## Executive Summary

## Stock

This assessment applies to lingcod (Ophiodon elongatus) off the West Coast of the United States, and is conducted as two separate single stock assessment models, Washington and Oregon in the north, and California in the south. Four fisheries are modeled in the north: commercial trawl (including limited landings in other net gears), commercial fixed gears (including all line gears), and WA and OR recreational fisheries. Three fisheries are modeled in the south: commercial trawl (including limited landings in other net gears), commercial fixed gears (including all line gears), and CA recreational fisheries. Both models start during 1889, at the onset of landings.

## Landings

Historical commercial landed catch reconstructions were provided by each state that extend through 1995, 1986, and 1980 for Washington, Oregon, and California, respectively. Recent landings, from 1981 forward, were obtained from PacFIN. However, WDFW and ODFW staff advised that the catch reconstructions be used rather than PacFIN for overlapping years as the reconstructions are regarded as more reliable. Commercial landings were aggregated into two fleets: 1) vessels using primarily trawl gear, but also including other net gear that caught a small fraction of the fish, and 2) vessels using gear such as longline, troll, and hook and line, hereafter referred to as "fixed gear" vessels (Tables a and b, Figures a and b). Commercial discards were modeled using discard rate and length composition data to estimate retention curves, while estimates of recreational discards were included in the total landings. Landings declined significantly during 1980 to 2000, with trawl landings dominating the catch in the north, and recreational landings dominating the catch in the south. More recently landings in both regions have been increasing, with the recreational component of the landings growing in the north, and the recreational landings continuing to dominate in the south.

Table a. Recent landings, north. All units are in metric tons.

| Years | North Trawl <br> Gear | North Fixed <br> Gears | WA <br> Recreational | Oregon <br> Recreational | Total <br> Catch |

## Data and Assessment

This assessment uses the Stock Synthesis (SS) fisheries stock assessment model, version 3.30.03.07. Lingcod has been modeled using various age-structured forward-projection models since the mid-1990s, with the most recent assessments conducted during 2005 (Jagielo et al. 2005) and 2009 (Hamel et al. 2009). Base model data sets include: landings data from each fleet; commercial discard data from the West Coast Groundfish Observer Program (WCGOP), NMFS Triennial bottom trawl survey, NWFSC bottom trawl survey, the NWFSC Hook and Line survey, PacFIN commercial logbook CPUE, OR nearshore commercial CPUE, both WA and OR recreational CPUE (North Only), commercial, recreational, and research length composition data, and survey age composition data (including Conditional-age-at-length (CAAL) data from the NWFSC bottom trawl survey). Concerns regarding biased sub-sampling for age-determination from commercial and recreational samples lead to these age composition data being excluded from the base models. In this assessment the impact of the currently available age data are shown in model sensitivity runs. A research age and length composition data set from WDFW was also removed from the base model as the data set was limited and uninformative.

Of the key productivity parameters female natural mortality is fixed at the median of the prior, male natural mortality is estimated, and stock-recruit steepness is 0.7 , in keeping with the treatment of $h$ for similar nest guarding species (e.g. Kelp Greenling). Time-invariant, sex-specific growth is estimated in this assessment, with all SS growth parameters being estimated except for female length at maximum age in the north model. The $\log$ of the unexploited recruitment level for the Beverton-Holt stock-recruit function is treated as an estimated parameter. Annual recruitment deviations are estimated beginning in 1889, just prior to reliable length and age composition entering the models. Selectivities are estimated using the double normal pattern for all fleets and surveys. Retention is estimated for the commercial fishing fleets and is fit with time blocks to account for management changes.

A wide range of sensitivity model runs for both the north and south stocks produce similar trajectories of stock decline and recovery, generally agreeing that both north and south lingcod stocks have increased since a low point during the 1990s. In the north, the base model is most sensitive to the inclusion of the fishery age data sets. Including only the Washington and Oregon conditional age-at-length data from the recreational fishery results in a lower estimate of unfished biomass but a similar estimate of stock status. Including only the marginal commercial age composition data results in a higher estimate of unfished biomass but similar stock status. In the south, the model is sensitive to removing the research data set collected by Lam et al., which results in a much higher unfished biomass estimate but a similar estimate of stock status. The south model is highly sensitive to the inclusion of the CA onboard observer index. If the index is included (see south model sensitivities) the estimate of unfished stock size is similar to the base model but stock status that is well below the overfished threshold.

## Stock Biomass

Tables c and d , and Figures c through f show the trends in spawning biomass and stock depletion. The north base model indicates that the lingcod female spawning biomass off of Washington and Oregon declined rapidly in the 1980s and 1990s, hitting a low during the mid-1990s, and has subsequently recovered to levels above the target reference point ( $40 \%$ of the estimated unfished spawning biomass). The south base model indicates that the lingcod female spawning biomass off of California declined rapidly in the 1970s and early 1980s, reaching a low point during the 1990s, but that the southern stock has recovered above the minimum stock size threshold ( $10 \%$ of the estimated unfished spawning biomass) and remains in the precautionary zone (i.e. below the target reference point).

Stock status is currently estimated to be above the target reference point at $57.9 \%$ ( $47.9-67.8,95 \%$ asymptotic interval) in the north and in the precautionary zone at $32.1 \%$ (11.1-53.1, $95 \%$ asymptotic interval) in the south. Unfished spawning biomass was measured at $37,947 \mathrm{mt}$ ( $25,776-50,172 \mathrm{mt}, 95 \%$ asymptotic interval) in the north and $20,260 \mathrm{mt}(15,304-25,215 \mathrm{mt}, 95 \%$ asymptotic interval) in the south. Spawning biomass at the beginning of 2017 was estimated to be $21,976 \mathrm{mt}$ ( $12,517-31,434 \mathrm{mt}, 95 \%$ asymptotic interval) in the north and $6,509 \mathrm{mt}$ ( $1,624-11,394 \mathrm{mt}, 95 \%$ asymptotic interval) in the south. The north stock is estimated to have been below the target reference point from approximately the 1980s through the early 2000s, while the south stock is currently estimated to be in the precautionary zone (between $25 \%$ and $40 \%$ of the estimated unfished spawning biomass).

Table c. Recent trend in spawning biomass and stock depletion, north.

| Years | Spawning <br> Biomass $(\mathrm{mt})$ | $95 \%$ Asymptotic <br> Interval | 95\% Asymptotic <br> Interval |  |
| :---: | :---: | :---: | :---: | :---: |

## Recruitment

Recruitments in both the north and south were estimated from the model start (1889) through 2016 (Tables e and f, Figures g and h). Recruitments from 2017 forward are drawn exclusively from the stock-recruit curve, with corresponding levels of uncertainty. Large recruitment events in the north are estimated to have occurred during 1964-1965, 1969-1970, 1978-1980, 1985, 1990-1991, 2008, 2013 and 2015, while low recruitments were estimated to have occurred during 1986, 1996-1998, 2002-2007, 2011-2012, and 2014. Large recruitment events in the south are estimated to have occurred during 1961, 1973-1974, 1976-1977, and 1984-1985, while low recruitments were estimated to have occurred during 1981-1982, 1992-1993, 1995, 1997-1998, 2002-2009, and 2014-2016. It is notable that lingcod in the south have not had a recruitment near historical high values since the mid-1980s.

## Exploitation Status

Historical harvest rates rose steadily through the 1990s, exceeding the target spawning potential ratio (SPR) harvest rate for several decades (Tables g and h, Figures i through l). Estimated harvest rates for the north and south models have not exceeded management target levels in recent years (Tables g and h, Figures ithrough l). However, in the south during the early 2000s it appears that harvest rates exceeded the management target for two years. In recent years, the SPR for lingcod in both areas has been above the proxy target of $45 \%$ (indicating fishing mortality rates are below the target). The full exploitation histories in terms of both biomass and relative SPR, (1-SPR)/(1-SPR $45 \%$ ), are portrayed graphically via phase plots (Figures k and 1 ).

Table g. Recent exploitation status, north. Harvest rate is catch/Age-3+ summary biomass.

## Ecosystem Considerations

In this assessment, ecosystem considerations were not explicitly included in the analysis. Lingcod often feed on species of rockfish that are targeted by fisheries, potentially influencing the natural mortality of these rockfish species (e.g., Beaudreau and Essington 2007). However, there is a paucity of relevant data to provide quantitative information on this effect directly to the assessment. Recently available habitat information was used to select the data used in the onboard observer indices.

## Reference Points

The north and south stocks are estimated to have been below the target reference point (SB40\%) from approximately the 1980s through the early 2000s. Fishing intensity since approximately 2005 has been below the target (SPR45\%) for both the north and south stocks (Figures i-1). The phase plots show the interaction of fishing intensity and biomass targets (Figures k and l ). The target stock size based on the biomass target (SB40\%) is $15,190(10,311-20,069 \mathrm{mt}, 95 \%$ asymptotic interval) in the north and $7,780 \mathrm{mt}(5,877-9,683 \mathrm{mt}$ $95 \%$ asymptotic interval) in the south, which gives catches of $3197 \mathrm{mt}(2,184-4,210 \mathrm{mt}, 95 \%$ asymptotic interval) for the north and 1746 mt ( $1,372-2,121,95 \%$ asymptotic standard deviation) for the south (Tables i and j). Equilibrium yield at the proxy FMSY harvest rate is $3,409 \mathrm{mt}(2,329-4,489 \mathrm{mt}, 95 \%$ asymptotic interval) and $1,856 \mathrm{mt}(1,458-2,253 \mathrm{mt}, 95 \%$ asymptotic interval) for the north and south, respectively (Tables i and j).

## Management Performance

The 2009 stock assessment estimated lingcod to be at $61.9 \%$ and $73.7 \%$ of unfished spawning stock biomass in the north and south, respectively. Based on the 2009 stock assessment, the most recent 2017 and 2018 annual catch targets (ACTs) were set to 3066.4 and 2861.2 in the north and 1517.6 and 1392.8 in the south. Note that these values are based on $48 \%$ of the CA biomass being in the 40-10 to 42 region. This value is based on the 5 year average biomass distribution in the NWFSC West Coast Groundfish Bottom Trawl Survey (WCGBTS). Recent coast-wide annual landings have not exceeded the annula catch limit (ACL). Table k shows recent management quantities.

Table k. Recent trends in landings and total catch (mt) relative to management guidelines. Total dead catch represents the total landings plus the model estimated dead discard biomass. Note that the model estimated total dead catch may not be the same as the WCGOP estimates of total mortality (Somers et al. 2017), which are the "official" records for determining whether the ACL has been exceeded.

## Unresolved Problems and Major Uncertainties

A few outstanding issues remain for lingcod stock assessment on the west coast of the U.S. First, in many cases the commercial age data are not randomly sampled with respect to lengths, there is evidence of bias in some years with respect to age sampling. One option for dealing with this situation includes resampling the ages to ensure that they are representative of the sampled lengths. However, the SSC should agree an acceptable range of options for dealing with this issue prior to the 2019 stock assessment cycle. While this issue was not able to be fully resolved at the STAR panel, a resolution is possible for the next lingcod assessment. Future assessments should also investigate implementing a spatial model that considers the results of ongoing genetic analyses with respect to lingcod stock structure and that is able to explore linkages between the north and south regions. Current publications on lingcod stock structure suggest that lingcod are a single genetic stock but show differences in biological traits, such as growth and allometry, which may be attributable to physical and ecological differences across this large geographic expanse. There is evidence that the recreational lingcod fishery in California is landing fish taken from Mexican waters. Landings of lingcod from Mexican waters need to be removed from the U.S. landings in future lingcod assessments. The south model also lacks fishery dependent age data due to a lack of sampling for age structures, which increases uncertainty in the south area model estimates. Finally, it would be useful to explore the availability of transboundary lingcod data (both Canada and Mexico) and how these data could be used in the PFMC stock assessment process. Both of these issues require communications and research activity outside of the PFMC stock assessment cycle. Time limitations during this assessment did not allow for exploration of Canadian lingcod data or inclusion in the assessment model. Mexico may also have relevant lingcod data but this has not been investigated. Given that a majority of the jitter runs were unable to converge to the south base model, this issue should be investigated during future lingcod south assessments. Finally, the south model lacks fishery dependent age data. Obtaining recreational fishery data from California could provide improved information on recent stock trends.

## Harvest Projections and Decision Table

The lingcod stock assessments are Category 1 stock assessments, thus projections and decision tables are based on using $\mathrm{P}^{*}=0.45$ and sigma $=0.36$, resulting in a multiplier on the over fishing limit (OFL) of 0.956 (PFMC preferred option). Stock projections for the south are also provided for the PFMC default management option, and use an OFL multiplier of 0.913. The OFL multipliers are combined with the $40-10$ harvest control rule to calculate OFLs, ABCs and ACLs. The total catches in 2017 and 2018 were set at the PFMC groundfish management team (GMT) requested values of $\sim 1000 \mathrm{mt}$ in the north and 750 mt in the south, the average 20152017 exploitation rate was used to distribute catches among the fisheries.

Table 1 shows stock projections of management quantities, as requested by PFMC council staff, for both the stock assessment areas and converted to the management areas under alternative harvest policies requested by the PFMC. Note that the conversion between stock assessment areas and management areas assumes that $20.31 \%$ of the CA biomass is in the $40-10$ to 42 region. This value is based on the 5 year average biomass distribution in the NWFSC West Coast Groundfish Bottom Trawl Survey (WCGBTS).

Standard harvest projections that include both management quantities and trends in stock size and status are provided in Tables $\mathrm{m} 1, \mathrm{~m} 2$, and m 3 . In the north, current medium-term projections of expected catch, spawning biomass and depletion from the base model project a declining trend through 2028 as recent large cohorts increase in age (note that all projections assume average recruitment from the stock-recruit curve) and the 40-10 control rule ACLs move the stock towards the target reference point. The stock is expected to remain above the target stock size of $\mathrm{SB}_{40 \%}$ through 2028, assuming average recruitment based on the stock-recruit curve. In the south, the current medium term projection of expected catch under both harvest policies, shows increasing
spawning biomass and depletion from the base model, with the stock remaining in the precautionary zone during the projection period. Note that the difference in final stock status (depletion) between the council preferred and default options is $<1 \%$. The lack of strong increases in stock sizes during the projections is due, in part, to a large number of poor recruitments since 2000 ( 11 out of 17 years) and a lack of recruitments near historical highs.

Decision tables are provided in Tables n and o . Uncertainty in management quantities for the north and south models was characterized using the asymptotic standard deviation for the 2017 spawning biomass from the base model. Specifically, the 2017 spawning biomass for the high and low states of nature are given by the base model mean $+/-1.15 *$ standard deviation (the 12.5 th and 87.5 th percentiles). A search across fixed values of Ro was used to attain the 2017 spawning biomass values for the high and low states of nature. The high catch streams were based on the 40-10 harvest control rule. At the request of the PFMC GMT representative on the STAR panel the moderate catch streams were set to $40 \%$ ACL attainment for the north management area and $70 \%$ ACL attainment in the south management area. Finally, the low catch stream was set to $\sim 700 \mathrm{mt}$, a level similar to recent average catches.

In the north, current medium-term forecasts based on the alternative states of nature project that the stock will fall below the target stock size in only one case, in which the current control rule is applied to the low stock state of nature (bottom left corner of the table). Note that the catches specified in the above scenario (ranging from 4497 to 3542 mt ) are much larger than recent landings ( $\sim 700 \mathrm{mt}$ ). All other decision table scenarios keep the stock near or above the target stock size. In the south, current medium-term forecasts based on the alternative states of nature project a range of outcomes from overfished (lower left corner) to well above target stock size (upper right corner). All states of nature from the constant catch scenario, that specifies catches similar to recent levels, suggest that the stock will increase towards, or exceed the target reference point. However, catching the full ACL catches result in stock declines at the low state of nature and modest stock increases under the base case and high state of nature.

Table 1. PFMC requested management options: 1) preferred harvest control rule (HCR) (Alt. 1) and 2) default HCRs (No Action Alt.) for 2019 through 2026, all units are in metric tons. Note that the south area ACL has the $40-10$ control rule catch reduction applied because the stock is estimated to be in the precautionary zone. The both HCRs implement a GMT request to assume partial attainment of the 2017-2018 ACLs of 1000 mt in the north model area and 750 mt in the south model area and assume full ACL attainment from 2019 forward. The preferred HCR implements buffers of 0.956 in the north and south. The default HCR implements buffers of 0.956 and 0.913 , respectively.

## Research and Data Needs

Most of the research needs listed below entail investigations that need to take place outside of the routine assessment cycle and require additional resources to be completed.

