum)
# max totalcatch by fleet (-1 to have no max)
-1 -1 -1 -1 -1 -1 -1 -1
# max totalcatch by area (-1 to have no max)
    -1
# fleet assignment to allocation group (enter group ID# for each fleet, 0 for not
included in an alloc group)
0 0 0 0 0 0 0 0
#_Conditional on >1 allocation group
# allocation fraction for each of: 0 allocation groups
# no allocation groups
0 # Number of forecast catch levels to input (else calc catch from forecast F)
2 # basis for input Fcast catch: 2=dead catch; 3=retained catch; 99=input Hrate(F)
999 # verify end of input
```
