# Deriving estimates of OFL for species in the "Other Fish" complex or potential alternative complexes 

Ian Taylor, Jason Cope, Owen Hamel, and Jim Thorson<br>NMFS, NWFSC, FRAM

The current "Other Fish" complex and proposed alternatives include a number of species for which estimates of OFL contributions are not available from stock assessments or data-poor methods. Four of the species had OFL contributions for the 2013-2014 management cycle calculated by applying approximate MSY harvest rates to estimates of stock biomass from the NWFSC West Coast Bottom Trawl Survey (Bradburn et al., 2012). This approach is described in detail in Cope et al. (2012). This document expands the set of species to those associated with proposed alternatives to the Other Fish complex described in Agenda Item H.4.b, GMT Report, November 2013 and updates those species previously considered to account for more recent biomass estimates. Species for which OFL estimates were available from other methods or for which the survey did not have adequate coverage of their depth range were not included in the calculations presented here.

This survey-based approach to setting OFLs is based on the calculation

$$
O F L=F_{M S Y} B_{w}
$$

where $F_{M S Y}$ is the fishing mortality rate that maximizes long-term yield, and $B_{w}$ is an inversevariance weighted average of recent survey biomass estimates. To account for uncertainty in this OFL estimates, one million samples of $F_{M S Y}$ and $B_{w}$ were drawn from assumed distributions for these quantities (Table 1, Figure 2) and the median of the products of these values is presented here as the estimated OFL (Table 3, Figure 2). In general, the estimated OFL values are similar to the 2014 OFL based Cope et al. (2012) for the four species that had the same methods applied (Table 1).

Following Cope et al. (2012), the most recent 3 years of the survey were used in the calculation of $B_{w}$. For most species, a longer, 6-year average was found to be very similar to the recent years (Table 1, Figure 1). For long-lived, but infrequently encountered species, a longer range would likely be a better estimate of abundance. Aleutian skate only occur in an average of only 2 survey tows per year (out of an average of 645 tows per year over the past 10 years), so their survey estimate are more variable than the other species considered here. In this case, a preferable option might be grouping Aleutian skate with "all other skates" to reduce the sampling variability associated with this contribution to a complex that included skates.

The $F_{M S Y}$ values are based on the product of values for natural mortality $(M)$ and the ratio $F_{M S Y} /$ $M$. The estimates of $M$ were obtained from a variety of published sources (listed in Table 1) or in some cases assumed to be the same as those estimated for similar species (all grenadiers were
assumed to have the same $M$ ). Two values for $F_{M S Y} / M$ were used based on the estimates in Zhou et al. (2012). Samples of these two quantities were generated from assumed distributions and multiplied together to get a distribution of $F_{M S Y}$ values. For two species, roughtail/black skate and ratfish, two estimates of $M$ were available. In Cope et al. (2012), the $M$ values for ratfish were drawn from a uniform distribution bounded by the two values. However, using the uniform distribution resulted in less uncertainty for these species with multiple estimates than the distributions assumed for those species with a single estimate. To avoid this contradiction, the previously applied methods were extended so that samples from the uniform distribution were used as the expected values for a second stage of sampling from a lognormal distribution. The resulting distributions are compared in Figure 2. In all cases, the lognormal distributions for $M$ were assumed to have a log-scale standard deviation of 0.4 (CV $=0.417$; Dick and MacCall, 2011).

These methods depend on the both the accuracy of the parameters contributing to $F_{M S Y}$ as well as a large set of assumptions about the survey. The population is assumed to not have significant trends in abundance and the survey is assumed to have catchability equal to 1.0 . Furthermore, survey selectivity and fishery selectivity are assumed to be equal. In benchmark stock assessments, these assumptions are typically not met. In the future, meta-analytic methods could be considered to refine the values presented here by estimating the relationship between this survey-based estimation of biomass and OFL with values developed in benchmark assessments.

## OFL estimates from other sources

## Cartilaginous Fish

Among the cartilaginous fish, leopard shark and soupfin shark have 2014 OFL estimates based on DB-SRA and DCAC, respectively, which may be used again in 2015-2016. Spiny dogfish has a benchmark assessment conducted in 2011 which has been used to derived OFL values for 2015-2016.

## Shallow Water Roundfish

The NWFSC West Coast Bottom Trawl Survey does not sample depths shallower than 55 meters (30 fathoms). This prevents it from being a good sampling method for any of the species that might be considered in a Shallow Water Roundfish group, including kelp greenling, all other greenlings, or cabezon (WA). Kelp greenling in California has an OFL estimate from DB-SRA but additional analyses would be needed to get estimates for Oregon and Washington. All other greenlings and cabezon off Washington could have OFL estimates based on recent average catch or some other data poor method, but such calculations are not included in this document.

## Acknowledgements

We thank Beth Horness for providing survey data, and E.J. Dick and Alec MacCall for their contributions to the methods applied here. We further thank all members of the GMT for their wisdom, insight, and endless discussions of the complexities of "Other Fish".

Figure 1. Time series of estimated survey biomass (mt), 2003-2012, with estimated 95\% confidence intervals. Horizontal lines indicate weighted average value over most recent 6-year and 3-year periods. No 6-year average for Aleutian skate is reported because they were not encountered in the 2009 survey.

Figure 2a. Assumed distributions for $M$ (first column) and $F_{M S Y} / M$ (second column), weighted average survey biomass for the years 2010-2012 (third column) and resulting OFL (fourth column) for 8 species of cartilaginous fish. Vertical lines indicate medians of each distribution. Shaded boxes in the first column for roughtail/black skate and Bering/sandpaper skate indicate the uniform distribution of $M$ values used as expected values in sampling from lognormal distributions for these species.

Figure 2b. Assumed distributions for $M$ and $F_{M S Y} / M$ (left two columns), weighted average survey biomass (third column 2010-2012) and resulting OFL (fourth column) for 5 species of round fish.