1. Age validation of lingcod aging is needed to verify the level of age bias, if any.
2. A transboundary stock assessment and the management framework to support such assessments would be beneficial.
3. A survey in untrawlable habitat and/or a near shore survey would improve this stock assessment. Other survey techniques could include longline, combined lingcod/sablefish pot survey, or trap surveys.
4. Investigate environmental covariates for recruitment and time-varying growth and availability inshore.
5. The impact of nest-guarding on reproductive output should be investigated. The current assessment focuses on female spawning biomass as the limiting factor in reproductive output, but nest guarding by lingcod males and the availability of nesting habitat may also play roles. A cursory look at the sex ratio in the catch did not appear to indicate any serious changes for either north or south populations in recent years. However, we do not know what kind of change in sex ratio would indicate a serious change in reproductive success.
6. Investigation of the proportion of fish caught in Mexico and landed in U.S. ports as there is evidence that California recreational fisheries, primarily out of San Diego, are fishing in Mexican waters. These catches should be allocated appropriately between U.S. and Mexican waters.
7. Given that a majority of the jitter runs were unable to converge to the south base model, this issue should be investigated during future lingcod south assessments.
8. The south model lacks fishery dependent age data. Obtaining recreational fishery data from California could provide improved information on recent stock trends.

## Rebuilding Projections

Lingcod stocks in the California Current are not overfished and do not require rebuilding analyses.

Table n . North model decision table of 12-year projections for alternate states of nature (columns) and management options (rows). Summary of model outputs for the preferred council HCR, north (WA + OR). Uncertainty in management quantities for the north and south models was characterized using the asymptotic standard deviation for the 2017 spawning biomass from the base model. Specifically, the 2017 spawning biomass for the high and low states of nature are given by the base model mean $+/-1.15^{*}$ standard deviation (the 12.5th and 87.5 th percentiles). A search across fixed values of Ro was used to attain the 2017 spawning biomass values for the high and low states of nature. The total catches in 2017 and 2018 were set at the GMT requested values of $\sim 1000 \mathrm{mt}$.

Table q. Summary of model outputs, south model area (CA). Note that exploitation rate is Catch/(Age-3+ biomass).

## Introduction

This assessment applies to lingcod (Ophiodon elongatus) off the West Coast of the United States, and is conducted as two separate single stock assessment models, Washington and Oregon in the north, and California in the south. This is the same approach implemented in recent lingcod assessments. Four fisheries are modeled in the north: commercial trawl (including limited landings in other net gears), commercial fixed gears (including all line gears), and WA and OR recreational fisheries. Three fisheries are modeled in the south: commercial trawl (including limited landings in other net gears), commercial fixed gears (including all line gears), and CA recreational fisheries. Both models start during 1889, at the onset of landings. These areas were chosen due to latitudinal trends in weight-length and growth relationships observed in the Northwest Fishery Science Center (NWFSC) survey data, evidence that lingcod do not generally move across large areas (tagging data suggest the scale of movement is at tens of kilometers), little stock connectivity at moderate ( $\sim 10 \mathrm{~km}$ ) to large ( $\sim 1000 \mathrm{~km}$ ) scales (Marko et al. 2007), and different fleet structures and sampling programs between the states. While there is evidence for a limited demographic connectivity at moderate to large scales ( $\sim 100-1000 \mathrm{~km}$ ) along the coast, analysis of genetic variation indicates that lingcod are genetically similar throughout their range (Marko et al. 2007).

## Life History and Ecosystem Considerations

Lingcod (Ophiodon elongatus, family Hexagrammidae) are large opportunistic top predators in the nearshore demersal ecosystem of the northeast Pacific Ocean and are valued both commercially and recreationally in the U.S. groundfish fishery. They range from Kodiak Island, Alaska down to Baja California, Mexico, though abundance tapers off quickly south of Point Conception (Wilby 1937, Hart 1973). The historical center of abundance is off of British Columbia and Washington State (Hart 1973). While the NWFSC survey catches lingcod up to depths of approximately 450 m , they typically occur at depths of less than 200 meters. Lingcod are demersal on the continental shelf, display a patchy distribution and are most abundant in areas of hard bottom with rocky relief (Rickey 1991). Studies using DNA markers (Marko et al. 2007) have found that lingcod are genetically similar throughout their coastal range, suggesting extensive gene flow among populations throughout the West Coast. Through 2010 the lingcod stock was managed as a coast-wide population, during 2011 and 2012 lingcod were managed as having a Northern population (Washington and Oregon), and a Southern population (California), finally during 2013 to present northern and southern lingcod populations have been managed with a break at 40 degrees 10 minutes north latitude.

Lingcod are sexually dimorphic, with females typically attaining larger sizes ( $L \infty=131 \mathrm{~cm}$ for females and $L \infty=93 \mathrm{~cm}$ for males sampled off of British Columbia) (Richards et al. 1990). Female lingcod reach maturity at larger sizes, between 3-5 years of age, while males are smaller, grow faster initially (before sexual maturation), and reach maturity earlier at 2 years (Miller and Geibel 1973, Cass et al. 1990). Growth rate and size at maturity has been seen to vary regionally, with lingcod off Washington waters growing slower and maturing at larger sizes (females at 64 cm , males at 52 cm ) than lingcod from warmer waters in California (females 59 cm ; males 40 cm ) (Richards et al. 1990, Silberberg et al. 2001). Given that the age at maturity does not differ significantly between the regions, the observed geographic differences in size at maturation are likely attributed to spatial variation in growth rates.

In the late fall, male lingcod aggregate and become territorial in areas suitable for spawning, these areas are generally in shallower water with rocky high relief habitat. The proportion of male lingcod sampled from offshore trawl landings declines in the late fall, suggesting a pre-spawning departure of males from the trawl grounds (Miller and Geibel 1973 (California), Cass et al. 1990 (British Columbia), Jagielo 1994 (Washington)). Males are in spawning condition earlier in the year than females, and it appears that larger and older females
spawn first (Cass et al. 1990). Mature females are rarely seen on the spawning grounds and appear to move into spawning areas for only a brief period to deposit eggs (Giorgi 1981). Spawning behavior has been reported from the intertidal zone to a depth of 126 m (Giorgi 1981, O’Connell 1993). Spawning typically begins in early December, with the observed timing of peak spawning activity ranging from January (Wilby 1937) to early March (La Riviere et al. 1981). However, recent maturity studies suggest that lingcod are batch spawners with ability to spawn year round, with, peak spawning taking place during October - December (pers. comm, Melissa Head, NWFSC). Mature females move in from deeper offshore areas (100-200 m) to shallow (10-40 m) rocky habitats to deposit eggs in favorable nesting sites (Wilby 1937). Mature males will initially select and guard optimal nesting areas, crevices or rocky outcrops with high flow, before the arrival of spawning females. After eggs are deposited, female lingcod will return to depth, leaving the male to guard the eggs until they hatch, usually between 5-7 weeks (Low and Beamish 1978, Miller and Geibel 1973). Nest guarding by males has been shown to be imperative for egg survival by protecting against opportunistic fish predators like perches (Embiotocidae), greenlings (Hexagrammidae), and sculpins (Cottidae) (Jewell 1968). Males appear to be more effective at guarding the nest from predation by vertebrates than by invertebrates (La Riviere et al. 1981, Low and Beamish 1928). In experiments where males were removed from nests, new males sometimes assumed a guardian role, but in one removal experiment, 4 of 7 nests were lost to predators within 22 days. (Low and Beamish, 1978). Ambient oxygen levels (Giorgi 1981), salinity and temperature affect egg survival as well (Cook et al. 2005).

Eggs hatch between January and June (Jewell 1968, Low and Beamish 1978). Upon hatching, the larvae are about 12 mm in total length and become epipelagic until they reach about 70 mm and settle to soft bottom habitats (Phillips and Barraclough 1977, Cass et al. 1990). Larvae in the Strait of Georgia first appear in the plankton in late February. Numbers peak in late April. Larvae were concentrated in the upper 3 m of the water column by day and disperse or migrate to deeper depths at night. Larvae begin to disappear from the upper water column by late May to early June and become demersal at about $70-80 \mathrm{~mm}$ and at about 3 months of age. Epipelagic larvae feed on small copepods and copepod eggs, shifting to larger copepods and fish larvae as they grow (Phillips and Barraclough 1977).

At about 3 months old, juveniles settle on sandy bottom areas near eelgrass or kelp beds. Juvenile lingcod will stay on the soft bottom until they grow to at least 350 mm in length, when they move into rocky areas with high relief as protection from large predators (Petrie and Ryer 2006). By age 1 or 2, lingcod move into rocky habitats similar to those occupied as adults, but shallower. Fishery and survey data indicate that male lingcod tend to be more abundant than females in shallow waters, and the size of both sexes increase with depth (Jagielo 1994). Newly settled juveniles have been sampled nearshore in June on sandy bottom areas near eelgrass or kelp beds (Buckley et al. 1984), and have been found at depth ranging from 20m in Canada (Phillips and Barraclough 1977) to 55 m in California (Miller and Geibel, 1973). In Washington, juveniles have been collected from the mouth of the Pysht River in the Strait of Juan de Fuca, from Grays Harbor and Willapa Bay, and from coastal waters nearshore to these embayments (Buckley et al. 1984, Jagielo 1994). Coley et al. (1986) found juvenile lingcod in Grays Harbor in October, over hard bottom shell-cobble habitat near rocks in $9-15 \mathrm{~m}$ of water.

Outside of spawning season, male and female lingcod are segregated by depth where females tend to inhabit deeper offshore waters and males inhabit nearshore rocky reefs. Consequently, each sex is vulnerable to different types of fishing gear. The majority of nearshore males ( $66.3 \%$ ) are caught using hook-and-line or spearfishing gear, and a majority of deep water females ( $62.4 \%$ ) are caught by trawl gear (Miller and Geibel 1973). Miller and Geibel (1973) reported that juvenile lingcod in California are about 35 cm in length ( 1 year old) when they first move into nearshore rocky areas typical of adult habitat. Surveys off the west coast of Vancouver Island suggest that juveniles move from inshore areas to a wider range of flat bottom areas by September (Cass et al. 1990), and begin to move into habitats of similar relief and substrate as adult lingcod by
age 2, but remain at shallower depths. Juvenile lingcod feed on small fishes including herring (Clupea pallasii), Pacific sand lance (Ammodytes hexapterus), flatfish (Pleuronectidae), shiner perch (Cymatogaster aggregate), and walleye pollock (Theragra chalcogramma), and an assortment of invertebrates including shrimp (Neomysis macrops) and prawns (Pandalus danae) (Cass et al. 1990).

Phillips and Barraclough (1977) estimated that young-of-the-year (YOY) growth was approximately 1.3 $\mathrm{mm} /$ day. Buckley et al. (1984) reported YOY growth from June to September in the Strait of Juan de Fuca also averaged $1.3 \mathrm{~mm} /$ day. Samples from the mouth of the Pysht River averaged 96 mm in June, 135 mm in July, 173 mm in August and 200 mm in September (Jagielo 1994).

The movement and migration of lingcod has been extensively studied through tag-recapture methods and acoustic arrays. As adults, lingcod have a high degree of site fidelity and tend to stay within an 8 km home range. In Cape Flattery, Washington, Jagielo (1990) reported that $80.7 \%$ of tagged fish were recovered $<8 \mathrm{~km}$ from their original release site though recaptures came from as far north as Queen Charlotte sound ( 195 km ) and as far south as Cape Falcon ( 120 km ). U.S. and Canadian tagging studies have demonstrated movement between coastal areas off Washington and southwest Vancouver Island. However, there is little interchange between these areas and the inland marine waters of Puget Sound and the Strait of Georgia (Cass et al. 1990, Jagielo 1990). Most fish recovered in tagging studies are found near the point of release, but some exceptional movements have been reported. Cass et al. (1990) found that $95 \%$ of fish recovered from a tagging study off the west coast of Vancouver Island were recaptured near the point of release. One fish tagged as a juvenile was recovered 510 km to the south in Oregon. Jagielo (1990) reported that only 19\% of recoveries were further than 10km from the release point at Cape Flattery, Washington. However, recaptures came from as far north as Queen Charlotte sound ( 195 km ) and as far south as Cape Falcon (120 km). Starr et al. (2005) in Alaska and Greenley (2009) in Central California used acoustic tags for tracking lingcod movement and both observed that while lingcod exhibit high site fidelity with an established location of residence, they frequently leave for brief periods of time ( $1-5$ days) over short distances ( 2 km ) to feed, then return home for a longer duration. Large females generally had shorter residency times, spending more time outside of their tagged site. Additional acoustic studies by Bishop et al. (2010) and Stahl et al. (2014) in Prince William Sound have reported that younger individuals ( $2-4$ year olds, around 50 cm ) disperse from nearshore reefs during spawning season, most likely due to displacement by older and larger spawning individuals. Overall, residency times appear vary by sex, size, season, and habitat of residence.

There are no clear stock delineations for lingcod in U.S. waters. No distinct breaks are seen in the fishery landings, catch distributions, or survey data, although latitudinal trends in life history parameters are apparent. Genetic studies have found coastal lingcod populations to be genetically similar throughout their range (Jagielo et al. 1996). More recent analyses indicate limited genetic changes in the stock along the coast, but no distinct stock breaks. Marko et al. (2007) found surprisingly little connectivity between stocks at moderate ( $\sim 10 \mathrm{~km}$ ) to large ( $\sim 1000 \mathrm{~km}$ ) ranges, suggesting that regionally structured assessments are appropriate.

Lingcod are top order predators of the family Hexagrammidae. Among the Hexagrammidae, the genus Ophiodon is ecologically intermediate between the more littoral genera Hexagrammos, Agrammus and Oxylebius and the more pelagic Pleurogrammus (Rutenberg 1962). Lingcod are opportunistic predators, feeding on a variety of fishes (pelagic and demersal), cephalopods, and crustaceans (Wilby 1937). Juvenile lingcod in soft bottom habitats prey upon small fishes including herring (Clupea pallasii), Pacific sand lance (Ammodytes hexapterus), flatfish (Pleuronectidae), shiner perch (Cymatogaster aggregata), and an assortment of invertebrates including shrimp (Neomysis macrops) and prawns (Pandalus danae) (Cass et al. 1990). As juvenile lingcod begin to move into rocky habitats and exceed 30 cm TL, rockfishes (Sebastes spp.) become a more prominent component of their diet, making up $19 \%$ of total prey biomass by weight. Rockfish biomass in
lingcod diet increases by three-fold for lingcod found inside marine reserves (Beaudreau and Essington 2007). Preliminary observations (B. Brown, Moss Landing Marine Laboratories, personal communication, 6 April 2017) from lingcod stomachs contents sampled from Washington to California in both nearshore and offshore habitats indicate a higher occurrence of bony fishes from Washington and Oregon waters, and a higher occurrence of cephalopods in lingcod from California waters with an overlapping region near southern Oregon. This latitudinal shift in prey composition suggests differences in feeding behavior and the predatory role of lingcod in coastal environments.

## Map

Figure 1a shows the geographic scope of the assessment and depicts boundaries for fisheries and data collection strata. The stock assessment is split into two areas, north and south of the California border.

## Historical and current fishery

Lingcod fisheries have a long history, with the earliest evidence of lingcod fishing coming from the remains of 51 archaeological sites representing the period between 6200 BC and 1830 AD on the central California coast from San Mateo to San Luis Obispo (Gobalet and Jones 1995). More recently, the commercial fishery off of California dates back more than a century, and the fishery off of Washington and Oregon dates back nearly as far. Recorded commercial and recreational take of lingcod began during the 1920s in southern California, then Oregon and Washington later during the 1940s.

Lingcod are harvested commercially by trawl and longline gear, and recreationally by hook-and-line and spear (see executive summary figures $a$ and $b$ ). The fishery steadily grew with the rise of the groundfish trawl industry, reaching peak landings during in the early 1980s. Landings decreased during the late 1980s due to population declines and the implementation of seasonal closures and size limits. During 1999 the lingcod fishery was declared overfished coast-wide. With the combination of a federal rebuilding plan implemented during 2003 and favorable ocean conditions for lingcod recruitment, the population was deemed recovered in 2005, four years ahead of the projected recovery time.

In California, the recreational lingcod fishery has substantial landings that have surpassed that of the CA commercial fleet since 1998. At the peak of the lingcod fishery during 1974, the landings were nearly equally divided between the commercial and recreational fleets. From 1980 to 2008, $95 \%$ to $97 \%$ of lingcod caught were taken by boat-based anglers (commercial passenger fishing vessel, CPFV, and private/rental boats). Private boat landings (including kayaks) were higher than those from CPFVs. A small fraction of landings are from spear fishers using SCUBA or free diving gear (Lynn 2008).

Catches of lingcod in Oregon and Washington have shifted from the commercial trawl fleet, accounting for $90 \%$ of landings during its mid-1980s peak, to a fishery evenly split between commercial and recreational in recent years. Between 1980 and 1996, the majority of lingcod were caught by the bottom trawl fishery ( $>75 \%$ ), followed by troll and hook-and-line (between 10-20\%), with a small fraction of additional landings from pots and traps, nets, and shrimp trawls (Jagielo et al. 1997). From 1999 to 2016, however, the recreational fishery has contributed about half of all lingcod landings, on average.

## Management history and performance

Prior to 1977 , lingcod stocks in the northeast Pacific were managed by the Canadian Government within its waters, and by the individual states in waters (out to three miles) off of the United States. With implementation
of the Magnuson-Stevens Fishery Conservation and Management Act (MSA) in 1976, primary responsibility for management of the groundfish stocks off Washington, Oregon and California shifted from the states to the Pacific Fishery Management Council (PFMC). The U.S. west coast allowable biological catch (ABC) for lingcod was set at $7,000 \mathrm{mt}$, but catch was consistently below this level. In 1994, a harvest guideline (HG) of $4,000 \mathrm{mt}$ was set. In 1995, both the ABC and HG were dropped to $2,400 \mathrm{mt}$ based on a quantitative assessment (Jagielo et al. 2000). Trip limits on commercial Lingcod catch were first instituted in 1995, when a 20,000 lbs. /month limit was imposed, and a minimum size was imposed for recreational fisheries of 22 inches. During 1998 to present, individual year ABC and OY levels were set, commercial trip limits became much more restrictive (starting at $1,000 \mathrm{mt} / 2$ months in 1998), and recreational bag limit were set at 2 (or 1 ) lingcod with minimum sizes ranging from 22 to 30 inches.

PFMC implemented an initial Lingcod Rebuilding Plan in 2000 with size and seasonal limitations in the recreational fishery and a change to limited entry and open access sectors in the commercial fishery. The coastwide ABC was further reduced by $27.1 \%$ ( 700 mt , down from 960 mt ). In the commercial fishery sector, harvest guidelines in 2000 were reduced by over $80 \%$ from 1998 limits. In order to achieve these low harvest goals, all commercial fishing for lingcod was closed for six months (January to April, and November to December). During the open period between April and November, all commercial vessels were limited to 400 pounds per month, and lingcod landed by non-trawl vessels south of Cape Mendocino had a minimum size limits of 26 inches long, and 24 inches long in all other areas. During the rebuilding period between 2000 and 2005, cumulative trip limits were very low at 800 pounds for every 2 months with frequent closures.

After 2006, the population had rebuilt, and the ABC and trip limits began rising, with a bimonthly limit of 1,200 pounds. Concurrently, Marine Protected Areas (MPAs) in California, Rockfish Conservation Area (RCA) and Cowcod Conservation Area (CCA) were implemented, prohibiting take of all groundfish within specified depths, habitats, and locations.

During 2011, the limited entry trawl sector became a catch share program with $100 \%$ observer coverage, while during the period 2002 to 2011 observed trips were chosen by random stratified sampling. The Trawl Catch Share Program requires $100 \%$ at-sea observer coverage since all catch of Individual Fishing Quota (IFQ) species must be accounted for to allow fishers and managers to track and monitor their individual quotas.

The first recreational regulations for lingcod were set in 1994, with a bag limit of 3 fish in Washington and Oregon, 5 fish in California, and coast-wide size limit of 22 inches. In 1998, the bag limit in all three states dropped to 2 fish per day at 24 inches, where it largely remained until 2008. Regulations in California fluctuate frequently, where during the stock rebuilding period between 2000 and 2004 the California recreational bag limit dropped to 1 fish per day, and the size limit increased from 26 inches to 30 inches. In 2015, the bag limit was increased to 3 fish per day in California, 2 fish per day in Oregon and Washington, and a size limit of 22 inches. Most recently, the bag limit in California has decreased back to 2 fish per day.

Summaries of regulatory histories for both federal and state management actions are available as supplementary materials to this stock assessment. See table k in the executive summary for a recent history of OFLs, ACLs, landings, and catch (landings plus discards) for each area.

## Fisheries off of Alaska, Canada, and Mexico

Lingcod fisheries in the Gulf of Alaska are managed in state waters by the State of Alaska Board of Fisheries and in federal waters by the North Pacific Management Council. The sport fishery is restricted by daily bag and
possession limits. Commercial fisheries are restricted by catch and bycatch quotas. Lingcod are a non-target species in the subsistence fishery. No formal lingcod stock assessment has been done in Alaskan waters.

Lingcod in Canada are managed under the Pacific Integrated Goundfish Fishery by the Department of Fisheries and Oceans for take by First Nations and the commercial and recreational sectors. Beginning in 1997, the Canadian commercial groundfish trawl fishery implemented an IVQ (Individual vessel quota) program that now incorporates all commercially caught trawl and hook and line groundfish. Stocks in distinct management areas are regularly assessed, with the most recent lingcod assessment in outer British Columbia waters in 2011, and in the Strait of Georgia in 2014 (DFO, 2016). The 2011 assessment implements a Bayesian surplus production model to assess lingcod stock status within four assessment areas. Overall the stock appears to have remained stable from 1927-1970, declined until 1980, increased until 1990 and has continued to decline since then. However the stock is still estimate to be healthy with respect to reference points. The 2016 assessment implement a two-sex statistical catch-at-age model in a Bayesian model. Results suggest that spawning biomass in 2014 is greater than spawning biomass at the start of the current management regime during 2006, and that the stock is likely in a precautionary management zone.

Southern CA recreational fishers have reported fishing in Mexican waters and landing fish in U.S. ports. This is an issue that requires further investigation. There are no known Mexican stock assessments for lingcod.

## 2. Data

The following sources of data were used in building this assessment, which is partitioned into two independent assessment areas: a northern area for WA and OR and a southern area for CA:

1. Fishery independent data including bottom trawl survey-based indices of abundance and biological data (age and length) from the NWFSC survey and AFSC Triennial survey.
2. Research length and age composition data from WDFW (north model only) and L. Lam (pers. Comm.)
3. Estimates of fecundity, maturity, length-weight relationships and ageing error from various sources.
4. Commercial landings, length, and age composition data.
5. Estimates of commercial discard length frequencies and fraction discarded in the fishery obtained from the West Coast Groundfish Observer Program (WCGOP).
6. Recreational landings, length, and age composition data.
7. Commercial and recreational fishery CPUE.

Data availability by source and year is presented in Figures 2 and 3 as well as in the more detailed data sections below. A description of each of the specific data sources follows.

## Fishery Independent Data: NWFSC WCGBTS trawl survey

Three sources of information are produced from the West Coast Groundfish Bottom Trawl Survey (WCGBTS): an index of relative abundance, length-frequency distributions, and age-frequency distributions. Only years in which this survey included the continental shelf are considered (2003 forward), since lingcod are primarily a shelf species.

The WCGBTS is based on a random-grid design, covering the coastal waters from a depth of 55 m to $1,280 \mathrm{~m}$ (Keller et al. 2007). This design uses four industry chartered vessels per year, assigned to a roughly equal number of randomly selected grid cells and divided into two 'passes' of the coast that are executed from north to south. Two vessels fish during each pass, and survey tows are conducted from late May to early October each year. This design therefore incorporates both vessel-to-vessel differences in catchability as well as variance
associated with selecting a relatively small number ( $\sim 700$ ) of possible cells from a very large set of possible cells spread from the Mexican to the Canadian border. Much effort has been expended on appropriate analysis methods for this type of data, culminating in the West Coast trawl survey workshop held in Seattle in November, 2006.

Data from the WCGBTS are analyzed using a spatio-temporal delta-model (Thorson et al. 2015), implemented as an R package titled VAST (Thorson and Barnett 2017) and publicly available online (https://github.com/James-Thorson/VAST). This method for constructing survey abundance indices was reviewed, endorsed, and recommended by the Pacific Fishery Management Council's Scientific and Statistical Committee (SSC). The particular VAST model applied to the survey data includes spatial and spatio-temporal variation in both encounter probability and positive catch rates, a logit-link for encounter probability, and a loglink for positive catch rates. Vessel-year effects are included for each unique combination of vessel and year in the database, to account for the random selection of commercial vessels used during sampling (Helser et al. 2004, Thorson and Ward 2014). Spatial variation is approximated using 250 knots, and the bias-correction algorithm (Thorson and Kristensen 2016) in Template Model Builder (Kristensen et al. 2016) is used. Further details regarding model structure are available in the user manual (https://github.com/JamesThorson/VAST/blob/master/examples/VAST_user_manual.pdf). To confirm convergence of the model estimation algorithm, we checked that the Hessian matrix is positive definite and that the absolute-value of the final gradient of the log-likelihood with respect to each fixed effect was $<0.0001$ for each fixed effect. We selected among two alternative model configurations, i.e., treating positive catch rates as following a lognormal or gamma distribution. Following advice from the Science and Statistical Committee, we used the following three diagnostics for model fit:

1. The Quantile-Quantile plot, generated by comparing each observed datum with its predicted distribution under the fitted model, calculating the quantile of that datum, and comparing the distribution of quantiles with its expectation under a null model (i.e., a uniform distribution). This Q-Q plot shows no evidence that the model fails to capture the shape of dispersion shown in the positive catch rate data (Figure 4).
2. A comparison of predicted and observed proportion encountered when binning observations by their predicted encounter probability. This comparison shows no evidence that encounter probabilities are over-estimated for low-encounter-probability observations, or vice versa (Figure 5).
3. A visualization of Pearson residuals for encounter probability and positive catch rates associated with each knot. This comparison shows no evidence of residual spatial patterns for either model component (Figures 6 and 7).

VAST indices were calculated from separate model runs for the both north and south model areas, covering the extent of lingcod observations in the survey, the lognormal model was selected (Table 2 and Figure 8). The survey biomass density (weight per area swept) was a function of year, latititude, longitude, and vessel-year. Note that a single area model run initially used to produce the indices was nearly identical to the separate area VAST model run. Trends for the north and south areas are similar. Note that the VAST indices were compared with the survey design based index, these indices were similar. Additional tables with VAST model output and a comparison with the design based indices are available in Appendix I.

Length bins in 2 cm increments from 10 to 130 cm in the north and 4 to 130 cm in the south were used to summarize the length frequency of the survey catches in each year. The first bin includes all observations less than 10 cm and 4 cm for the north and south, respectively, and the last bin includes all fish larger than 130 cm . The observed length compositions were expanded to account for subsampling tows by expanding each length sample from a tow to represent the entire tow by dividing the total lingcod catch weight by the total weight of
lingcod measured for length and multiplying the observed length frequencies by the expansion factor, the resulting length frequencies are then summed. Figures 9 and 10 show the length frequency distributions for the WCGBTS north and south areas. Tables 3 and 4 show sample sizes.

Age-frequency data from the WCGBTS (Figures 11 and 12) were included in the model as conditional age-atlength distributions by sex and year, and therefore were not expanded. Individual length- and age-observations can be thought of as entries in an age-length key (matrix), with age across the columns and length down the rows. The approach consists of tabulating the sums within rows as the standard length-frequency distribution and, instead of also tabulating the sums to the age margin, the distribution of ages in each row of the age-length key is treated as a separate observation, conditioned on the row (length) from which it came. This approach has several benefits for analysis above the standard use of marginal age compositions. First, age structures are generally collected as a subset of the fish that have been measured. If the ages are to be used to create an external age-length key to transform the lengths to ages, then the uncertainty due to sampling and missing data in the key are not included in the resulting age-compositions used in the stock assessment. If the marginal age compositions are used with the length compositions in the assessment, the information content on sex-ratio and year class strength is largely double-counted as the same fish are contributing to likelihood components that are assumed to be independent. Using conditional age distributions for each length bin allows only the additional information provided by the limited age data (relative to the generally far more numerous length observations) to be captured, without creating a 'double-counting' of the data in the total likelihood. The second major benefit of using conditional age-composition observations is that in addition to being able to estimate the basic growth parameters ( $L_{\text {minAge }}, L_{\text {maxAge }}, K$ ) inside the assessment model, the distribution of lengths at a given age, governed by two parameters for the standard deviation of length at a young age and the standard deviation at an older age, is also quite reliably estimated. This information could only be derived from marginal age-composition observations where very strong and well-separated cohorts existed and where they were quite accurately aged and measured; rare conditions at best. By fully estimating the growth specifications within the stock assessment model, this major source of uncertainty is included in the assessment results, and bias in the observation of length-at-age is avoided. Therefore, to retain objective weighting of the length and age data, and to fully include the uncertainty in growth parameters (and avoid potential bias due to external estimation where size-based selectivity is operating) conditional age-at-length compositions were developed using the WCGBTS age data.

Age distributions included bins from age 0 to age 20+, with the last bin including all fish of greater age. Note that these survey age data are used as CAAL and, therefore, are not expanded. The numbers of fish are used without any adjustment. These data show the growth trajectory of females reaching a maximum size between $120-130 \mathrm{~cm}$ and males reaching a maximum size of about $80-90 \mathrm{~cm}$. Tables 5 and 6 show sample sizes.

## Fishery Independent Data: Triennial trawl survey

The Triennial Shelf Trawl Survey that was conducted every third year from 1977-2004 is the second source of fishery-independent data regarding the lingcod abundance (Dark and Wilkins 1994). However, the 1977 data were not used due to concerns about the first year of the survey's implementation. The sampling methods used in the survey over the 21-year period are most recently described in Weinberg et al. (2002). The basic design was a series of equally spaced east-west transects from which searches for tows in a specific depth range were initiated. In general, all of the surveys were conducted in the mid-summer through early fall, although survey timing between years was variable. While the AFSC conducted all of the previous triennial surveys, the 2004 survey was conducted by the NWFSC Fishery Resource Analysis and Monitoring (FRAM) division following the AFSC survey protocols. Haul depths ranged from 91-457 m during the 1977 survey with no hauls shallower than 91 m . In all subsequent years the survey sampled depths from 55-366 m. Water hauls (Zimmermann et al., 2003), tows that were not on the bottom, and tows located in Canadian and Mexican waters were also excluded
from the analyses for this assessment. Due to changes in survey timing, the triennial data have been split into early (1980-1992) and late (1995-2004) survey time series and treated independently, due to the changes in survey timing and the expected change in stock catchability because of the stock's seasonal onshore-offshore spawning movements.

Spatial variation is approximated using 250 knots, the bias-correction algorithm (Thorson and Kristensen 2016) in Template Model Builder (Kristensen et al. 2016) is used. Further details regarding model structure are available in the user manual (https://github.com/James-
Thorson/VAST/blob/master/examples/VAST_user_manual.pdf). To confirm convergence of the model estimation algorithm, we checked that the Hessian matrix was positive definite and that the absolute-value of the final gradient of the log-likelihood with respect to each fixed effect was $<0.0001$ for each fixed effect. We selected among two alternative model configurations, i.e., treating positive catch rates as following a lognormal or gamma distribution. Following advice from the Science and Statistical Committee, we used the following three diagnostics for model fit:

1. The Quantile-Quantile plot, generated by comparing each observed datum with its predicted distribution under the fitted model, calculating the quantile of that datum, and comparing the distribution of quantiles with its expectation under a null model (i.e., a uniform distribution). This Q-Q plot shows no evidence that the model fails to capture the shape of dispersion shown in the positive catch rate data (Figures 13 and 14).
2. A comparison of predicted and observed proportion encountered when binning observations by their predicted encounter probability. This comparison shows no evidence that encounter probabilities are over-estimated for low-encounter-probability observations, or vice versa (Figures 15 and 16).
3. A visualization of Pearson residuals for encounter probability and positive catch rates associated with each knot. This comparison shows no evidence of residual spatial patterns for either model component (Figures 17-20).

VAST indices were calculated for the north and south areas using two separate model runs, using lognormal models (Table 2 and Figures 21 and 22). The survey biomass density (weight per area swept) was a function of year, latititude, longitude, and vessel-year. The early Triennial survey shows a decline in relative abundance, while the late Triennial shows an increase in relative abundance. Note that a single area model run initially used to produce the indices was nearly identical to the separate area VAST model run. Additional tables with VAST model output are available in Appendix I.

Length bins in 2 cm increments from 10 to 130 cm in the north and 4 to 130 cm in the south were used to summarize the length frequency of the survey catches in each year. The first bin includes all observations less than 10 cm and the last bin includes all fish larger than 130 cm . Length data preparation follow the same methods as applied to the WCBTS data. Figures 23-26 show the length frequency distributions for the Triennial survey. Tables 3 and 4 show the number of tows with lingcod samples.

Age distributions included bins from age 0 to age $20+$, with the last bin including all fish of greater age. Age data preparation follow the same methods as the WCBTS length data. The Triennial Shelf Trawl Survey agefrequency data were included in the model as marginal age compositions and are shown in Figures 27-28. Tables 5 and 6 show the number of tows with lingcod samples.

## Fishery Independent Data: NWFSC Hook and Line Survey

The lingcod index of abundance from the Hook and Line survey is based on numbers of fish caught in the Southern California Bight. This index uses survey data from 2004-2016 and was created following the methods described in Harms et al. (2010). The final index is averaged over all crew staff and sites. (Note that vessels are confounded with crew staff.) Two vessels were employed for the survey in 2004-12 and three vessels in 201316. Data from inside the Cowcod Conservation closed area was not used in this index as this area has not been consistently surveyed through time. A Bayesian delta GLM was used to estimate the probability of capture for a lingcod on each hook as a function of year, site, staff, drop number, hook number, and sea state where sea state covariates (swell height, wave height, and the percentage of daylight passed at the time of each drop) are modeled as polynomial functions. The binomial model with a logit link was used to model the presence/absence of lingcod. The posterior median index values and their associated posterior log-SD are from a converged, 2.5 million draw MCMC. Table 2 and Figure 29 shows the index. Length compositions from this survey were used as numbers of fish, all fish were measured, and were not expanded.

## Fishery Independent Data: WDFW Research Compositions

WDFW conducted mark-recapture experiments in the nearshore area at the Cape Flattery from 1986-1994. Though study results were published in several journal articles (Jagielo 1991, 1994, and 1999), original data were misplaced. Additional surveys were conducted in the following years using bottom fish troll gear. Biological data collected from these surveys are presented in Figures 30 and 31. These data were ultimately removed from the base model as they did not provide any additional information to the model.

## Fishery Independent Data: Lam Research

In collaboration with the NWFSC and Moss Landing Marine Labs, lingcod in nearshore and offshore rocky reef habitats were collected between January 2016 and January 2017 via hook and line on chartered CPFVs. Sixteen latitudinally distinct sampling sites, or ports, were chosen from northern Washington to southern California. 85 to 120 individuals were caught per port ( $\mathrm{N}=1784$, 922 Males, 862 Females) using methods identical to those used by the onboard recreational lingcod fishery except that shorts were retained (individuals smaller than the legal-size limit of 22 inches) and areas closed to recreational harvest were occasionally utilized (CDFW Permit \#SC-6477, ODFW Permit \#20237, WDFW Permit ID Samhouri 16-138). This was to ensure an even distribution of size and age classes from each port for purposes of comparing lingcod von Bertalanffy growth curves by spatially explicit regions. A random stratified subsample by size and sex was selected per region for ageing and genetics analysis. These composition data are used as CAAL, and therefore are not expanded. The Lam research composition data are shown in Figures 32-35.

## Fishery Independent Data: Other

The International Pacific Halibut Commission (IPHC) longline survey data were examined for their utility in building a fixed gear index of abundance. However, depth and hook size are not appropriate for lingcod so these data are not used.

A WDFW hook and line survey includes 5-7 years of sampling but methods changed over time as this was a pilot study so these data are not used.

## Biological Data: Weight-Length

The weight-length relationship is based on the standard power function: $W=a L^{b}$ where $W$ is weight in kilograms and $L$ is length in centimeters. Hart (1967) reported the relationship between length and weight as W $=0.000282406 \cdot \mathrm{~L}^{3.011}$. The length-weight relationship was estimated by Jagielo (1994) using available survey
data and was fit to mean weight-at-length measured in the West Coast survey. Jagielo (1994) estimated the following relationship for males, $\mathrm{W}=0.000003953 \mathrm{~L}^{3.2149}$, and females, $\mathrm{W}=0.00000176 \mathrm{~L}^{3.3978}$, where W is weight $(\mathrm{kg})$ and L is fork length $(\mathrm{cm})$.

Between 2003 and 2015, lengths and weights were measured for 10789 lingcod on the WCBTS. Data from 2016 and 2017 were not available early enough during the stock assessment cycle to include them in these analyses. Spatial differences were investigated by fitting an overall exponential relationship between length and weight, and then comparing the residuals across latitude and depth using Tukey HSD pairwise multiple comparison tests. Although the parameter estimates for females and males appeared different, functionally the relationships were nearly identical. Residuals of the fit between length and weight showed significant differences among States, but not north and south of Point Conception, California. The relationship between length and weight did not change with depth.

The parameters were re-estimated using data from the WCBTS. New length and weight data from the NWFSC survey for this year's assessment estimate the following length-weight relationships for females, $W=0.00000276 L^{3.28}$, and males, $W=0.00000161 L^{3.42}$ in the north, and for females, $W=0.000003308 L^{3.248}$, and males, $W=0.000002179 L^{3.36}$ in the south (Figures 36-37).

## Biological Data: Maturity and Fecundity

Richards et al. (1990) examined coast-wide trends in lingcod maturity and observed that male lingcod mature at a smaller size and younger age than female lingcod. They also noted that size at maturity increases with latitude (distance from the equator). Size at $50 \%$ maturity was estimated to be 63.6 cm for females and 57.1 cm for males (ages 3.9 and 3.5) off of Vancouver Island, whereas Miller and Geibel (1973) found size at $50 \%$ maturity to be 58.8 cm and 39.8 cm (and ages 5 and 2) for females and males off of California. Jagielo (1994) found ages of $50 \%$ maturity of 3.4 years for males and 4.6 years for females off Washington. The 2009 stock assessment used values estimated in the previous assessment, with $50 \%$ maturity occurring at 68 cm in the north and 60 cm in the south.

This assessment uses an updated functional maturity ogive for lingcod, collected in 2013 - 2016 from the WCGBTS, 2014 - 2016 Oregon Department of Fish and Wildlife (ODFW), 2016 Washington Department of Fish and Wildlife (WDFW), and the 2014, 2016 Southern California Bight Hook and Line Survey of untrawlable habitat (Figures 38 and 39). The functional maturity approach accounts for abortive maturation that has been observed in adolescent females, while previously estimated maturity curves do not. The estimated size at $50 \%$ maturity ( cm ) with $95 \%$ confidence intervals for lingcod is 56.693 (1.546) in the north ( $\mathrm{n}=302$ ) and 52.269 (1.940) in the south ( $\mathrm{n}=222$ ).

Fecundity was assumed to be proportional to weight. Hart (1967) found fecundity to be essentially proportional to length cubed.

## Biological Data: Natural Mortality

Jagielo 1994 estimated $M$ for male and female lingcod using three empirical models based on life history parameters (Hoenig 1983, Alverson and Carney 1975, and Pauly 1980). Estimates of $M$ for male lingcod ranged from 0.23 to 0.39 , while estimates for female lingcod range from 0.16 to 0.19 . The averages of the estimates were 0.18 for females and 0.32 for males.

Starr et al. 2005 estimated natural mortality rates from a short term tag-recapture study and came up with ranges of 0.24-0.34 for females and 0.13-0.23 for males. However, these estimates do not take into account variation in $M$ across the year (or between years), especially for males during nest-guarding.

Hamel (2015) developed a method for combining methods for calculating $M$ via meta-analytic approaches to relating the natural mortality rate $M$ to other life-history parameters such as longevity, size, growth rate and reproductive effort, to provide a prior on M. In that same journal issue, Then et al. (2015), provided an updated data set of $M$ values and covariates estimates of $M$ and related life history parameters across a large number of fish species, from which to develop an $M$ estimator for fish species in general. They concluded by recommending $M$ estimates be based on maximum age alone, based on an updated Hoenig non-linear least squares (nls) estimator $\mathrm{M}=4.899 \mathrm{Amax}^{\wedge}(-.916)$. The approach of basing $M$ priors on maximum age (Amax) alone was one that was already being used for west coast rockfish assessments. However, in fitting the alternative model forms relating $M$ to the Amax, Then et al. did not consistently apply their transformation. In particular, in real space, one would expect substantial heteroscedasticity in both the observation and process error associated with the observed relationship of $M$ to Amax. Therefore, it would be reasonable to fit all models under a log transformation. This was not done. Revaluating the data used in Then et al. (2015) by fitting the one-parameter Amax model under a log-log transformation (such that the slope is forced to be -1 in the transformed space (as in Hamel 2015)), the point estimate for M is: $\mathrm{M}=5.4 / \mathrm{Amax}$. Note that the data used by Then et al. (2015) include a wide range of genera.

This formula for M provides the median of the prior. The prior is defined as a lognormal with mean $\ln$ (5.4/Amax) and a standard error of 0.4384343 . Using a Maximum age of 21 for females the point estimate and median of the prior for lingcod is 0.257 .

## Biological Data: Length at age

Lingcod display sexually dimorphic growth. Females grow faster than and reach larger sizes than males. Jagielo (1994) estimated growth using a fixed length at age 1 of 30 cm , and estimated $L_{\infty}$ for males of 93.21 cm and females of 131.05 cm , and k of 0.1694 for males and 0.1137 for females. He also found that the average length for young-of-the-year (age 0) lingcod was 11.99 cm and for age $2(48.1 \mathrm{~cm}$ ) for Washington samples, and that growth trajectories diverge considerably by sex after age 3, as female lingcod tend to grow faster and live longer than male lingcod, while male lingcod mature at age 3.

Estimates of growth parameters were investigated and starting values for model inputs were updated using the WCBTS data. Spatial differences were investigated by fitting an overall von Bertalanffy relationship between age and length, and then comparing the residuals across latitude and depth using Tukey HSD pairwise multiple comparison tests. Although the parameters for females and males appeared different, functionally the relationships look similar. Residuals of the fit between age and length showed significant differences among States. Sampled fish were larger at higher latitudes (linear regression of latitude on length, coefficient $=2.087$, t $=54.75, \mathrm{df}=10787, \mathrm{p}<0.0001$ ). Unlike with the length-weight relationship, age and length fits did vary with depth. However, patterns were not statistically distinguishable between shallow ( $<85 \mathrm{~m}$ ) and mid-shallow (85110 m ), or between mid-deep ( $140-183 \mathrm{~m}$ ) and deep ( $>183 \mathrm{~m}$ ).

Externally estimated lingcod von Bertalanffy growth parameters using the 2003-2015 WCBTS are: $\mathrm{k}=0.0173$ and $\operatorname{Linf}=108.6$ (females), and $\mathrm{k}=0.268$ and $\operatorname{Linf}=79.3$ (males) for the north, and $\mathrm{k}=0.191$ and $\operatorname{Linf}=100.9$ (female) and $\mathrm{k}=0.214$ and $\operatorname{Linf}=86.3$ (male) for the south. Internally estimate growth curves are shown in figures 40-41.

## Biological Data: Ageing precision and bias

A new aging error analysis was derived using the double reads from the NWFSC Cooperative Aging Project (CAP) and Washington State labs using a software designed for that purpose (Punt et al. 2008). Within lab reads for WDFW and CAP had 336 and 811 samples, respectively. Between lab reads had 404 samples. The results used are shown in Figure 47. The software is publicly available at https://github.com/nwfscassess/nwfscAgeingEror. The variability in age readings was estimated under an assumption of a linear increase in standard deviation with age. The resulting estimate indicated a standard deviation in age readings increasing from 0.13 years at age 1 by about 1 year of uncertainty per 10 years of age to a standard deviation of 3.16 years at age 25 (Figure 42). Note that all ages are from fin rays.

Using otoliths, McFarlane and King (2001) validated that the observed annuli are generally annual marks, via a mark-recapture study which used oxytetracycline (OTC) injections to leave a distinct mark on the otoliths that could be observed upon recapture of the fish and extraction of the otoliths, their results did find some error in ageing ( $>5 \%$ miss-aged) even for a single year at large, and under research settings, which generally have higher precision than under production ageing conditions. More work needs to be done to identify potential biases in production ageing of lingcod. One of the sources of error in ageing lingcod using otoliths is that the first and second annuli can be re-absorbed as the fish ages. Beamish and Chilton (1977) developed a method that used mean annual diameter measurement to locate the position of the first and second annuli and thus minimize, but not eliminate, error due to this re-absorption. Recent unpublished work suggests that ages produced from fin rays and otoliths are similar.

## Fishery Dependent Data: Commercial Landings

Historical commercial catch reconstructions were provided by each state that extend through 1995, 1986, and 1980 for Washington, Oregon, and California, respectively. Recent landings, from 1981 forward, were obtained from PacFIN. However, WDFW and ODFW staff advised that their catch reconstructions be used rather than PacFIN for overlapping years as the reconstructions are regarded as more reliable. While there is evidence for commercial landings in California prior to 1931, the historical catch reconstruction for lingcod does not address this period. Therefore, in the south, a linear ramp was applied from the start of the model period to the first year of available reconstructed landings data. Estimates of landings in CA from WA and OR waters provided late in the assessment process (pers. Comm. J. Field) were investigated as a model sensitivity run and did not impact the assessment. Commercial landings were aggregated into two fleets: 1) vessels using primarily trawl gear, but also including other net gear that caught a small fraction of the fish, and 2) vessels using longline, troll, and hook and line, refered to as fixed gear in this document. Table 1, and Figure 43 shows the commercial landings used in this assessment. Figure 43 also shows comparisons with commercial landings used in the 2009 assessment. Landings have declined significantly during the past two decades, with trawl landings dominating the catch in the north, and recreational landings dominating the catch in the south. More recently landings in both regions have been increasing, with the recreational component of the landings growing in the north, and the recreational landings continuing to dominate in the south.

WDFW's commercial catch reconstruction focused on pre-1980 landings, especially for time periods without fish ticket data (1889-1943). The two main challenges for historical Washington landings data are separating catches from marine waters off of Washington from catches taken off of Alaska, Canada, and in Puget Sound; and determining catches by gear types. The main sources of information include the US Commission of Fish and Fisheries reports, WA Department of Fishery Statistical Bulletins, and the WDFW fish receiving ticket data.

## Fishery Dependent Data: Commercial Discards

The WCGOP estimates commercial fishery discard ratios of lingcod for the period between 2003 to present. The WCGOP data are collected by gear type, fishery (e.g., open access, limited entry) and species/management units. The discard ratios were computed as the total estimated discarded weight (in pounds) on observed trips divided by the estimated total catch (discarded and retained). To aggregate these ratios into the fleet modeled in this assessment, each state, fishery and gear combination was weighted by the total estimated catch (discarded and retained weight). Thus, the discard rates used for each commercial fishing fleet represent the weighted estimates from each contributing segment within that fleet. Uncertainty in these values was quantified via bootstrapping the individual observations and then aggregating to the total estimate, providing a distribution of the discard rate. From this distribution a standard error associated with year specific discard ratio estimate was provided.

Annual commercial fishery discard estimates (Figures 44-47) and length compositions for both the trawl and fixed gear fleets in the north and south (Figures 48-51) are provided by the West Coast Groundfish Observer Program (WCGOP) from 2003 forward. Differences in discard rates between the north (lower) and south (higher) as well as the trawl and fixed gear fleets are apparent. Prior to the beginning of the catch shares program discard rates were generally high. However, post catch shares discard rates in the north trawl fishery show a strong decrease while the south trawl fishery exhibits higher discard rates.

Analysis of discard mortality rates have been conducted as part of the PFMC process (via the Groundfish Management Team during April 2008) and reviewed/accepted by the Science and Statistical Committee (during March 2012). Discard mortality rates of $7 \%$ for fixed gears and $50 \%$ for trawl gears are applied in this assessment.

## Fishery Dependent Data: Recreational Landings

Recreational landings for WA and OR were provided by the states. California recreational landings were obtained from John Field for the years 1928-1980, with 1981-2004 being taken from the 2009 assessment, and 2005 forward being provided by RecFIN (pers. comm R. Ames). Recreational catches include retained plus estimated discarded dead catch (catch types A and B1) and were aggregated across boat mode ("PC" = party/charter, "PR"=private/rental), year and area. Table 1 and Figures 52-53 show both commercial and recreational landings for this assessment.

## Fishery Dependent Data: PacFIN Commercial Logbooks

Two commercial fishery catch-per-unit-effort (CPUE) indices spaning the years 1981-1997 were derived from PacFIN logbook data for this assessment, north and south trawl indices. Significant changes in management beginning in 1998 result in a truncated index, ending during 1997 for both the north and south time series.

Logbook information went through several data quality filters, including filtering to attain the best possible consistent and representative data set through time to estimate a relative abundance trend. Erroneous tow locations outside of the EEZ, on land, or with extreme depths (e.g. in the abyssal plain) were removed from the data set. However, tows with reasonable depths but with map coordinates that correspond to deep areas, such as trenches or unreasonably shallow areas have been identified and removed, as these appear to be miss-reported. Likewise, tows with large differences between logbook reported and map depths have also been identified and removed. Only tows within the EEZ but not within Puget Sound were retained in the data set. This takes care of most of the tows reported to be on land, however there were erroneous tows west of the customary commercial
groundfish fishing grounds but still inside the EEZ so another filtering step was needed. The following steps were used to define good tows in the rest of the logbook data based on location and reported depth: 1) polygons representing the customary groundfish fishing grounds (using data from 1981-2015) were identified using a convex hull function ('ahull' in the R alphahull package), and 2) points not in the hull were removed.

Many records in the PacFIN logbooks lack depth data. Estimated depths using GIS data were calculated for each tow using lat/long, with the 'depthMeters' function (R Imap package). Over all years, this increased the percentage of entries with a depth estimates from $85.7 \%$ to $99.7 \%$. Note that for those tows recorded only by Fishing Block the centroid of the block is used for the beginning tow lat/long. In cases where depth was recorded in the logbooks, the GIS depth was used to double check reliable reporting of depth. To be retained in the data set 1) the depth reported in PacFIN must be within 500 meters of the GIS depth and 2) the reported depth, or the GIS depth if the reported depth is missing, must be smaller than 1,500 meters. These rules balance depth differences being generously large, since the GIS depth is based on the start of tow coordinates whereas the reported depth is a skipper estimated average depth over the tow, and depth difference being small enough to ferret out erroneous coordinates and depth.

For tows reported by 10-minute fishing blocks before 1997, largely in California, the above rules were not applied since the actual location and depth of a tow can be far different than the centroid of a block. For example, the centroid of a block may be outside of the polygons of the customary catch area, but the tow could be within a polygon. The reported depth, or GIS depth if no depth is recorded, must still be less than 1,500 meters (and greater than zero). Note that before 1997 there appears to be almost no erroneous reporting of blocks. However, from 1997 forward the recording of inaccurate data increased with the request for specific tow locations.

Finally, if a tow was identified as 'midwater' and the GIS bottom depth or the reported bottom depth was smaller than 1,646 meters ( 900 fathoms) then the tow was identified as good. Nine hundred fathoms is the default depth for midwater tows in the GIS estimated depth since it appears the reported depth may sometimes be the depth of the net (PacFIN has a placeholder to enter type of depth (net, bottom, etc.) but it is not used in more recent years). This depth limit is based on recent year bottom depth limits for midwater tows. The midwater tow filter was used because there are clusters of tows identified in PacFIN as 'midwater' but whose species composition clearly show bottom dwelling species.

The resulting filtered dataset reduces the size of logbook dataset over all years, 1981-1997, by $6.04 \%$. Finally, the data set for analysis for this assessment was limited to vessels that catch the top $90 \%$ of the lingcod catch over the duration of the logbook data, essentially removing vessels that rarely caught lingcod. Issues with management constraints on landing due to trip limits have not been explicitly addressed. However, the index has been truncated in 1997 to avoid the series of management measures that had strong impacts on the groundfish fishery beginning in 1998.

The PacFIN logbook data were analyzed using the spatio-temporal delta-model (Thorson et al. 2015), implemented as an R package titled VAST (Thorson and Barnett 2017) and publicly available online (https://github.com/James-Thorson/VAST). VAST specifically includes spatial and spatio-temporal variation in both encounter probability and positive catch rates, a logit-link for encounter probability, and a gamma-link for positive catch rates. Spatial variation is approximated using 100 knots, the bias-correction algorithm (Thorson and Kristensen 2016) in Template Model Builder (Kristensen et al. 2016) is used. Further details regarding model structure are available in the user manual (https://github.com/James-
Thorson/VAST/blob/master/examples/VAST_user_manual.pdf). To confirm convergence of the model estimation algorithm, we confirmed that the Hessian matrix is positive definite and that the absolute-value of
the final gradient of the log-likelihood with respect to each fixed effect was $<0.0001$ for each fixed effect. We selected among two alternative model configurations, i.e., treating positive catch rates as following a lognormal or gamma distribution. Following advice from the Science and Statistical Committee, we used the following three diagnostics for model fit:

1. The Quantile-Quantile plot, generated by comparing each observed datum with its predicted distribution under the fitted model, calculating the quantile of that datum, and comparing the distribution of quantiles with its expectation under a null model (i.e., a Uniform distribution). This Q-Q plot shows that the model generally captures the shape of dispersion shown in the positive catch rate data (Figures 54).
2. A comparison of predicted and observed proportion encountered when binning observations by their predicted encounter probability. This comparison shows that encounter probabilities are acceptable (Figures 55).
3. A visualization of Pearson residuals for encounter probability and positive catch rates associated with each knot. This comparison shows generally small residuals with some spatial patterning, particularly for the southern California. (Figures 56-57).

Tow-by-tow catch rates (CPUE), calculated as pounds per hour, were fitted using VAST using year, vessel, month, depth, and PFMC area, and vessel-year as covariates Both gamma and lognormal models were explored, the gamma model better fit the data. Model diagnostics show adequate fit and general consistency with GLM model assumptions for the positive catch component. Similarly to past analyses (Jagielo 2000), the northern trawl logbook index trend shows a sharply declining stock since 1976, and the southern trawl logbook index indicates a declining stock since 1979 (Table 2 and Figure 58). Both stocks remain at low levels through the end of the time series in 1997. Additional tables with VAST model output are available in Appendix I.

## Fishery Dependent Data: OR Fixed Gear Nearshore Commercial Logbook Index

The ODFW has required nearshore commercial fishers (both nearshore permitted vessels and open access vessels) to submit fishing logbooks since 2004. Responses from submitted logbooks have been entered into a central database. Fisher compliance is generally high, averaging around $80 \%$, but has varied through time ranging from $65 \%$ in 2007 to $95 \%$ in recent years. Although required to provide all requested information in the logbook per fishing gear set, there has been substantial variation in the quantity and quality of information reported in logbooks.

Logbook information went through several data quality filters recommended by ODFW staff to attain the best possible consistent and representative data set through time to estimate a relative abundance trend. Individual observations of catch (kg) and effort (hook hour) were at the trip level, where multi-set trips were aggregated to the trip level. Gear type was restricted to hook-and-line (excluding longline gear) because this method accounted for a majority of sets.

Covariates considered in the full model included month, vessel, port, depth, and people. All covariates were specified as categorical variables, except depth was a continuous variable. Depth was included to account for general differences in bathymetry and fishing depth restrictions. People were included in an attempt to control for the potential oversaturation of hooks at a given fishing location and the interaction that multi-crew trips (\# fishers onboard) may have on fishing efficiency. The selection of covariates included in final models were evaluated using standard information criterion for relative goodness of fit (AIC), where a covariate remained in the model if model fit was improved relative to an otherwise identical model without the covariate.

CPUE was modeled using a delta-GLM approach, where the catch occurrence (binomial) component was modeled using a logit link function and the positive catch component was modeled according to a lognormal distribution with a log link function. CPUE was calculated for each trip, where total catch was defined as the sum total of all reported retained catch (in weight) and released catch (numbers converted to weight by applying a median catch weight) and total effort was defined by hook-hours (number of hooks used multiplied by the number of hours fished). A gamma distribution for the positive catch component was also evaluated, but graphical summary diagnostics of model adequacy favored the lognormal distribution.

Model selection of all main effects models identified the full model with covariates month, vessel, port, depth and people as the best fit to the data, along with the categorical year factor of interest for the index. A bootstrap resampling routine was conducted to estimate the standard error (and CV) of the year effects. Standard model diagnostics show adequate fit and general consistency with GLM model assumptions for the positive catch component (Table 2 and Figure 59). Figure 60 shows the index.

## Fishery Dependent Data: Commercial Biological Sampling

Sex specific commercial fishery landed length and age compositions (Figures 61-64) were obtained from PacFIN. Annual commercial length- and age-frequency distributions were developed for each state for which observations were available, following the same bin structure as was used for research observations. For each fleet, the raw observations were expanded to the sample level, to allow for any fish that were not measured, then to the trip level to account for the relative size of the landing from which the sample was obtained. Length and age data collected from commercial landings for each region are summarized by the number of port samples, where a port sample consists of fish sampled from a single fishing trip. The number of port samples is the input N for each year and area. Tables 3 to 5 show biological data sample sizes. Note that the early Washington data contain a large proportion of unsexed fish, therefore all samples collection prior to 1993 are included in this assessment as sex combined compositions. Durng this stock assessment cycle it was found that the proportion of unsexed fish prior to 1993 was high in the north model area, leading to the use of sex-combined length compositions prior to 1993 and sex specific length compositions after 1993.

## Fishery Dependent Data: WA Dockside Recreational Index

The WDFW provided recreational dockside fisheries data from 1981 to present. In consultation with state representatives, it was determined that the dockside index was more reliable so the MRFSS recreational data were not used. These data went through several data quality filters to identify the best subset of the available data that are likely to be consistent over the time series and provide a representative relative index of abundance once standardized. Analyses were conducted both with and without the Stephens and MacCall (2004) data filter. The Stephens-MacCall method is an objective approach for identifying trip records of catch and effort data when fishing locations are unknown, based on inference regarding the species composition of the catch, and identifying trips to habitats where the target species is likely to occur (Stephens and MacCall 2004). Since recreational fishing trips target a wide variety of species, standardization of the catch rates requires selecting trips that are likely to have fished in the target species habitat. The method of Stephens and MacCall (2004) was used to identify trips with a high probability of catching the target species, based on the species composition of the catch in a given trip. Coefficients from the Stephens-MacCall analysis (a binomial GLM) are positive for species that co-occur with the target species, and negative for species that are not caught with the target species. Covariates considered in the full model included year, month, boat type, area, and a covariate for management that captured management actions likely to impact the fisher (e.g. depth restrictions, bag limits, and size limits). All covariates were specified as categorical variables. The stepwise selection of covariates in main effects models was evaluated using standard information criterion for relative goodness of fit (AIC). Depth was not
included in the analysis because it was not uniformly recorded through time; depth data collection began during 2003. The covariates for daily bag limits and allowable landing size of fish represent management changes.

CPUE was modeled using a delta-GLM approach, where the catch occurrence (binomial) component was modeled using a logit link function and the positive catch component was modeled after log-transformation of the response variable, according to a normal distribution with an identity link function. Data are collected at the trip level, with the number of fish landed and the number of anglers on each vessel being recorded. The amount of time fished by each angler is not recorded. Therefore, the units for CPUE are fish landed/angler-trip. A gamma distribution for the positive catch component was also explored, but model selection favored the lognormal model.

Model selection from all main effects models selected the full model with covariates month, boat type, area, and management as important for both the catch occurrence and positive catch component models for all data sets, along with the categorical year factor used for the index of abundance. The management covariate accounts for changes in bag limits and allowable landing size. A bootstrap analysis ( $\mathrm{N}=500$ ) was used to estimate the standard errors (and CVs) of the year effects. Standard model diagnostics show adequate fit and general consistency with GLM model assumptions for the positive catch component (Figure 65). CPUE indices produced both with and without the Stephens-MacCall data filter produced highly similar indices so the index without Stephens-MacCall filtering was used in the stock assessment model (Figure 66).

## Fishery Dependent Data: OR Ocean Recreational Boat Sampling (ORBS)

The OR Ocean Recreational Boat Sampling (ORBS) dockside sampling program has a more comprehensive coverage and greater sample sizes (i.e., 50-70 times more trips than the onboard observer program), but somewhat less confidence in the data elements compared to onboard observer programs, as only retained catch and the number of anglers were verified by biologists (all other trip details were angler reported). The onboard and dockside sampling programs are not fully independent as a single fishing trip can be sampled in both the onboard observer program and the dockside within ORBS. In order to provide estimates of total catch and effort for the Oregon sport fisheries, ORBS obtains catch rates from a portion of vessels via a dockside survey, and applies them to total effort counts. During the dockside survey, biologists intercept vessels returning from fishing trips and record catch, effort, and other trip-related details (e.g., grid area fished, target species, depth, port, etc.). Since catch and effort per sampled trip are both obtained, the dockside survey of ORBS was also used to develop an index of abundance for lingcod. Note that, in consultation with state representatives, it was determined that the ORBS sampling was more reliable so the MRFSS recreational data were not used.

Modifications were made to trip hours from the original ORBS dataset to create a standardized unit of effort. Since trip hours in ORBS are not hours fished, but rather the total duration of the trip (as measured from the time the boat crossed into the ocean until the time they were interviewed at the dock), travel times had to be determined and subtracted from trip hours in order to get a standardized measure of fishing effort per trip. Accordingly, a total distance function was created for each trip based on the river miles (distance along the navigable channel from the port to the bar (river mouth)) and ocean miles (i.e., straight distance from the river bar to the ocean grid fished, wrapping around obstructions if needed). Total distance was then converted to travel time based on generalized vessel speeds for private (i.e., 18 mph ) and charter boats (i.e., 13 mph ) following methods applied by Dick et al. (2015). It is important to note that the original trip hours minus travel hours still does not equal hours fished because it does not account for time needed to move from drift to drift; however, since the number of resets between drifts would be expected to be related to fish abundance (as with catch rates), the modified trips hours was deemed a viable effort unit for the assessment.

Some trips had erroneous trips hours (discrepancies between values entered on paper and then entered electronically later). These were the steps taken to correct the issue:

1. Trip hours is computed automatically by the data logger based on the time the interview is entered electronically
2. If samplers write their interviews on paper and enter them electronically later when they have time (as believed to have happened despite being instructed not to), then the trip hours are inflated.
3. To potentially remove these errors, we computed time intervals between interviews. Pulses of interviews a minute or two apart are very likely to have been from bunches of paper interviews entered electronically in one sitting, as normal interviews are somewhat sporadic and take more than a minute to complete.

The ORBS dockside charter boat spans the years 2001-2016. As with the other trip-based CPUE data sets, analyses were completed with and without the Stephens-MacCall data filtering method that is used to identify trips with a high probability of catching the target species. Prior to using the Stephens-MacCall approach to select relevant trips, a number of other filters were applied to the data to minimize variability in CPUE estimates. Criteria for valid trips included vessels with trip hours <12. Trips targeting tuna and dive trips were excluded from the analysis.

CPUE was modeled using a delta-GLM approach, where the catch occurrence (binomial) component was modeled using a logit link function and the positive catch component was modeled after log-transformation of the response variable, according to a normal distribution with an identity link function. The units for CPUE are fish landed/angler-hours, with covariates being year, month, boat type, bag limits, minimum length regulations, and maximum length regulations. Both lognormal and gamma distributions for the positive catch component were explored, but model selection favored the lognormal model.

Model selection using all main effects models selected the covariates year, month, and boat type as important for both the catch occurrence and positive catch component models for all data sets, along with the categorical year factor used for the index of abundance. A bootstrap analysis ( $\mathrm{N}=500$ ) was used to estimate the standard errors (and CVs) of the year effects. Standard model diagnostics show adequate fit and general consistency with GLM model assumptions for the positive catch component (Figure 67). CPUE indices produced both with and without the Stephens-MacCall data filter produced highly similar indices so the index without StephensMacCall filtering was used in the stock assessment model (Table 2 and Figure 68).

Note that the Oregon recreational fishery has been subject to a seasonal depth restriction since 2004, this was 40 fathoms until 2012 and changed to 30 fathoms after 2012. However, this depth restriction was not modeled due to the relatively small change in depths.

## Fishery Dependent Data: OR and CA Onboard Observer Recreational Indices

All data elements for the onboard observer indices were verified by a biologist, and thus there was a high degree of certainty in the catch, effort, and locations fished; however, there was limited spatial-temporal coverage and only charter boats were included (not private boats). The goal of the Observer Programs in California and Oregon is to collect data including charter boat fishing locations, catch and discard of observed fish by species, and lengths of discarded fish. Both states sample the Commercial Passenger Fishing Vessel (CPFV), i.e., charter boat or for-hire fleet. The onboard observer programs collect drift-specific information at each fishing stop on an observed trip. At each fishing stop recorded information includes start and end times, start and end location (latitude/longitude), start and/or end depth, number of observed anglers (a subset of the total anglers), and the catch (retained and discarded) by species of the observed anglers.

Data for the onboard observer indices for the recreational CPFV fleet are from four sampling programs. The CDFW conducted an onboard observer program in central California from 1987-1998 (Reilly et al. 1998). These data were previously used in the 2013 data moderate assessments (Cope et al. 2015), at the level of a fishing trip. Since the 2013 assessments, the original data sheets were acquired and data were key punched to the level of fishing stop. One caveat of these data is that locations were recorded at a finer scale than the catch data. We aggregated the relevant location information (time and number of observed anglers) to match the available catch information. Between April 1987 and July 1992 the number of observed anglers was not recorded for each fishing stop, but the number of anglers aboard the vessel is available. We imputed the number of observed anglers using the number of anglers aboard the vessel and the number of observed anglers at each fishing stop from the August 1992- December 1998 data (see Dick et al. 2015, Appendix E for details, p.E-1).

California implemented a statewide onboard observer program in 1999 (Monk et al. 2014). California Polytechnic State University (Cal Poly) has conducted an independent onboard sampling program as of 2003 for boats in Port San Luis and Morro Bay (Stephens et al. 2006), but follows the protocols established in Reilly et al. (1998), and was modified to reflect sampling changes that CDFW has also adopted, e.g., observing fish as they are landed instead of at the level of a fisher's bag. Therefore, the Cal Poly data area incorporated in the same index as the CDFW data from 1999-2014. Cal Poly collects lengths of both retained and discarded fish.

We generated separate relative indices of abundance in California for the 1987-1998 and 1999-2016 datasets due to the number of regulation changes occurring throughout the time period, and the difference in sampling regimes between these periods. Regulatory changes implemented by CDFW during 1999 through 2001 resulted in removal of these years from the index. A regulation of three hooks during 2000 was reduced to (and remains at) two hooks during 2001.

The ODFW initiated an onboard observer program in 2001, which became a yearly sampling program in 2003 (Monk et al. 2013). Both California and Oregon provided onboard sampling data through 2016.

Prior to analyses preliminary data filters were applied. Trips/drifts from the CDFW 1988-1998 database meeting the following criteria were excluded from analyses:

1. Drift associated with a fishing location code that was not assigned to a reef.
2. Drifts identified as having possible erroneous location, observed anglers, or time data.
3. Trips encountering $<50 \%$ groundfish species (number of fish).
4. Drifts/trips missing any of the following: year, month, district, depth, angler hours, number of lingcod kept or discarded, latitude or longitude, trip-level percentage of catch containing groundfish
5. Drifts with a value of zero for depth or angler hours
6. Drifts missing the number of lingcod encountered (after determining whether this could be reconstructed from the number kept and discarded)
7. Drifts in depths 500 ft . (depth at which relatively few positive observations of lingcod occurred)

Trips/drifts from the CDFW 1999-2014, and Cal Poly databases meeting the following criteria were excluded from analyses:

1. Drifts identified as having possible erroneous location, observed anglers, or time data
2. Drifts/trips missing any of the following: year, month, district, depth, angler hours, number of lingcod kept or discarded, latitude or longitude, trip-level percentage of catch containing groundfish
3. Drifts with a value of zero for depth or angler hours
4. Drifts missing number of lingcod encountered (after determining whether this could be reconstructed from the number kept and discarded)
5. Drifts with locations outside of a polygon representing depths from 0-305m.
6. Drifts within Arcata Bay, Humboldt Bay, South Bay, or San Francisco Bay
7. Drifts occurring $>500 \mathrm{~m}$ from a reef (distance at which relatively few positive observations of lingcod occurred), for northern or central California (where such habitat data were available)
8. Drifts occurring on a reef with < 3 cumulative positive encounters of lingcod over the period of the time series, for northern or central California (where such habitat data were available)
9. Drifts in southern California occurring outside the area of likely lingcod catch, determined by the convex hull of positive lingcod catch records $(a l p h a=0.28)$
10. Trips encountering $\leq 50 \%$ groundfish species
11. Drifts in months with relatively few observations (January and February)
12. Drifts in depths $>400 \mathrm{ft}$. (depth at which relatively few positive observations of lingcod occurred)
13. Drifts with fish times $\leq 2$ minutes or 290 minutes

Trips/drifts from the ODFW database meeting the following criteria were excluded from analyses:

1. Drifts associated with a fishing location code that was not assigned to a reef
2. Drifts identified as having possible erroneous location, observed anglers, or time data
3. Trips encountering < $50 \%$ groundfish species (number of fish)
4. Halibut-targeted trips
5. Drifts/trips missing any of the following: year, month, county, depth, angler hours, number of lingcod kept or discarded, latitude or longitude
6. Drifts with a value of zero for depth or angler hours
7. Drifts missing the number of lingcod encountered (after determining whether this could be reconstructed from the number kept and discarded)
8. Drifts where midwater groundfish made up $95 \%$ of the catch
9. Drifts occurring $>400 \mathrm{~m}$ from a reef (distance at which relatively few positive observations of lingcod occurred)
10. Drifts occurring on a reef with < 3 cumulative positive encounters of lingcod over the period of the time series
11. Drifts with fish times $\leq 2$ minutes
12. Drifts in months with relatively few observations (March and October)
13. Drifts in depths > 200 ft . (depth at which relatively few positive observations of lingcod occurred)

CPUE was modeled using a delta-GLM approach, where the catch occurrence (binomial) component was modeled using a logit link function and the positive catch component was modeled after log-transformation of the response variable, according to a normal distribution with an identity link function. Data were analyzed at the drift level and catch was taken to be the sum of observed retained and discarded fish, i.e., the number of fish encountered per angler hour. Potential covariates for all indices were year, month, depth, area, and year-area interaction. Both lognormal and gamma distributions for the positive catch component were explored, but
model selection favored the lognormal model in all cases. A bootstrap analysis ( $\mathrm{N}=500$ ) was used to estimate the standard errors (and CVs) of the year effects for all models. Standard model diagnostics showed adequate fit and general consistency with GLM model assumptions for the positive catch component (Figures 69-71). The final models included all main effects. Although the model with the year-area interaction had the lowest AIC value, the index was unrealistically erratic and the CVs were very large. Table 2 and Figures 72-73 show the onboard recreational observer indices. Note that the base assessment model does not use both the OR onboard index as well as the OR dockside as they show similar trends. The dockside index is used due to the longer time series.

## Fishery Dependent Data: Central CA Recreational Index

A central California (Point Conception to Point Mendocino) PSMFC recreational dockside boat survey, also referred to as MRFSS, index (1980-1997) was included in the 2009 south assessment (Hamel et al. 2009). Data after 1997 were not included due to a succession of changes in management regulations that may have affected the CPUE and length distribution of the catch. This index (Figure 74) is not included in the base model in this document, as other data sets were viewed as more reliable, and was explored in model sensitivity runs during the assessment process.

## Fishery Dependent Data: Recreational Biological Sampling

Recreational fishery landed length and age compositions (Tables 3 to 5 and Figures 75-79) were obtained directly from WDFW and ODFW, and from John Field and RecFIN for CA. Note that, in consultation with WDFW and ODFW representatives, it was determined that the state databases were more reliable so the data were not obtained via RecFIN (MRFSS). Additionally, the RecFIN database was undergoing restructuring during this stock assessment cycle, leading to delays in obtaining data. Annual recreational length- and agefrequency distributions were developed for each state for which observations were available, following the same bin structure as was used for research observations. Many of these composition data lack information on the number of fish sampled out of those landed in a given trip, and therefore are used without expansion to the sample level. Unexpanded recreational composition data are commonly used in West Coast stock assessments for the above reason. Input N values were set at the number of fish sampled for each year and data set.

In Oregon the minimum size limits for lingcod have changed from 22 inches during 1995 to 1997 and 2006 to present, but were 24 inches during 1998 to 2006. It has also been reported that recreational fishers in Oregon sometimes release large, assumed to be female fish, so that they can spawn. However other anglers tend to target and retain these large fish.

## 4. Model

## Data changes since 2009 assessment

Changes in data for this assessment include:

1. Expansion of the time period of the assessments back to 1889 .
2. Splitting of the 2009 commercial fleet into trawl and fixed gear components.
3. Splitting the 2009 north recreational fleet into OR and WA.
4. Updated landings and length composition data
5. Use of conditional age-at-length data for only the NWFSC survey and the research study by L. Lam.
6. Re-analysis of the commercial fishery CPUE time series with VAST (last investigated during the late 1990s - early 2000s).
7. Addition of an OR commercial nearshore CPUE index.
8. Addition of a WA recreational dockside CPUE index.
9. Addition of an OR ORBS recreational dockside CPUE index.
10. Exploration of an OR charter boat onboard observer recreational CPUE index (in agreement with dockside sampling).
11. Exploration of early and late CA charter boat onboard observer recreational CPUE index (model sensitivity).
12. Addition of the NWFSC hook and line survey CPUE index and length data.
13. Addition of length and age composition data from L. Lam's research study.
14. Exploration of length and age data from a WDFW research study (removed from base model).
15. An updated prior on natural mortality (Hamel).
16. A new maturity relationship based on recent data collections.
17. Updated length weight relationships based on NWFSC survey data.
18. Re-analysis of double read age data for revised estimates of aging variability.
19. Re-analysis of the AFSC Triennial survey index with VAST.
20. Exploration of conditional age-at-length composition data for the WA and OR recreational fisheries (model sensitivity).
21. Exploration of marginal age composition for the commercial fleets (model sensitivity).

## History of Modeling Approaches

There have been six assessments of lingcod since 1986 covering part or all of the West Coast of the United States.

Adams (1986) conducted a yield per recruit analysis. Jagielo (1994) conducted an age-structured assessment of the status of the lingcod stock between Cape Falcon in Northern Oregon to $49{ }^{\circ} \mathrm{N}$ (off of southwest Vancouver Island in British Columbia - PMFC areas 3A, 3B, and 3C, including Canada), using the Stock Synthesis program (Methot, 1990). Data included trawl and recreational catch from 1979-1993 with equilibrium catch before then, triennial shelf survey and trawl CPUE indices, and length and age composition data. The final spawning output levels were estimated to be about $20 \%$ of pristine levels, and catch level recommendations ranged between 2500 and 3000 mt based on $\mathrm{F} 40 \%$ to $\mathrm{F} 20 \%$.

The 1997 assessment (Jagielo et al.1997) expanded the area south to Cape Blanco ( $42^{\circ} 50^{\prime} \mathrm{N}$ ), and retained the northern boundary of $49^{\circ} 00^{\prime} \mathrm{N}$ and the use of the Stock Synthesis model. Depletion in spawning output in this model was below $10 \%$ for 1997.

Adams et al. (1999), conducted a length-based, age-structured population model implemented in AD Model Builder (ADMB, Fournier 1996) for the southern area which had not yet been assessed (Eureka, Monterey, and Conception INPFC areas).

Jagielo et al. (2000) conducted age structured models in ADMB for two areas of the US: US VancouverColumbia (no longer including Canadian waters) and Eureka, Monterey, Conception INPFC areas. Jagielo et al. (2003) conducted age structured assessments for the two areas using Coleraine. Finally, Jagielo et al. (2005) conducted age structured assessments for the two areas using Stock Synthesis 2 (SS2). They found that the northern stock had recovered substantially from a low point in the 1990s was at $87 \%$ depletion, while the southern area had not recovered as well and was at $24 \%$ depletion, with a $64 \%$ coast-wide depletion.

The 2009 stock assessment, completed in Stock Synthesis 2, divides the Northern (Washington and Oregon) and Southern (California) stocks by state line (Hamel et al. 2009). The point estimate for the spawning stock depletion at the start of 2009 was $61.9 \%$ for the North, $73.7 \%$ for the South, indicating the stock is recovered. The axis of uncertainty for the decision table provided to managers was natural mortality for the north, with the base model $M=0.18$ for females and 0.32 for males. The "Low M" alternative uses $M=0.16$ and 0.285 for females and males respectively, and the "High M" alternative uses $M=0.20$ and 0.355 . The axis of uncertainty for the South model was for the high alternative including age data, and for the low alternative excluding the dockside recreational CPUE index. The 2009 stock assessment removed all age data due to issues with outliers and possible aging bias. The north and south models were made as equivalent as possible by keeping fixed and estimated parameters largely the same for the two assessments. Natural mortality (M) was fixed at 0.18 for females and 0.32 for males in both assessments, while stock-recruitment steepness (h) was fixed at 0.8 .

## GAP and GMT input

Two meetings were held to prior to the STAR panel to discuss data and modeling issues relevant to this 2017 lingcod stock assessment. The first was with GAP and GMT members during the March 2017 Pacific Fishery Management Council meeting held in Vancouver, WA. The second was at a pre-assessment workshop held during March 2017 at the PFMC offices in Portland, OR. GAP and GMT members were also active participants at the STAR panel review during June 2017. Finally, a series of phone calls with the GMT, PFMC staff, and SSC took place during December 2017 to discuss the treatment of the 2017-2018 ACLs.

## Response to 2009 STAR Panel Recommendations

Issues with respect to data that were raised during the 2009 lingcod stock assessment are reviewed below. Actions taken between the 2009 and current assessments are provided below.

1. The need for age validation

- An age validation study has not been completed for lingcod.

2. Problems noted with NWFSC survey length and age sampling during the 2003 survey.

- Standard sampling protocols have been instituted for the NWFSC groundfish trawl survey and are reviewed annually.

3. The need for alternative survey methods for untrawlable habitat.

- No new surveys have been implemented.

4. Evaluate use of IPHC survey for lingcod

- This data set is not suitable for lingcod due to an inappropriate sampling depth range and hook size.

5. Evaluate usefulness of WA tagging data.

- This tagging data is from Puget Sound, outside of the scope of the assessment area, and the data reside on paper records that are not readily available for analyses.

6. Investigate reasons for outliers in length-at-age data.

- Length and age data have been restructured for this assessment and large outliers are no longer a problem. The models were able to fit the composition data well. However, the STAR panel identified concerns with biased sampling of ages with respect to lengths, leading to the removal of the fishery age data from the base model. The inclusion of the recreational age composition data as conditional-age-at-length is able to address the sampling bias, these data were included in the model as a sensitivity run. The amount of commercial age data prohibits the use of conditional compositions, the marginal age compositions are included as a model sensitivity. The sampling bias problem can be addressed for the next lingcod assessment.

7. Look at environmental covariates for recruitment, time-varying growth, and in-shore availability.

- No studies have been completed since the last assessment.

Issues with respect to the stock assessment modeling raised during the 2009 lingcod stock assessment are reviewed below. Actions taken between the 2009 and current assessments are provided below.

1. The definition of length at age in SS was unclear.

- SS documentation is now readily available.

2. Evaluate the assumption that fishery CPUE is proportional to stock biomass.

- During the 2017 model development the proportionality assumption was investigated for all indices. Assuming indices are not proportional to abundance results in similar or more favorable stock trends. While arguments could be made for why each of the indices are not proportional to abundance, this 2017 stock assessment maintains the assumption of proportionality as the indices generally provide similar information on stock trends.

3. Investigate the inability to estimate growth or poor growth estimation

- The 2017 assessment is able to reliably estimate male growth and female growth in the south but is not able to reliably estimate female L at maximum age in the north model where large fish that were observed historically are not present in the NWFSC conditional length-at-age data. This value is fixed.

4. Investigate the inability to fit the NWFSC survey data

- This 2017 assessment fits the NWFSC survey data.

5. Sensitivity to recruitment estimation start year

- This 2017 assessment is able to estimate recruitment from the model start and no longer shows an unrealistically large recruitment at the beginning of the main recruitment deviation period.

6. Consider the impact of male nest guarding on the definition of reproductive output

- Time did not permit for the investigation of this issue. The PFMC SSC may consider a range of alternative definitions of reproductive output that they may be interested inconsidering in the future.

7. Undertake a Bi-national assessment.

- Lingcod are a transboundary stock with both Canada and Mexico. However, a legal mandate and management framework for using the advice of a transboundary stock assessment does not exist. Data sharing is currently happening at a scientific level with Canadian scientists.

Responses to the current 2017 STAR Panel are detailed in the 2017 STAR Panel report for lingcod with the following exception. The Panel's requested approach (Request 4.1) for constructing the low and high states of nature in the decision tables would have resulted in states of nature that were less extreme than the uncertainty implied by the standard errors for the base models' estimates of 2017 spawning biomass.

## Transition from 2009 to 2017 Stock Assessment Models

This assessment uses SS version V3.30.03.07, and implements two separate assessments for the north and south areas, as did the 2009 assessment. Similarly to the 2009 assessment the two areas are defined by state boundaries with the north area including Washington and Oregon, and the south area including California. The 2009 models were transitioned into SS version 3.03.05, these transitioned models matched the time series of spawning biomass and stock depletion estimated in the 2009 stock assessment. The 2017 model implements model structural changes including:

1. Disaggregating both the commercial fleets into trawl and fixed gears and the north recreational fleet into WA and OR.
2. This assessment implements plus and minus groups for the data length bins are larger and smaller that those used in 2009.
3. This assessment implements a larger plus group for ages than that used in the 2009 assessment.
4. A broader set of time blocks are used to model selectivity for both commercial and recreational fisheries to better reflect management impacts.

Given structural changes to this model a step-by-step transition to the final accepted base model in not provided, as required by update stock assessments. However, the comparison between the final 2009 and 2017 base models are provided below.

## Summary of data for fleets and areas

Commercial fishery removals were divided among four fleets and two assessment models:

1. north trawl gears
2. north fixed gears
3. south trawl gears
4. south fixed gears

Recreational fishery removals were divided into three fleets and two assessment models:

1. north WA
2. north OR
3. south CA

All available data are described in Figures 2 and 3.

## Modeling software

This assessment used the Stock Synthesis V3.30.03.07 modeling framework written by Dr. Richard Methot at the NWFSC (Methot and Wetzel, 2013).

## Data weighting

Indices of relative abundance all had variance estimates generated as part of the analysis of raw catch data. These variances are converted to standard deviations in log space for use in the model; additional variances for the fishery indices of abundance were estimated inside the model. The number of trawl tows or port samples was used as the initial input sample sizes for length and marginal age compositional data for survey and fishery samples, respectively. The number of fish aged by length class was used as the input sample size for the survey and L. Lam conditional age-at-length compositions, as well as for recreational composition data. Each observation of CAAL composition consists of multiple age-composition vectors, one for each length class.

This assessment follows the iterative re-weighting approach to developing consistency between the input composition sample sizes (or standard errors) and the effective sample sizes based on model fit. This approach attempts to reduce the potential for particular data sources to have a disproportionate effect on total model fit, while creating estimates of uncertainty that are commensurate with the uncertainty inherent in the input data. Iterative re-weighting was applied to all compositional data. Two approaches were considered. One approach, attributed to McAllister and Ianelli (1997), consisted of comparing the mean input sample size for compositional data with the mean effective sample size based on model fit. A single iteration was completed using a multiplicative scalar to tune the input sample sizes for all length- or age-compositions for a given fleet or survey. The second approach, developed by Francis (2011), considers the influence of compositional weights on fits to average lengths or average lengths-at-age.

Sensitivity to the two methods for model tuning of composition data were investigated, it was determined that the model was not sensitive to implementing either Francis (2011) or McAllister and Ianelli (1997). The estimated 2017 stock depletion and unfished spawning biomass for both the north and south models were inside the estimated assympotic standard deviations for these quantitites. Specifically, the difference in estimates of stock depletion for both the north and south models between the two methods was $<2 \%$, the difference in estimates of unfished spawning biomass between the two methods was -2841 mt in the north and 125 mt in the south. As each method provided similar results, the model sensitivity section below focuses on other explorations. The base model in both the pre-STAR and post-STAR models uses the Francis (2011) method.

The value of $\sigma_{R}$, the parameter controlling recruitment variability, was determined using an iterative procedure to ensure that the value of $\sigma_{F}$ assumed by the assessment model and the empirical variance in recruitment were self-consistent. This involved setting $\sigma_{R}$ to an initial value, fitting the model and calculating the variance of the recruitment deviations for the years for which recruitments are estimated in the model, then replacing the assumed value of $\sigma_{R}$ by the calculated value. Very little iterative reweighting was necessary for $\sigma_{R}$.

## Priors

Priors were applied only to Male natural mortality based on a meta-analysis completed by Hamel (2015). The prior female natural mortality was fixed at the median of the prior based on a maximum observed age of 21, where $M=0.257$. See the discussion of natural mortality in the data section for justification of the estimation of sex specific M.

## General model specifications

Stock synthesis has a broad suite of structural options available. Where possible, the 'default' or most commonly used approaches are applied to this stock assessment. The assessment is sex-specific, including the estimation of separate growth curves, natural mortality, and selectivity for males and females. Therefore, the assessment only tracks female spawning biomass for use in calculating stock status.

This assessment consists of two independent models that cover the U.S. west coast with time-series of landings beginning in 1889 . The sex-ratio at birth is fixed at $1: 1$, although by allowing increased natural mortality for males, size-based selectivity, and dimorphic growth, the sex ratio will vary by age and time. The model starts at equilibrium, assuming an unfished initial age structure.

The internal population dynamics include ages 0-25, where age 25 is the 'plus-group'. As there is little growth occurring at age 25 and very few observations, the data use a plus group of age 20.

The following likelihood components are included in this model: catch, indices, discards, length compositions, age compositions, recruitments, parameter priors, and parameter soft bounds. See the SS technical documentation for details (Methot and Wetzel 2013). Estimated likelihood components from the base models can be found in the model output Report.sso files archived with the PFMC.

Electronic model files including the SS executable, data, control, starter, and forecast files are archived with the PFMC.

## Estimated and fixed parameters

A full list of all estimated and fixed parameters is provided in Tables 7 and 8. Time-invariant, sex-specific growth is estimated in this assessment, with all SS growth parameters being estimated except for female length at maximum age in the north model 1 , which was fixed at 110 cm for age 14 fish. The $\log$ of the unexploited recruitment level for the Beverton-Holt stock-recruit function is treated as an estimated parameter. Annual recruitment deviations are estimated beginning at the model start, 1889, with the main period of recruitment deviation estimation starting during 1965, just prior to reliable length and age composition entering the models. Female natural mortality is fixed, male natural mortality is estimated, as is commonly done for groundfish stocks that exhibit dimorphic growth such as lingcod. Sex specific size selectivities are estimated, where sex specific data allowed, using the double normal pattern (SS pattern 24) for all fleets and surveys. All surveys as well as the Oregon and California recreational data were modeled using combined male and female selectivity due to either combined sex data, or good fits to the data without sex specific selectivity curves. Retention is estimated for the commercial fishing fleets. In the north model selectivity and retention are estimated with time blocks such that: 1) the fixed gear fleet uses blocks from 1998 to 2010 and 2011 to 2016 to account for management changes (e.g. gear changes and closed areas) and the implementation of the catch shares program, respectively, 2) the trawl fleet uses blocks from 1998 to 2006, 2007 to 2009, 2010 to 2010, and 2011 to 2016 to account for management changes and the implementation of the catch shares program, and 3) the Oregon recreational fleet uses blocks from 1999 to 2016 to account for management changes and observed changes in the composition data. In the south model selectivity and retention are estimated with time blocks such that: 1) the fixed gear fleet uses blocks from 1998 to 2001, 2002 to 2002,2003 to 2010, and 2011 to 2016 to account for management changes and the implementation of the catch shares program, 2) the trawl fleet uses blocks from 1998 to 2006, 2007 to 2009, 2010 to 2010, and 2011 to 2016 to account for management changes and the implementation of the catch shares program, and 3) the California recreational flees uses blocks from 1959 to 1974, 1975 to 1989,1990 to 2003, and 2004 to 2016 to account data collection by different agencies and in different regions of the state. See tables 7 and 8 for information on estimated and fixed selectivity parameters. The six parameter double normal selectivy pattern was reduced to three parameters by fixing the width at the peak (P2), the initial selectivity (P5), and final selectivity (P6) to large negative values ( $-15,-999$, and -999 , respectively) and estimating the remaining parameters, where the data allowed. The survey catchability parameters are calculated analytically (set as scaling factors) such that the estimate is median unbiased, which is comparable to the way $q$ is treated in most groundfish assessments.

## 2017 Model

## Key Assumptions and Structural Choices

All structural choices for stock assessment models are likely to be important under some circumstances. Assessment choices were generally made to 1 ) be as objective as possible and 2) follow generally accepted methods of approaching similar models and data. The relative effect on assessment results of each of these choices is often unknown; however, an effort is made to explore alternate choices through sensitivity analysis. Major choices in the structuring of this stock assessment model include two separate area models (north and south), splitting the triennial survey into an early and late time period, and estimates of selectivity curves for each fleet and retention curves for the commercial fleets. Length and age bins in this assessment are expanded from those used in the previous two assessments. In the north, length bins range from 10 to 130 in two cm increments, with the first bin containing all fish less than 10 cm and the maximum bin containing all fish $\geq 130$ cm . In the south, length bins range from 4 to 130 in two cm increments, with the first bin containing all fish less than 4 cm and the maximum bin containing all fish $\geq 130 \mathrm{~cm}$. Smaller fish are observed in the southern survey area, hence the need for the length bins to start at a smaller size. Age bins for both models range from 0 to 20 in single year increments, with the upper bin serving as a plus group for all fish older than age 20.

## Alternate Models Explored

Comparison of key model assumptions include comparisons based on nested models (e.g., asymptotic vs. domed selectivity, constant vs. time-varying selectivity). Many variations on the base case models were explored during this analysis; only the most relevant and recent are reported in this document. Some of these are reported as sensitivity and retrospective analyses. Prior to the STAR panel, detailed exploration was made to evaluate:

1. Estimation of natural mortality with a prior.

- Estimation of $M$ is possible for both males and females if the commercial age data are retained in the north model. Without the commercial age data the model is not able to estimate female M , but male M can be estimated if the female value is fixed. There is not enough information in the available data to estimate female M in the south model, even if all of the age data are retained. However, similarly to the north model, male M can be estimated if the female value is fixed.

2. Alternative fixed values for female natural mortality.

- Scale the estimates of unfished biomass up and down as expected (higher $\mathrm{M}=$ lower estimate of unfished biomass, and vice versa), retaining similar estimates of current biomass.

3. Alternative fixed values for $h$.

- Scale the estimates of current biomass up and down as expected (higher $\mathrm{h}=$ faster population recovery and larger current stock size, and vice versa), retaining similar estimates of unfished biomass.

4. Tuning of composition sample sizes.

- The models were not sensitive to the choice of weighting method, see the data weighting section below for more detail.

5. The period over which recruitment deviations are estimated.

- Early explorations show that the model estimates of stock depletion are highly sensitive to this choice, the final model follows best practices and estimates recruitment deviations beginning at the start of the model period.

6. Time varying, combined female and male versus sex specific selectivity, and asymptotic versus domeshaped selectivity for fishing fleets and surveys.

- Results varied, with fits to the data guiding the modeling of selectivity.

7. The tuning of recruitment variability.

- Estimates of current stock size from the south model are somewhat sensitive to this value.

8. Commercial age data and aging error estimates.

- Fits to the commercial and recreational age data were improved compared to those from the 2011 stock assessment. Better fits to the data were due, in part, to the re-bining of the age and length data as well as to the use of age selectivity pattern 11 rather than 10. Age error estimates were similar to the previous stock assessment.

9. Fishery dependent CPUE indices.

- Six new indices were evaluated for this assessment: Oregon commercial nearshore CPUE, Washington Dockside recreational CPUE, Oregon ORBS CPUE, Oregon charter onboard observer CPUE, California onboard observer CPUE, and Central California onboard observer CPUE. The south model is sensitive to the California onboard observer CPUE.

10. The impact of the 2016 NWFSC survey data and the 2016 research study data from L. Lam on derived model outputs.

- The south model is sensitive to the Lam research age and length data.

11. Time blocking of retention parameters.

- Time blocking improved the model fits to fishery dependent composition data.

12. Estimation of the added standard deviation parameters for all indices of abundance.

- Estimating the added standard deviations improved model fits to the fishery dependent indices but not to the fishery independent indices.

13. Removal of individual index data sets.

- Indices for the north model generally provide similar information with respect to stock size and trends. The south model NWFSC survey index and the California onboard observer index provide different information with respect to the rate of stock increase during the past $\sim 15$ years, with the NWFSC survey index being more favorable.

14. Estimation of growth parameters

- The north model is unable to estimate both female k and the Lenth-at-maxium age so the later was fixed at a value based on the data. This may be due to large lingcod being present in the early fishery dependent data that are never, or rarely, observed in more recent data. All male parameters could be estimated in the north model. All growth parameters could be estimated in the south.

## Convergence

Convergence testing through use of over dispersed starting values often requires very extreme values to actually explore new areas of the multivariate likelihood surface. For this reason, a good target for convergence testing is to 'jitter' or randomly adjust starting values between reasonable upper and lower bounds by a factor. Jitter is a SS option that allows for the generation of a uniform random deviate equal to the product of the input value and the range between upper and lower parameter bounds for each parameter. These random numbers are then added to initial parameter values in the input files and the model minimization started at these new conditions. The SS jitter option was used to explore the identification of a global best estimate for the base models. In the north none of these trials found a different minimum. A total of 100 jittered model runs, using a jitter value of 0.1 resulted in $76 \%$ of the model runs returning to the base case, and the rest went to local minima with larger negative log-likelihood values. In the south, out of a total 300 jitter runs using combinations of jitter values of 0.1 and 0.15 as well as alternative start values for Ro, $4 \%$ of the model runs found a slightly better solution ( 0.22 likelihood units better), $2.7 \%$ went back to the base model likelihood, and the rest went to local minima with larger negative log-likelihood values. This indicates the south model has a flat likelihood space, and therefore less informative likelihood profiles, with data that are less informative than the data available for the north model. Given that a majority of the jitter runs were unable to converge to the base model, this issue should be investigated during future lingcod south assessments. A comparison of the south base model and the model that converged to a slightly better solution revealed that their results are virtually identical. The model run with the slightly better solution is presented in this document.

## Base Model Results

All r4ss plot files (see the Auxiliary files section of this document) for both the north and south base models are provided in supplementary materials. Parameters, both estimated and fixed are provided in tables 7 and 8 . Note that fishery ages were removed from the base case model due to concerns with age sampling not being representative of length sampling. However, these data are used in model sensitivity runs below.

The base case model for the north model fit the indices, lengths and fishery independent ages well (Figures 80109). Good fits to the indices were, in part, due to strong agreement among various indices, except for a few years during the 1990s when the recreational indices trended up while the commercial index remained low. Fits
to the time aggregated length compositions were good except for a limited amount of miss-fitting to the Triennial survey compositions and the Lam research length compositions. The Triennial survey compositions are noisy due to lower sample sizes and most likely to the line transect nature of the survey design. The Lam research data were collected with age and growth studies in mind, and are therefore, not random samples, resulting in greater difficulty in fitting these data. The fits to the age compositions were also generally good, with the exception of some larger residuals in the Lam data.

North model selectivity curves were well estimated for all fleets, with the commercial and recreational fleets using time blocks to capture changes in management that drove corresponding changes in composition data. See the Estimated and Fixed parameters section above for parameterization details. Figure 110 shows the end year selectivity for each fleet. Early selectivity patterns for the trawl, fixed gear commercial fleets are estimated to be asymptotic, while selectivity patterns for recent years were estimated as dome shaped. Estimated growth curves for females and males were reasonable (Figure 111), suggesting that on average females grow to a maximum size of about 120 cm and males grow to a maximum size of about 80 cm . Variability in growth was greater for younger fish than for older fish.

Tables 1 and 8, along with Figures 112-116 shows the time trajectories of the estimates of total dead fish (landings plus estimated dead discards), spawning biomass, fishery exploitation rate, recruitment, and depletion in spawning output from the north model. Figures 117-119 show management quantities: equilibrium yield plots and time series of surplus production from the north model. This assessment estimated that the stock size was well over the management target, and has generally been on an upward trajectory since its low point during the 1990s. Large recruitment events in the north are estimated to have occurred during 1964-1965, 1969-1970, 1978-1980, 1985, 1990-1991, 2008, 2013 and 2015, while low recruitments were estimated to have occurred during 1986, 1996-1998, 2002-2007, 2011-2012, and 2014.

The base case model for the south model was able to fit the indices, lengths and fishery independent ages well with the exception of the CA recreational onboard observer index and recent length compositions (Figures 120144). The model sensitivity run with the CA recreational observer index estimates a large added standard deviation and the length compositions shows strong residual patterns in recent years (Figure 132). Fits to the time aggregated length compositions were good except for a limited amount of miss-fitting to the Triennial Shelf Trawl Survey compositions, and the NWFSC Hook and Line survey length compositions. The Triennial survey compositions were noisy due to smaller sample sizes and most likely to the line transect nature of the survey design. The Hook and Line survey sample sizes were also lower and lingcod were less common in this survey. The fits to the age compositions were also generally good.

South model selectivity curves were well estimated for all fleets, with the commercial and recreational fleets using time blocks to capture changes in management that drove corresponding changes in composition data. See the Estimated and Fixed parameters section above for parameterization details. Figure 144 shows the end year estimated selectivity curves. Early selectivity patterns for the trawl fleet and Triennial survey were estimated to be asymptotic. Fishery selectivity patterns for recent years were estimated as dome shaped. Estimated growth curves for females and males were reasonable (Figure 145), suggesting that on average females grow to a maximum size of about 120 cm and males grow to a maximum size of about 100 cm . Similarly to the north model, variability in growth was greater for younger fish than for older fish. Female growth patterns between the north and south models are estimated to be more similar than those for the males, this difference needs to be investigated during the next benchmark lingcod stock assessment.

Tables 1 and 10, along with Figures 146-150, shows the time trajectories of the estimates of total dead fish (landings plus estimated dead discards), spawning biomass, fishery exploitation rate, recruitment, and depletion
in spawning output from the south model. Figures 151-153 show management quantities: time series of SPR ratios and the phase plot from the south model. This assessment estimated that the stock is in the precautionary zone, and while it has generally been on an upward trajectory since its low point during the 1990s, the rate of increase is slower than in the north. Large recruitment events in the south are estimated to have occurred during 1961, 1973-1974, 1976-1977, and 1984-1985, while low recruitments were estimated to have occurred during 1981-1982, 1992-1993, 1995, 1997-1998, 2002-2009, and 2014-2016. It is notable that lingcod in the south have not had a recruitment near historical high values since the mid-1980s.

## Sensitivity Analyses

Sensitivity analyses were performed to determine the sensitivity of the model results to a range of different assumptions. For the most part, conclusions from the models remained generally consistent across the assumptions that were explored.

Results from the north base case sensitivity runs that produced the most extreme results are shown in Table 11, and Figures 154-155 (the table and figures show the same sets of model runs). The sensitivity model runs all produced similar trajectories of stock decline and recovery. In the north, the model is most sensitive to the inclusion of the fishery age data sets. Model runs that add data to the base model (note that the base model uses the NWFSC survey conditional age data) show the impact of adding first only the recreational age data, then only the commercial age data, and finally, both the recreational and commercial age data. Including only the Washington and Oregon conditional age-at-length data from the recreational fishery results in a lower estimate of unfished biomass but a similar estimate of stock status. Including only the marginal commercial age composition data results in a higher estimate of unfished biomass but similar stock status. In pre-STAR model runs, not shown here, fixing $M$ at either lower or higher values than the base model resulted in similar estimates of unfished spawning biomass, but stock status changed systematically with the assumed value of $M$ : lower values of $M$ resulted in lower stock status, although all values resulted in estimates of stock status that were over the management target reference point. Asuming that female and male M are both fixed at 0.257 suggests similar stock status, but a slightly lower unfished spawning biomass.

Results from the south base case sensitivity runs that showed the most extreme results are shown in Table 12, and Figures 156-157 (the table and figures show the same sets of model runs). Many of the sensitivity model runs produced similar trajectories of stock decline and recovery. In the south, the model is sensitive to removing the research age and length data set collected by Lam et al., which results in a much higher unfished biomass estimate but a similar estimate of stock status (Figures 160-161). Note that the Lam data are collected from rocky reef areas that are not accessible to the NWFSC survey, and are the only source of age data from California that characterizes the ages of fish caught by the California recreational fishery. The south model is highly sensitive to the inclusion of the California onboard observer index, which suggests a similar unfished stock size but a stock status that is well below the overfished threshold. While both the California onboard observer index and the NWFSC survey both suggest that the lingcod south stock has been increasing during the past few decades, these data sets provide conflicting information regarding the rate of stock increase. The NWFSC survey, which covers the deeper waters than the California onboard observer index, suggests a faster rate of stock increase than the California onboard observer index, which spans only nearshore waters and suggests a much slower rate of increase. The conflicting information provded by the CA onboard observer index and the NWFSC survey may indicate localized depletion in the regions repeatedly visited by the California recreational fleet. In the pre-STAR model runs, not shown here, fixing $M$ at either lower or higher values than the base model resulted in similar estimates of unfished spawning biomass for all runs with stock status changing systematically with the assumed value of $M$ : lower values of $M$ resulted in lower stock status.

## Retrospective Analyses

A retrospective analysis was conducted by comparing the base models with data through 2016 to models sequentially removing up to 7 years of data. The north model does not show a retrospective pattern (Figures 158-159). A retrospective pattern in the south model between 2016 and the rest of the years was identified (Figures 160-161), with investigations showing that this pattern is caused by the addition of the 2016 conditional age-at-length composition data from the Lam research study. Note that the Lam age composition data provide the only source of age data that are representative of the California recreational catches in the south model. The base model that includes the Lam age data suggests a slower rate of stock increase that models without the Lam data. Changes in the estimation of recruit deviations also contributes to this retrospective pattern. The base model estimates that the most recent 3 years have had recruitment well below the long term average from the stock recruitment curve, while the preceding 4 years were well above average.

## Historical Assessment Analyses

Comparisons between the base model estimates for spawning biomass and stock depletion from the 2009 assessments suggest similar patterns of stock increases from a low point during the 1990s to present (Figures 162-163). However, the rate of the stock increase is slower and lower in magnitude than those estimated/projected in the 2009 assessment, particularly for the south. The 2017 south model shows a strong divergence from the 2009 assessment beginning during the early 2000s.

## Likelihood profiles

Likelihood profiles for log unfished recruitment and female natural mortality were completed to investigate the information in the data with respect to these parameters. (Figures 164-167).

Given the removal of the commercial marginal age data from the north base model, there is no longer adequate information in the data to produce informative $M$ or $h$ profiles. North model likelihood profiles for $\log R_{o}$ show a strong conflict between the length and age data with respect to the value of unfished recruitment, with the length data suggesting a higher value and the age data suggesting a lower value. In the north the OR recreational index, NWFSC conditional age data, WA recreational lengths and Trawl commercial length data sets most strongly inform stock scale. In aggregate plausible values for log unfished recruitment range from about 8.7 to 9.8. South model likelihood profiles are uninformative with repsect to both $M$ and $h . \log R_{o}$ likelihood profiles show a strong influence of the recruitment estimates, with plausible values ranging from about 8.3 to 8.7 . In the south Lam research data, the indices (except the hook and line index), the late triennial length data, and the commercial trawl data most strongly inform stock scale.

## Rebuilding Parameters

Both the north and south lingcod stocks are estimated to be above the minimum stock size threshold, therefore a rebuilding plan is not necessary.

## Reference Points

The north and south stocks are estimated to have been below the target reference point from approximately the 1980s through the early 2000s. Fishing intensity since approximately 2005 has been below the target for both the north and south stocks. The phase plots show the interaction of fishing intensity and biomass targets. Stock
status is currently estimated to be above the target reference point ( $40 \%$ of the estimated unfished spawning biomass) at $57.9 \%$ ( $47.9-67.8,95 \%$ asymptotic interval) in the north and in the precautionary zone at $32.1 \%$ (11.1-53.1, $95 \%$ asymptotic interval) in the south. Unfished spawning biomass was measured at $37,947 \mathrm{mt}$ ( $25,776-50,172 \mathrm{mt}, 95 \%$ asymptotic interval) in the north and 20,260 $\mathrm{mt}(15,304-25,215 \mathrm{mt}, 95 \%$ asymptotic interval) in the south. Spawning biomass at the beginning of 2017 was estimated to be $21,976 \mathrm{mt}(12,517-$ $31,434 \mathrm{mt}, 95 \%$ asymptotic interval) in the north and $6,509 \mathrm{mt}(1,624-11,394 \mathrm{mt}, 95 \%$ asymptotic interval) in the south. The north stock is estimated to have been below the target reference point from approximately the 1980s through the early 2000s, while the south stock is currently estimated to be in the precautionary zone. The target stock size based on the biomass target (SB40\%) is $15,190(10,311-20,069 \mathrm{mt}, 95 \%$ asymptotic interval) in the north and $7,780 \mathrm{mt}(5,877-9,683 \mathrm{mt} 95 \%$ asymptotic interval) in the south, which gives catches of 3197 $\mathrm{mt}(2,184-4,210 \mathrm{mt}, 95 \%$ asymptotic interval) for the north and $1746 \mathrm{mt}(1,372-2,121,95 \%$ asymptotic standard deviation) for the south (Tables i and j). Equilibrium yield at the FMSY proxy harvest rate (F45) is $3,409 \mathrm{mt}(2,329-4,489 \mathrm{mt}, 95 \%$ asymptotic interval) and $1,856 \mathrm{mt}(1,458-2,253 \mathrm{mt}, 95 \%$ asymptotic interval) for the north and south, respectively.

## Harvest Projections and Decision Tables

The lingcod stock assessments are Category 1 stock assessments, thus projections and decision tables are based on using $\mathrm{P}^{*}=0.45$ and sigma $=0.36$, resulting in a multiplier on the over fishing limit (OFL) of 0.956 (PFMC preferred option). Stock projections for the south are also provided for the PFMC default management option, and uses an OFL multiplier of 0.913. The OFL multipliers are combined with the 40-10 harvest control rule to calculate OFLs, ABCs and ACLs. The total catches in 2017 and 2018 were set at the PFMC groundfish management team (GMT) requested values of $\sim 1000 \mathrm{mt}$ in the north and 750 mt in the south, the average 20152017 exploitation rate was used to distribute catches among the fisheries. All stock projections and decision tables (Tables 13-16) are based on the stock assessment model areas: north (WA and OR) and south (CA).

In the north, current medium-term projections of expected catch, spawning biomass and depletion from the base model project a declining trend through 2028 as recent large cohorts increase in age (note that all projections assume average recruitment from the stock-recruit curve) and the 40-10 control rule ACLs move the stock towards the target reference point (Table 13). The stock is expected to remain above the target stock size of $\mathrm{SB}_{40 \%}$ through 2028, assuming average recruitment based on the stock-recruit curve. In the south, the current medium term projection of expected catch under both harvest policies, shows increasing spawning biomass and depletion from the base model, with the stock remaining in the precautionary zone during the projection period (Table 14). Note that the difference in final stock status (depletion) between the council preferred and default options is $<1 \%$. The lack of strong increases in stock sizes during the projections is due, in part, to a large number of poor recruitments since 2000 ( 11 out of 17 years) and a lack of recruitments near historical highs.

Uncertainty in management quantities for the north and south models decision tables (Tables 15-16) was characterized using the asymptotic standard deviation for the 2017 spawning biomass from the base model. Specifically, the 2017 spawning biomass for the high and low states of nature are given by the base model mean $+/-1.15^{*}$ standard deviation (the 12.5th and 87.5th percentiles). A search across fixed values of Ro was used to attain the 2017 spawning biomass values for the high and low states of nature. The high catch streams were based on the 40-10 harvest control rule. At the request of the PFMC GMT representative on the STAR panel the moderate catch streams were set to $40 \%$ ACL attainment for the north management area and $70 \%$ ACL attainment in the south management area. Finally, the low catch stream was set to $\sim 700 \mathrm{mt}$, a level similar to recent average catches.

In the north, current medium-term forecasts based on the alternative states of nature project that the stock will fall below the target stock size in only one case, in which the current control rule is applied to the low stock state of nature (bottom left corner of the table). Note that the catches specified in the above scenario (ranging from 4497 to 3542 mt ) are much larger than recent landings ( $\sim 700 \mathrm{mt}$ ). All other decision table scenarios keep the stock near or above the target stock size. In the south, current medium-term forecasts based on the alternative states of nature project a range of outcomes from overfished (lower left corner) to well above target stock size (upper right corner). All states of nature from the constant catch scenario, that specifies catches similar to recent levels, suggest that the stock will increase towards, or exceed the target reference point. However, catching the full ACL catches results in stock declines at the low state of nature and modest stock increases under the base case and high state of nature.

## Regional Management Considerations

Regional management considerations are to some extent addressed by the two area assessments. Reallocation of catches from the south model area to the northern managment area based on the 40-10 management line can be done using the 5 year average percentage of survey biomass in either the region from the 40-10 management line to the OR/CA border or the section of CA between the 40-10 management line and 42 degrees. These values were obtained using VAST model runs with the above spatial delineations, and result in values of $8 \%$ of the coast wide survey biomass, or $21.31 \%$ of the CA biomass being in the $40-10$ to 42 region. Note that the proportion of the survey biomass estimated to be between the 40-10 management line and 42 degrees has declined over time.

## Research Needs

Most of the research needs listed below entail investigations that need to take place outside of the routine assessment cycle and require additional resources to be completed.

1. Age validation of lingcod aging is needed to verify the level of age bias, if any.
2. A transboundary stock assessment and the management framework to support such assessments would be beneficial.
3. A survey in untrawlable habitat and/or a near shore survey would improve this stock assessment. Other survey techniques could include longline, combined lingcod/sablefish pot survey, or trap surveys.
4. Investigate environmental covariates for recruitment and time-varying growth and availability inshore.
5. The impact of nest-guarding on reproductive output should be investigated. The current assessment focuses on female spawning biomass as the limiting factor in reproductive output, but nest guarding by lingcod males and the availability of nesting habitat may also play roles. A cursory look at the proportion of sex ratio in the catch did not appear to indicate any serious changes for either north or south populations in recent years. However, we do not know what kind of change in sex ratio would indicate a serious change in reproductive success.
6. Investigation of the proportion of fish caught in Mexico and landed in U.S. ports as there is evidence that California recreational fisheries, primarily out of San Diego, are fishing in Mexican waters. These catches should be allocated appropriately between U.S. and Mexican waters.
7. Given that a majority of the jitter runs were unable to converge to the south base model, this issue should be investigated during future lingcod south assessments.
8. The south model lacks fishery dependent age data. Obtaining recreational fishery data from California could provide improved information on recent stock trends.

## Acknowledgements

A number of people helped with this assessment; providing data, helping to solve modeling issues; and editing. Without their efforts, this assessment would not have been possible. Among those to whom much thanks is due are Owen Hamel, Beth Harness, Todd Hay, John Harms, Jim Hastie, John Field, Ali Whitman, Ian Taylor, Jason Cope, Chantel Wetzel, and John DeVore. Thanks to the STAR panel reviewers for a constructive week: Dr. David Sampson, Dr. Yiota Apostolaki, Dr. Norman Hall, Dr. Kevin Piner, Lynn Mattes, and Louie Zimm. Finally, many thanks to Stacy Miller for facilitating this process and keeping things running smoothly.

Table 15. North model decision table of 12-year projections for alternate states of nature (columns) and management options (rows). Summary of model outputs for the preferred council HCR, north. Uncertainty in management quantities for the north and south models was characterized using the asymptotic standard deviation for the 2017 spawning biomass from the base model. Specifically, the 2017 spawning biomass for the high and low states of nature are given by the base model mean +/-1.15*standard deviation (the 12.5th and 87.5th percentiles). A search across fixed values of Ro was used to attain the 2017 spawning biomass values for the high and low states of nature.

Figure 154. Sensitivity in spawning biomass to north model sensitivity runs. The run 2009 M and $h$ sets these values to those used in the 2009 stock assessment. The run + Conditional Rec Ages includes both WA and OR recreational age data as CAAL compositions. The run + Marginal Commercial Ages includes all commercial age data as prepared for the STAR panel version of this assessment. The run + Conditional Rec and Marginal Commercial Ages adds all fishery age data into the model. The runs Ro8.81 and Ro9.8 fix the parameter for unfished recruitment at each value; these runs bracket the base model. The run SigmaR0.6 fixed the input parameter for recruitment variability to 0.6. The runs Female Length at Amax $=108$ and Female Length at Amax = $\mathbf{1 1 2}$ fix the values for this parameter at 108 cm and 112 cm , respectively. The run $\mathrm{M}=0.257$ fixes male $M$ to the value of female $M(0.257)$ rather than estimating male $M$.

Figure 155. Sensitivity in stock depletion to north model sensitivity runs. The run 2009 M and h sets these values to those used in the 2009 stock assessment. The run + Conditional Rec Ages includes both WA and OR recreational age data as CAAL compositions. The run + Marginal Commercial Ages includes all commercial age data as prepared for the STAR panel version of this assessment. The run + Conditional Rec and Marginal Commercial Ages adds all fishery age data into the model. The runs Ro8.81 and Ro9.8 fix the parameter for unfished recruitment at each value; these runs bracket the base model. The run SigmaR0.6 fixed the input parameter for recruitment variability to 0.6. The runs Female Length at Amax $=108$ and Female Length at Amax = $\mathbf{1 1 2}$ fix the values for this parameter at 108 cm and 112 cm , respectively. The run $\mathrm{M}=0.257$ fixes male $M$ to the value of female $M(0.257)$ rather than estimating male $M$.

Figure 156. Sensitivity in spawning biomass to south model sensitivity runs. The run + Rec Onboard Index adds the CA recreational onboard observer index to the model as proportional to biomass. The run + Rec Onboard Index, Not Proportional adds the CA recreational onboard observer index to the model with a parameter that allows the index to be fit as not proportional to biomass. The run + Commercial Marginal Ages add the commercial age data as prepared for the pre-STAR draft assessment back into the model. The runs SigmaR $=0.7$ and SigmaR $=0.8$ change the fixed value for recruitment variability to 0.7 and 0.8 , respectively. The run No Lam Study removes the Lam research CAAL and length composition data from the model. The run $M=0.257$ fixes male $M$ to the value of female $M(0.257)$ rather than estimating male $M$.

Figure 157. Sensitivity in stock depletion to south model sensitivity runs. The run + Rec Onboard Index adds the CA recreational onboard observer index to the model as proportional to biomass. The run + Rec Onboard Index, Not Proportional adds the CA recreational onboard observer index to the model with a parameter that allows the index to be fit as not proportional to biomass. The run + Commercial Marginal Ages add the commercial age data as prepared for the pre-STAR draft assessment back into the model. The runs SigmaR = 0.7 and SigmaR $=0.8$ change the fixed value for recruitment variability to 0.7 and 0.8 , respectively. The run No Lam Study removes the Lam research CAAL and length composition data from the model. The run $M=\mathbf{0 . 2 5 7}$ fixes male $M$ to the value of female $M(0.257)$ rather than estimating male $M$.

Figure A4. Comparison of design based and VAST indices for the NWFSC survey data, north and south. The blue line is the design-based index; the red line is the VAST index.

[^0]:    * Note that the WA recreational landings are entered into Stock Synthesis as numbers of fish, as reported by WDFW, SS then internally converts these landings to weights. The quantities reported for WA landings are the model converted values in metric tons.
